One of the most important sanity problems in penaeid shrimp populations of trade important in the world, is originated by virus infection. Recently in our country was detected the White Spot Syndrome Virus (WSSV), that produce high mortality in the population of cultured shrimps, mainly in the states of Nayarit, Sinaloa and Sonora. For this research, we collected samples in summer of 2001. The samples were from different species associated to culture farms, (*Litopenaeus vannamei, L. stylirostris, Callinectes sapidus, Uca* sp. and copepods). The copepods were homogenized and proceed in integral form by Polymerase Chain Reaction (PCR) probe, one hemolymph sample was taken from each of the different species to which was done the PCR getting the result of sequence in acrilamide, and having the corresponding marks. The samples for processing by *in situ* hybridization, were fixed in Davidson's solution for 48 hours and then in OH 70. The histological cuts were done 5 μm of thickness and were put on positively slides. By *in situ* hybridization, infected tissues of samples of *Callinectes sapidus* and *Litopenaeus vannamei* were easily distinguished. The presence of the blue precipitations it was present in branchial and connective tissues and gut subcuticular epithelium. In the other species of carcinological faun was negative by *in situ* hybridization probe.

FACTORS, RISKS AND SIGNIFICANCE OF EMERGENT NEOPLASIA DISEASES IN CULTURED AND WILD SOFT-SHELL CLAMS (*MYA ARENARIA*) IN ATLANTIC CANADA.

Gregory MacCallum,* **Jeffery Davidson,** and **Garth Arsenault,** Atlantic Veterinary College, University of Prince Edward Island, 550 University Ave., Charlottetown, PEI, C1A 4P3; **Sharon McGladdery** and **Michelle Maillet,** Department of Fisheries and Oceans Canada, Gulf Fisheries Centre, 343 University Ave., PO Box 5030, Moncton, NB, E1C 9B6; **Neil MacNair,** PEI Department of Fisheries, Aquaculture and Environment, 11 Kent St., Charlottetown, PEI, C1A 7N8.

In 1999, mortalities of soft-shell clams (*Mya arenaria*) caused by or associated with haemic neoplasia occurred at several sites around Prince Edward Island (PEI) and in Richibucto, New Brunswick (NB). Haemic neoplasia has been well documented in bivalves (clams, mussels and oysters) worldwide since the early 1970's. The cause(s) of haemic neoplasia is/are unknown. They have been linked to infectious triggers (neoplastic cells *per se* or a viral vector), anthropogenic carcinogens (e.g., polychlorinated biphenyls) and changing natural conditions (e.g., abnormally high water temperatures). The most urgent question, from an environmental and clam production perspective, is whether the neoplasia is infective or non-infective.

The objectives of this study are to: i) examine the transmissibility of this disease; ii) determine the geographic and seasonal distribution of haemic neoplasia in soft-shell clams from PEI (including a study to relate disease prevalence to five PEI clam populations); iii) examine common environmental variables between affected and unaffected sites on PEI, NB, and Nova Scotia (e.g., temperature, bottom-type, terrestrial run-off, human activities/input); iv) determine whether or not sediment exposure affects emergence of haemic neoplasia; and v) determine whether or not clams which have survived haemic neoplasia have developed a resistance to the disease which can be passed onto their offspring.

IDENTITY OF UNITED STATES MOLLUSK PRODUCTION DECLINES IN THE 1900S.

Clyde L. MacKenzie, Jr.,* James J. Howard Marine Sciences Laboratory, Northeast Fisheries Science Center, 74 Magruder Road, Highlands, NJ 07732.

In the 1900s, the historical declines in landings of estuarine mollusks along the east coast of the United States rarely were caused by overfishing, that led to permanent sharp declines in production of their larvae. Instead, habitat degration including adverse algal blooms, domestic pollution which led to closure of production beds, poor markets, and diseases have been the main causes. The oyster, *Crassostrea virginica*, landings, mainly, suffered from poor markets, and oyster habitats were despoiled by siltation and by dredgers removing shells while oysters were being harvested, and finally by diseases. Oysters companies sold their shells to the poultry industry and for hardening roads rather than spreading them on beds to produce more oysters. Northern quahog, *Mercenaria mercenaria*, landings declined due to the narrowing of bay openings, adverse algal blooms, and bed closures due to domestic pollution. Soft clam, *Mya arenaria*, landings declined due to destruction of beds, bed closures due to domestic pollution, diseases, and high temperatures. Bay scallop, *Argopecten irradians*, landings declined due to adverse algal blooms, changes in bay openings, and losses of eelgrass, *Zostera marina*. Attributing the declines to overfishing leads resource managers away from the actual causes and delays habitat restoration.

DEVELOPMENT OF A PCR-BASED ASSAY FOR DETECTION OF THE JOD-ASSOCIATED *ROSEOBACTER*.

Aaron P. Maloy* and **Katherine J. Boettcher,** Department of Biochemistry, Microbiology and Molecular Biology, University of Maine, Orono, ME 04469; **Bruce J. Barber,** School of Marine Sciences, University of Maine, Orono, ME 04469.

Juvenile Oyster Disease (JOD) has resulted in substantial losses of cultured Eastern oysters, *Crassostrea virginica*, in the northeastern United States. Despite management strategies utilizing selected lines and early deployment of hatchery-produced seed, JOD continues to occur annually in Maine's Damariscotta River. Further, during the past two years, mortalities have also been documented in three previously unaffected areas throughout Maine. In all years and locations, affected animals were extensively colonized by a novel species of marine α-proteobacteria (in the *Roseobacter* clade). We are currently evaluating a PCR-based diagnostic assay for detection of the JOD-associated *Roseobacter*. This assay uses specific primers to amplify the approximately 1300 base-pair internal transcribed spacer (ITS) region between the *Roseobacter* 16S and 23S rRNA genes. Direct amplifications from suspended cells are successful at concentrations as low as 1,000 cells per reaction. From sequence data and restriction length fragment polymorphism analyses, two genetic signatures are distinguishable. One is characteristic of the 1997–98 isolates, while the other is characteristic of the 2000–01 isolates. Thus PCR amplification followed by restriction enzyme digestion provides data regarding both the presence of, and specific genotype of, the JOD-associated *Roseobacter*. It is expected that this assay will be invaluable as a screening and diagnostic tool, and for regional management efforts to control the spread of JOD.

PRELIMINARY STUDY ABOUT FEEDING ECOLOGY OF THE ROCK LOBSTER, *PANULIRUS HOMARUS*, LINNAEUS, 1785, AT IRANIAN SEASHORES OF OMAN SEA.

Nassrin Mashaii, Offshore Fisheries Research Centre, Chabahar, Iran.

Preliminary aspects of feeding ecology of the rock lobster, *Panulirus homarus*, specimens collected by diving from January 1999 to November 2000 was considered. Stomach contents were recorded by using the point method. Fi and Pi of different prey items were measured. Monthly and seasonally frequencies of empty stomachs and different preys were compared using Chi-square tests. Monthly changes of macrobenthic communities sampled by diving were studied. Ivlev index used for comparing the importance of items between stomach contents and macrobenthics. Pearson correlation coefficient of different prey items against some hydrological factors was obtained. Spearman correlation coefficient was used for correlation between different preys against size groups, sexes and ovigerous females.

EVALUATION OF THE STRUCTURE AND FUNCTION OF A CREATED BLUE MUSSEL (*MYTILUS EDULIS*) REEF.

Sean McDermott, National Marine Fisheries Service, 1 Blackburn Dr., Gloucester, MA 01930; **David Burdick, Raymond Grizzle,** and **Jennifer Greene**, Jackson Estuarine Laboratory, University of New Hampshire, 85 Adams Point Rd., Durham, NH 03824.

In May 2001, blue mussels (*Mytilus edulis*) were collected from a donor site and transplanted into South Mill Pond, Portsmouth, NH, as part of a broad scale project to restore a degraded tidal salt pond. A total of six mussel reefs were established in two locations: three at the inner South Mill Pond (ISMP) and three at the outer South Mill Pond (OSMP). Two general parameters were used to evaluate the structure and function of the created reefs: (1) reef population dynamics (survivorship, size frequency distribution, density, and movement) assessed mussel response to transplanting and local pond conditions and (2) faunal utilization to evaluate the establishment of ecological functions for living marine resources (LMR). Mussel population dynamics were sampled once per month (June, July, August) using a random sample protocol. Mussels initially responded negatively to pond conditions (poor water quality; minimal tidal exchange), resulting in high mortality. Smaller mussels had a greater survival ratio as noted in a decreased average shell length. Survival and average shell length increased after water quality and tidal flow improved. Fish community dynamics were evaluated in reefs and reference areas through the summer (June, July, August). Reef areas had greater species diversity per sampling effort than reference areas under slow water conditions. *Apletes quadracus* and *Menidia menidia* were most common in reef areas. *Fundulus heteroclitus* and *M. menidia* were most common in reference areas. The constructed mussel reefs functioned as habitat for LMR's immediately, providing shelter and forage for small fish. Further assessment of utilization by other LMR's (invertebrates) is required to properly evaluate the functions and value of the created mussel reef.

GENETIC MONITORING OF OYSTER STOCK ENHANCEMENT IN THE CHOPTANK RIVER, CHESAPEAKE BAY.

Coren A. Milbury* and **Patrick M. Gaffney**, Graduate College of Marine Studies, University of Delaware, Lewes, DE 19958.

The spread of parasitic diseases (primarily MSX and Dermo), in conjunction with overharvesting, has led to the rapid decline of Eastern oyster (*Crassostrea virginica*) populations. Regional variation in disease resistance may be useful in restoration efforts. In collaboration with the University of Maryland Horn Point Laboratory, we have assessed the success of recent enhancement efforts within the Chesapeake Bay using genetic markers. *C. virginica* exhibits regionally diagnostic 16s mitochondrial DNA haplotype profiles (North Atlantic, South Atlantic, and Gulf Coast). In 1997 oysters from Louisiana broodstock were planted in the Choptank River, Maryland. The presence of newly settled spat with the Gulf Coast haplotype in the Choptank River confirms the survival and propagation of the Louisiana broodstock. An automated mini-sequencing technique (Pyrosequencing Inc.) was used to determine the mitochondrial haplotypes of oyster spat collected throughout the Choptank River. This rapid mass screening method revealed that 95% of spat collected were of the North Atlantic haplotype and approximately 5% were South Atlantic. Of 4538 spat screened, four (0.1%) possessed the Gulf Coast haplotype. The use of these genetic markers has enabled us to assess the survival, propagation, and dispersal of the Louisiana oyster stock within the Choptank River, Chesapeake Bay.

PROGRESS IN THE BIOLOGICAL CONTROL OF ZEBRA MUSSELS WITH MICROBIAL TOXIN.

Daniel P. Molloy,* Denise A. Mayer, Michael J. Gaylo, Kathleen T. Presti, Alexander Y. Karatayev, and **Lyubov E. Burlakova**, Division of Research & Collections, New York State Museum, Albany, NY 12230.

Recent progress in the development of bacterial strain CL0145A as a biocontrol agent of zebra mussels, *Dreissena* spp., is reviewed. Strain CL0145A is a North American isolate of *Pseudomonas fluorescens*, a ubiquitous, soil-water, Gram-negative bacterium, and a U.S. patent for its use for zebra mussel control has recently been issued. *Pseudomonas fluorescens* is not a parasitic species, and histological analysis indicates that mussels die from a biotoxin associated with strain CL0145A cells, not from infection. Therefore, future commercial products based on this microbe could contain only dead cells, further reducing environmental concerns. When zebra mussels ingest strain CL0145A cells, the biotoxin specifically destroys their digestive gland tissues. All zebra mussel sizes tested to date (ca. 1–30 mm long) are susceptible to kill by strain CL0145A, and high mussel mortality is achievable at all temperatures examined (range, 5–27°C). Static cultures currently produce cells of the highest toxicity, but shaking culture protocols are being developed in order to proceed to large-scale fermentation production. Very small-scale trials, designed to simulate flow-through conditions, have been conducted in temporarily-installed pipes within a hydropower facility, and they have confirmed that exposure to bacterial cells for 2 days at 23°C achieves high mussel kill. Evidence of nontarget safety has been demonstrated in laboratory and mesocosms trials. Current studies are focusing on biotoxin identification, fermentation scale-up, and identification of the key biotic and abiotic factors needed to maximize zebra mussel mortality.

CHARACTERIZATION OF A PARASITIC AMOEBA IN THE AMERICAN LOBSTER BY MOLECULAR SYSTEMATICS.

Thomas E. Mullen, Jr. and **Salvatore Frasca, Jr.**, Department of Pathobiology and Veterinary Science, College of Agriculture and Natural Resources, University of Connecticut, 61 North Eagleville Road, U-3089, Storrs, CT 06269-3089.

Past mass mortality events of Long Island Sound (LIS) lobster (*Homarus americanus*) have been associated with a number of potential etiologies, one of which is neurologic infection by a parasitic amoeba. Histopathologic examinations of nerves and ganglia revealed tissue invasion by an amoeba, with and without attendant hemocytic infiltrates. This amoeba possessed a small, round, secondary nucleus differentially stained using the Feulgen technique. Transmission electron microscopic examination of nervous tissue confirmed the presence of this nucleus-like organelle, or Nebenkörper, a consistent feature of members belonging to the genus *Paramoeba* Schaudinn, 1896. Previous efforts to culture parasitic *Paramoeba* spp. and recent attempts to culture the lobster amoeba *in vitro* have been unsuccessful. Molecular data for the family Paramoebidae is absent, and the lack of such information contributes to the ambiguity associated with classification of these organisms. In this study we propose to characterize the rDNA of this parasitic *Paramoeba* by determining the molecular systematics of potentially related lobose amoeba. We have sequenced the small subunit (SSU) rRNA gene of twelve previously identified organisms that have morphologic (light microscopic and ultrastructural) similarity to the amoeba infecting lobster. This SSU rDNA has provided the data necessary to describe the current systematics of the Order Euamoebida using bioinformatic computer methods. Based on this rDNA sequence data, species of *Neoparamoeba and Korotnovella* occupy a separate clade between *Vannella* spp and the clade classically representing the Class Lobosa (*Acanthamoeba* spp and the leptomyxid amoebae). In addition, such rDNA nucleotide sequence data has allowed for identification of variable and conserved sequences that could be exploited for the purpose of amplifying SSU rDNA from the parasitic amoeba in lobster tissue. The rDNA sequence of this amoeba is expected to allow for molecular characterization using molecular evolution methods and provides the critical sequence elements necessary to develop primers and probes for future polymerase chain reaction (PCR) and in situ hybridization-based (ISH) diagnostic tests to detect the parasite in lobster tissue. These tests will be important to histopathologic and molecular diagnostics integral to future health surveillance programs.

SEASONAL CHANGES IN CELL PROLIFERATION OF OYSTER TISSUES.

Kim-Lien T. Nguyen and **Jerome F. La Peyre,*** Cooperative Aquatic Animal Health Research Program, Department of Veterinary Science, Louisiana State University Agricultural Center, Baton Rouge, LA 70803; **Terrence R. Tiersch,** Aquaculture Research Station, Louisiana Agricultural Experiment Station, Louisiana State University Agricultural Center, Baton Rouge, LA 70820.

Identification of mitotically active tissues should assist development of cell lines from oysters and other bivalve molluscs. Except for evaluation of embryonic tissues, limited consideration has been given to identification of optimal tissue types and time of year to establish oyster cell lines. Thus, cell proliferation in tissues of the eastern oyster, *Crassostrea virginica*, was evaluated monthly for one year by an immunohistochemical assay for proliferating nuclear antigen (PCNA), an endogenous marker of cell proliferation that is evolutionarily conserved and present in all active phases of the cell cycle (G1, S, G2, M). A commercial monoclonal antibody to PCNA (PC10) was used to calculate a labeling index (percentage of labeled nuclei for 1000 nuclei counted) at 400× magnification for each tissue. We found highest proliferation in somatic tissues (labial palps > digestive diverticula and stomach epithelium > gills > mantle) in late fall to early spring (November-April in southern Louisiana). Cell proliferation ceased in these tissues in late Spring while proliferation in maturing gonads persisted. After spawning, proliferation resumed in somatic tissues for a month or two before gonad proliferation resumed in late summer. This agrees with earlier observations that cell proliferation in bivalves is highly variable throughout the year.

DEVELOPMENT OF A MEDIUM TO INDUCE HYPNOSPORE FORMATION AND ZOOSPORULATION OF *PERKINSUS MARINUS.*

Amy D. Nickens and **Jerome F. La Peyre,*** Cooperative Aquatic Animal Health Research Program, Department of Veterinary Science, Louisiana State University Agricultural Center, Baton Rouge, LA 70803; **Sandra M. Casas,** Centro de Investigacións Mariñas, Xunta de Galicia, aptdo. 13, E-36620 Vilanova de Arousa, Spain.

The difficulty in inducing zoosporulation of *P. marinus* hinders our ability to study zoospores. We recently developed a medium to induce hypnospore formation and zoosporulation of *P. marinus*. This medium was formulated in 3 steps by determining the effects of various solutions, individually and in combination, on the size, viability and zoosporulation of cultured parasites. The solutions tested included fluid thioglycollate medium (FTM) components (i.e., yeast extract, casein hydrolysate, dextrose, cystine, sodium thioglycollate, agar) in step 1; solutions of amino acids, carbohydrates, lipids, vitamins or nucleotides in step 2; and media supplements (lactalbumin hydrolysate, Hyprep 4601, pancreatin, Ex-cyte VLE, egg yolk, oyster lysate) in step 3. Solutions tested at each step which had significant positive effects on the enlargement, viability, and/or zoosporulation of cultured parasites were included in a medium for testing all solutions of subsequent steps. The size (35 ± 13 μm, N = 100), viability (95%, N = 400) and zoosporulation (35%, N = 400) of parasites incubated in our final medium for 6 days were significantly greater than the enlargement (11 ± 2 μm), viability (30%) and zoosporulation (0%) of parasites incubated in the FTM for 1 week. The initial mean parasite size was 4 ± 1 μm (N = 100). Interestingly, enlargement and viability of parasites incubated in our medium was similar to the enlargement (35 ± 9 μm) and viability (95%) of parasites incubated in oyster lysate. Zoosporulation (12%) of parasites incubated in oyster lysate was however significantly lower. The availability of *P. marinus* zoospores for study will enable investigations on the role of this cell stage in *P. marinus* life cycle.

THE EFFECTS OF *MARTEILIA SYDNEYI* ON THE HOST DEFENSE RESPONSES OF THE SYDNEY ROCK OYSTER, *SACCOSTREA GLOMERATA*. **Rodney Peters*** and **David Raftos**, Marine Biology Laboratory, Macquarie University, Sydney, Australia 2109.

Marteilia sydneyi (paramyxean parasite) is the causative agent of QX disease in *Saccostrea glomerata*, which has mortality rates of 90 to 98%. Outbreaks of QX disease have reduced oyster farming in some of the major oyster producing estuaries in New South Wales, Australia to critical levels. Once, farmers had a productive period of 2 years during which they could grow out, or "fatten," the oyster to a reasonable market size. Now this period lasts only from April/May to December of the same year in the QX contaminated rivers.

Invertebrates, according to all available evidence, lack antibodies and lymphocytes. However, they are still capable of mounting highly efficient cellular and humoral immune responses. Our premise is that these immune responses must be either evaded or overpowered by *M. sydneyi* to initiate QX disease. Specifically, our investigations have centered on proteolytic cascades, such as the prophenoloxidase (proPO) system, that in other species are closely associated with host defense. The prophenoloxidase cascade catalyzes the hydroxylation of tyrosine to dopa and the oxidation of dopa to dopaquinone, finally forming the pigment melanin. A number of intermediates in this pathway are cytotoxic or bacteriostatic, and melanin itself contributes to defense by encapsulating foreign material.

Data presented here describes an outbreak of QX disease on the Georges River, NSW during 2000/2001. A strict correlation was evident between infection intensity and prophenoloxidase activity. ProPO activities declined rapidly at precisely the time that infection was established. The data supports the contention that proPO activity is specifically suppressed by *M. sydneyi* in order to establish infection.

POPULATION BIOLOGY OF MELONGENID WHELKS IN THE INTERTIDAL ZONE IN WASSAW SOUND, GEORGIA. **Alan J. Power,*** **Mary Sweeney-Reeves**, **Todd C. Recicar**, **Dodie M. Thompson**, and **Randal L. Walker**, Marine Extension Service, Shellfish Research and Aquaculture Laboratory, University of Georgia, 20 Ocean Science Circle, Savannah, GA 31411-1011.

Four species of whelk (family Melongenidae) are found within the coastal waters of Georgia: the knobbed whelk, *Busycon carica;* the channeled whelk, *Busycotypus canaliculatus;* the lightning whelk, *Busycon cantrarium;* and the pear whelk, *Busycotypus spiratus*. These whelks are commercially harvested using trawls and are also taken intertidally by oystermen, clammers, and sport fishermen. To date the whelk fishery remains one of the most economically successful molluscan fisheries in the state. There is, however, a lack of fundamental biological information to allow for sound management decisions regarding the sustainability of the fishery. Consequently, the present study was initiated to examine the temporal variability in the abundance and population structure of each species in the intertidal zone in Wassaw Sound, Georgia. Whelks were collected at low tide from six locations, on a seasonal basis, over an annual period. Prior to releasing, all were tagged with an identifying label, measured (shell length, shell width, total wet weight), and sexed. Size frequency distributions, sex ratios, and sexual dimorphism in terms of body size were determined. Growth rates and seasonal migration patterns were examined by recapturing previously tagged specimens. The implications of these results for the whelk fishery in Georgia are discussed.

A RAPID METHOD FOR ASSESSING STRESS IN THE AMERICAN LOBSTER USING A HAND HELD GLUCOMETER. **Deanna L. Prince**, **Robert Bayer,*** **Christina Congleton**, **Shannon Colby**, **Danielle LaVine**, **Danielle Volmuth**, **Katrina Brooks**, **Margaret Berry**, and **William Congleton**, Department of Animal Sciences, and School of Marine Studies, University of Maine, Orono, ME 04469; **John Vetelino**, Department of Electrical and Computer Engineering, University of Maine, Orono, ME 04469.

A number of parameters were measured in lobsters exposed to temperature stress and anoxia from air exposure. Measurements included electrical resistance across the tail membrane, resistance across the body from mouth to anus, pH, and hemolymph calcium, magnesium, and glucose. Hemolymph glucose appeared to be the best indicator of stress as a result of an increase in hyperglycemic hormone. Based on these preliminary findings, a rapid technique was developed to measure hemolymph glucose levels using a commercial hand held glucometer available from any pharmacy. The technique involves centrifugation of the samples and placing the serum on a disposable strip, which is read by the glucometer. In a field sampling using this technique lobsters from areas that tended not to survive well in shipping and storage showed elevated blood glucose.

ROUTES OF *HEMATODINIUM* SP. TRANSMISSION INTO BLUE CRABS. Michael Sheppard,* Florian Rambow, Marc E. Frischer, and **Richard F. Lee,** Skidaway Institute of Oceanography, Savannah, GA 31411.

Hematodinium sp. is a parasitic dinoflagellate which causes mass mortality of blue crabs during infection peaks in late spring and fall in salt marsh estuaries of coastal Georgia. The life cycle of *Hematodinium* sp. in blue crabs involves several different stages including dinospores, prespores, trophonts and plasmodia [Shields, J.D., Ann. Rev. Fish. Dis. 4:241–271 (1994)]. A series of studies were carried out to determine the source and possible routes of transmission of *Hematodinium* sp. into blue crabs in the Wassaw Sound estuary system. Both histological and a recently developed molecular diagnostic techniques, including a quantitative real-time PCR method, were used to quantify *Hematodinium* sp. in crabs and in estuarine water samples. Three possible routes of transmission were investigated in these studies; consumption of infected tissues, injection of hemolymph containing *Hematodinium* sp., and exposure to estuarine water and sediments where infected crabs were found. Hematodinium disease was transmitted by all of these routes, but the most effective route was the transmission to healthy uninfected crabs after feeding on infected tissues from the diseased blue crabs. In several experiments there was a lack of transmission of *Hematodinium* sp. into crabs from water found to contain *Hematodinium*, which we speculate was due to lack of infectious forms in the water, e.g. dinospores. Partially supported by Georgia Sea Grant.

THE RELATIONSHIP BETWEEN BLACK SPOT DISEASE AND LIMB-LOSS IN *CANCER PAGURUS* FROM THE SHETLAND ISLANDS, SCOTLAND. Shelly M. L. Tallack, North Atlantic Fisheries College, Scalloway, Shetland Islands, ZE1 0TS, UK.

The edible crab, *Cancer pagurus*, is a heavily exploited crustacean resource throughout the UK, including the peripherally located Shetland Islands. Black spot disease is the primary infection recorded in the local population and is believed to be most prevalent in specimens with reduced immune systems, resulting from, for example, injury. The confrontational, minority fishing activity of removing only claws from this species in offshore Shetland waters has led to concerns regarding a possible increase in the number of severely injured crabs. Shetland's infection rates were compared with other UK studies.

Black spot disease rates were higher in Shetland than in studies on populations in Norfolk (Ayres & Edwards, 1982) and Wales (Davies, 1999), but lower than findings from Ireland (Vogan *et al.*, 1999). A positive relationship was shown between crab size and black spot disease. Greater infection severity was associated with later intermoult stages. Sex differences were evident with the proportion of infected individuals being higher in males (25.61%) than in females (12.78%). Finally, limb-loss and crab injury were positively correlated with infection.

It cannot be determined whether black spot disease rates in Shetland are linked to claw fishing activity rates. However, as vulnerability to black spot disease may be increased through injury, findings from the current study in addition to earlier research, imply the need for handling techniques which minimize severe limb-loss and injury in discarded crabs.

OYSTER GRAZING ON TOXIC AND NON-TOXIC *PSEUDO-NITZSCHIA* AND *THALASSISIORA WEISFLOGGII*, AND *DITYLUM BRIGHTWELLII*. Anne Thessen,*[1,2] Q. Dortch,[1] T. M. Soniat,[2] and **G. J. Doucette,[3]** [1]Louisiana Universities Marine Consortium, 8124 Hwy 56 Chauvin, LA 70344; [2]Biology Department, Nicholls State University, Thibodaux, LA 70310; [3]Marine Biotoxins Program, NOAA/NOS, Charleston LAB, 219 Fort Johnson Rd, Charleston, SC 29412.

Pseudo-nitzschia spp. are chain-forming diatoms that sometimes produce domoic acid, a potent neurotoxin that causes Amnesic Shellfish Poisoning (ASP). Despite high abundances of *Pseudo-nitzschia* over Louisiana oyster (*Crassostrea virginica*) beds, there have been no documented cases of ASP. Two possible explanations are that oysters cannot feed on long, pointed chains or they discriminate against toxic cells while grazing. Short-term (<2 hr) grazing experiments were conducted with non-toxic *P. pseudodelicatissima*, toxic *P. multiseries* (22–87 μm/cell, depending on species and clone; 4 cells/chain median chain length), *Thalassisiora weisfloggii* (15–23 μm), and *Ditylum brightwellii* (70–140 μm). Oysters (73 to 85 mm) were collected in the field, maintained on flowing ambient seawater, and then starved for 48 hours. Cultures were added at approximately 10^6 cells/liter to containers with individual oysters and to controls with no oysters or killed oysters. During experiments grazing was monitored by measuring decreases in *in vivo* fluorescence, but cell counts and volumes were also measured. Oysters grazed rapidly on all diatoms and cells appeared in feces within 1 hour. Grazing rates, based on fluorescence, were lower on both types of *Pseudo-nitzschia* than for the other diatoms, but those differences may not be sustained when grazing is based on cell volume/carbon.

HISTORIC EASTERN OYSTER *(CRASSOSTREA VIRGINICA)* DREDGE AND PATENT TONG SURVEYS IN THE MARYLAND PORTION OF THE CHESAPEAKE BAY.

Jessica M. Vanisko,* Mary Christman, and **Kennedy T. Paynter,** University of Maryland, College Park, MD 20742; **Stephen J. Jordan,** Maryland Department of Natural Resources (MD-DNR), Cooperative Oxford Laboratory, 904 S. Morris Street, Oxford, MD 21654.

The distribution of the Eastern oyster, *Crassostrea virginica,* in the Chesapeake Bay remains spatially variable. The densities often range from 0 to 250 oysters per m^2. The conversion of historic oyster surveys to spatial files (GIS) has provided the means to examine the potential relationships between oyster biomass and spat settlement, as well as past distributions of oysters in spatially complex ways. Extensive patent tong sampling was conducted by the Maryland Department of Natural Resources (MD-DNR) during two surveys from 1975 to 1979, and again from 1989 to 1995. Data were compared to determine if significant changes in the density of spat, small, and market oysters occurred during the time period between the two surveys. Changes in oyster density in Maryland can be attributed to environmental disturbances and the impacts of disease. Oyster biomass, as calculated from the MD-DNR dredge survey, was paired with patent tong samples in an effort to test for, among other things, a relationship between oyster biomass and spat settlement on several spatial scales. A significant relationship between biomass and spat settlement could not be established with the data available, however data from current sampling regimes are being analyzed for relationships between oyster density, disease incidence, and/or spat settlement.

HEMATODINIUM INFECTION IN BLUE CRABS, SPIDER CRABS AND STONE CRABS.

Anna Walker,* Department of Pathology, Mercer University School of Medine, Macon, GA 31207; **Michael Sheppard, Richard F. Lee,** and **Marc Frischer,** Skidaway Institute of Oceanography, Savannah, GA 31411.

Hematodinium sp. is a histoinvasive parasitic dinoflagellate. We report heavy infections of *Hematodinium* sp. in blue crabs (*Callinectes sapidus*) and spider crabs (*Libinia emarginata*) collected during late fall in a Georgia estuary. The prevalence of *Hematodinium* sp. in blue crabs and spider crabs ranged from 20 to 80% at different sampling stations. Prevalence of *Hematodinium* sp. in stone crabs (*Menippe mercenaria*) from this estuary was only 5% (n = 20). Both hemolymph and tissues were examined microscopically and by molecular techniques. Most infected crabs had a high intensity of infection (15 to 90% of the hemolymph cells were parasite cells). A sequence analysis from the 18S rRNA gene (1682 bp) of *Hematodinium* sp. from spider crabs and stone crabs showed 99.6 and 99.5% sequence similarity, respectively, to *Hematodinium* sp. from blue crabs. Infected crabs had interstitial infiltrates of parasites in all tissues, but most notably in gills, hepatopancreas, cardiac and striated muscle. Focal muscle necrosis was present in heavy infections. Following injection of infected hemolymph, tissues of healthy crabs demonstrated an influx of granular hemocytes with encapsulations.

SHELL MOVEMENT AND JUVENILE SURVIVAL OF THE OYSTER *CRASSOSTREA VIRGINICA* ON INTERTIDAL REEFS ADJACENT TO WATERS WITH INTENSE BOATING ACTIVITY IN THE INDIAN RIVER LAGOON, FLORIDA.

Linda Walters,* Kevin Johnson, Lisa M. Wall, and **Neysa Martinez,** Department of Biology, University of Central Florida, 4000 Central Florida Blvd., Orlando, FL 32816; **Ray Grizzle,** Jackson Estuarine Laboratory, University of New Hampshire, Durham, NH 03824.

Resulting from anthropogenic influences such as boat wakes or natural disturbance events, reefs of the eastern oyster *Crassostrea virginica* in the Indian River Lagoon have been declining in size in recent years. Additionally, dead margins (i.e. mounds of tightly packed, disarticulated shells extending above the high tide line) are commonly found adjacent to boating channels. To determine the impact of boating activity on: 1) shell movements, and 2) juvenile oyster survival, experiments were run on eight oyster reefs in Mosquito Lagoon, the northernmost region of the Indian River Lagoon, Florida. Four reefs had large dead margins, while the other four monitored reefs had no dead margins. To measure shell movement, 25 pre-weighed, oyster shells were deployed within $0.25m^2$ quadrants on the exposed, middle and protected regions of each reef and dispersal of individuals was assessed weekly for 8 weeks. Boat activity adjacent to the eight reefs was also recorded during the eight-week trials. There was a positive correlation between shell dispersal in the exposed regions of reefs and the average number of boats per hour that passed by the study reefs. Additionally, shells that weighed less than 50 grams and those which exceeded 100 grams experienced the least amount of overall movement, and the protected sides of the reefs experienced the least amount of shell movement, even for those reefs with dead zones. To determine the impact of shell movement on juvenile oyster survival, 1-cm diameter clay mimics were attached to 20 shells at the exposed, middle and protected regions on all eight reefs. At weekly intervals for the first 4 weeks of the 8-week trial, damage to the clay was recorded and used as a proxy to estimate damage to *C. virginica* at this vulnerable stage in its life-history.

DEVELOPMENT AND TESTING OF A SIMPLE FIELD SYSTEM FOR MONITORING MUSSEL SHELL GAPE SIZE.

Win Watson, Steve Jury, Jennifer Wishinski, Dan O'Grady, Walter Golet, Darren Scopel, Heidi Pye, and **Chris Rillahan,** Zoology Department and Center for Marine Biology, University of New Hampshire, Durham, NH 03824.

Mussels and other bivalves are known to vary their shell gape size in response to changes in various environmental conditions such as salinity, current or the presence of contaminants. In fact, several research groups have developed biomonitoring systems based on measuring the shell status of freshwater bivalves. The purpose of our project was to develop and test a simple and relatively inexpensive system for measuring the shell gape size of estuarine and saltwater mussels (*Mytilus edulis*) in their natural habitat. Battery-powered Hall-Effect sensors were used to detect the gape size of mussels and their output, in volts, was logged at 10 sec intervals onto a HOBO datalogger. The datalogger, batteries and customized electronics were placed in a waterproof case inside a buoy that communicated with mussels on the bottom via a waterproof cable. Monitoring systems were deployed at 6 different locations in the Great Bay Estuary, NH and along the N.H. coastline. Data obtained was examined to determine if changes in gape size were correlated with changing tides, light levels and/or ambient concentrations of heavy metal contaminants. Laboratory studies, under more controlled conditions, were used to determine their response thresholds to these same stimuli. While the system developed proved very sensitive and reliable, the complex factors influencing the gape size of mussels made it difficult to definitively explain all the variations in gape size recorded from mussels in their natural habitat. This study was supported by CICEET and Gulf Watch grants to W.H.W.

THE NATIONAL SHELLFISHERIES ASSOCIATION

The National Shellfisheries Association (NSA) is an international organization of scientists, management officials and members of industry that is deeply concerned and dedicated to the formulation of ideas and promotion of knowledge pertinent to the biology, ecology, production, economics and management of shellfish resources. The Association has a membership of more than 1000 from all parts of the USA, Canada and 18 other nations; the Association strongly encourages graduate students' membership and participation.

WHAT DOES IT DO?

—Sponsors an annual scientific conference.
—Publishes the peer-reviewed *Journal of Shellfish Research.*
—Produces a Quarterly Newsletter.
—Interacts with other associations and industry.

WHAT CAN IT DO FOR YOU?

—You will meet kindred scientists, managers and industry officials at annual meetings.
—You will get peer review through presentation of papers at the annual meeting.
—If you are young, you will benefit from the experience of your elders.
—If you are an elder, you will be rejuvenated by the fresh ideas of youth.
—If you are a student, you will make useful contacts for your job search.
—If you are a potential employer, you will meet promising young people.
—You will receive a scientific journal containing important research articles.
—You will receive a Quarterly Newsletter providing information on the Association and its activities, a book review section, information on other societies and their meetings, a job placement section, etc.

HOW TO JOIN

—Fill out and mail a copy of the application blank below. The dues are 65 US $ per year ($35 for students) and that includes the *Journal* and the Newsletter!

NATIONAL SHELLFISHERIES ASSOCIATION—APPLICATION FOR MEMBERSHIP
(NEW MEMBERS ONLY)

Name: ______________________ For the calendar year: _____ Date: __________
Mailing address: ______________________________________
____
____

Institutional affiliation, if any: ______________________________
Shellfishery interests: ______________________________

Regular or student membership: __________
Student members only—advisor's signature REQUIRED: ______________________

Make checks (*MUST* be drawn on a US bank), international postal money orders or VISA for $65 ($35 for students with advisor's signature) payable to the National Shellfisheries Association and send to Nancy Lewis, Bookkeeper, PO Box 350, V.I.M.S. Eastern Shore Lab, Wachapreague, VA 23480, USA.

INFORMATION FOR CONTRIBUTORS TO THE *JOURNAL OF SHELLFISH RESEARCH*

Original articles dealing with all aspects of shellfish research will be considered for publication. Manuscripts will be judged by the editors or other competent reviewers, or both, on the basis of originality, content, merit, clarity of presentation, and interpretations. Each article should be carefully prepared in the style followed in prior issues of the *Journal of Shellfish Research* before submission to the Editor. Papers published or to be published in other journals are not acceptable.

Title, Short Title, Key Words, Abstract: The title of the paper should be kept as short as possible. Please include a "short running title" of not more than 48 characters including spaces, and key words. Each manuscript must be accompanied by a concise, informative abstract, giving the main results of the research reported. The abstract will be published at the beginning of the article. No separate summary should be included.

Text: Manuscripts must be typed double-spaced throughout on one side of the paper, leaving ample margins, with the pages numbered consecutively. Scientific names of species should be underlined or in italics and, when first mentioned in the text, should be followed by the authority. Common and scientific names of organisms should be in accordance with American Fisheries Society Special Publications 16 and 17: *Common and Scientific Names of Aquatic Invertebrates from the United States and Canada: Mollusks and CSNAIUSC: Decapod Crustaceans,* or relevant publications for other geographic regions.

Abbreviations, Style, Numbers: Authors should follow the style recommended by the sixth edition (1994) of the *Council of Biology Editors [CBE] Style Manual,* distributed by the American Institute of Biological Sciences. All linear measurements, weights, and volumes should be given in metric units.

Tables: Tables, numbered in Arabic, should be on separate pages with a concise title at the top.

Illustrations: Line drawings should be in black ink or laser print and planned so that important details will be clear after reduction to page size or less. No drawing should be so large that it must be reduced to less than one third of its original size. Photographs and line drawings should be prepared so they can be reduced to a size no greater than 17.3 cm × 22.7 cm, and should be planned either to occupy the full width of 17.3 cm or the width of one column, 8.4 cm. Photographs should be glossy with good contrast and should be prepared so they can be reproduced without reduction. Originals of graphic materials (i.e., line drawings) are preferred and will be returned to the author. Each illustration should have the author's name, short paper title, and figure number on the back. Figure legends should be typed on separate sheets and numbered in Arabic.

Digital Figures: Authors may provide digital figures (they are not required); they must be accompanied by hardcopy figures of equal quality, which the printer will use for comparison and backup. If digital figures are supplied, please note the following instructions:

- Each piece of art should be saved as its own file.
- Files must be one of the following formats: TIF, EPS, or JPG.
- Each file should be named according to its figure number and format (e.g., "fig2b.tif").
- Figures must not be embedded in a word-processor or spreadsheet document: the printer cannot use images stored in Word, WordPerfect, Excel, Powerpoint, etc.
- Resolution: *line shots:* 1000 dpi; *halftones/grayscales:* 300 dpi if no lettering, 500 dpi if figure contains lettering.
- Color figures: save the files as CMYK-encoded TIF images (preferred) or CMYK-encoded EPS or JPG images. Color figures have the same resolution requirements a B/W, above.

Color illustrations will not be accepted unless the author agrees to cover the cost of associated reproduction and printing.

Literature Cited: References should be listed alphabetically at the end of the article. Abbreviations in this section should be those recommended in the *American Standard for Periodical Title Abbreviations,* available through the American National Standard Institute, 1430 Broadway, New York, NY 10018. For appropriate citation format, see examples below:

Page Charges: Authors or their institutions will be charged $100.00 per printed page. All page charges are subject to change without notice. A handling fee of $50 will be charged for all manuscripts accepted for publication.

Proofs: Page proofs are sent to the corresponding author and must be corrected and returned within seven days. Alterations other than corrections of printer's errors may be charged to the author(s).

Reprints: Reprints of published papers are available at cost to the authors. Information regarding ordering reprints will be available from The Sheridan Press at the time of printing.

Cover Photographs: Appropriate photographs may be submitted for consideration for use on the cover of the *Journal of Shellfish Research.* Black and white photographs and color illustrations will be considered.

Corresponding: An original and two copies of each manuscript submitted for publication consideration should be sent to the Editor, Dr. Sandra E. Shumway, Department of Marine Sciences, University of Connecticut, 1080 Shennecossett Rd., Groton, CT 06340. E-mail: sandra.shumway@uconn.edu or sandrashumway@hotmail.com

COVER PHOTO: Carpet shell clam, *Tapes decussatus* (Linnaeus, 1758). The species is of Atlantic-Mediterranean origin and is distributed along the Euro-African coast from England to Senegal and throughout the Mediterranean with penetration in the Red Sea. While the introduced short-necked clam or striped venus (*Tapes philippinarum*) has almost superseded the carpet clam in Italian waters, *T. decussatus* is grown commercially in Sardinia. IN MEMORIUM
HAROLD HALEY HASKIN
1915–2002

Hal Haskin died on June 23, 2002 at the place he loved best—his Cape Shore cottage on Delaware Bay. Most of his 87 years–since he spent the summer after his junior year at Rutgers working on oyster drills—had been devoted to teaching and research on the marine environment, and Delaware Bay was its focus. Hal's "Honored Life Member Biography" appeared in 1999 in Volume 18(2) of the Journal of Shellfish Research. Here we reflect more on his character and recount memories of the man.

Hal was born in 1915 at Niagara Fall, NY to George and Laura Haley, the second of three children. Three years later, the children were orphaned when both parents and a grandmother died within a week of each other in the 1918 flu pandemic. A family friend, Frederick Haskin, adopted Hal—an unusual arrangement, particularly for the time, because Fred Haskin was a bachelor. Haskin was a pipefitter, a job that forced him to travel around the country, so he lodged young Hal with a retired farm family living in southern New Jersey, near the DuPont chemical plant where he sometimes worked. The daughter of the family, whom Hal knew as Aunt Jenny, supervised the home and became his *de facto* mother. Later, Aunt Jenny and Fred Haskin married so that Jenny officially became the mother that she had unofficially been throughout most of his childhood. It wasn't until many years later that Hal became reacquainted with his many Haley relatives still living around Niagara Falls and for the first time was called "Uncle Hal".

Always a good student and with an unusually strong work ethic, Hal graduated from Rutgers College in 1936, the first student to do so with a perfect grade score. It was at Rutgers that he came under the tutelage of Thurlow Nelson and began his life-long fascination with oysters. During summers spent investigating the predatory oyster drills, Hal observed that the snails preferred young oysters to older ones. Curious about mechanisms of chemoattraction, he entered Harvard to work with John Welsh on this phenomenon, but he spent his first summer as a graduate student at the Bermuda Biological Station studying lobster neurohormones. He grew a beard, which came in red, was introduced to sailing, and acquired a taste for his research subjects.

Hal switched to algal physiology for his PhD dissertation, which he carried out under the supervision of the oceanographer Alfred Redfield. His work included the development of a method for estimating chlorophyll concentrations using spectrophotometry—a precursor to the present-day Strickland and Parson's method. At Harvard, Hal supported himself as a dorm proctor and a teaching assistant. He was a natural teacher who excelled at hands-on instruction in both the laboratory and the field.

Upon receiving his PhD in 1941, Hal entered the US Army and spent the next 5 years training troops and supervising units guarding the coast from Long Island to the Virginia Capes. He returned to Rutgers as an assistant professor in the Department of Zoology in 1946 and began developing a research program devoted to marine bivalves. His early work involved culturing and rearing of hard clams on a grant from Campbell's Soup Company. In 1950, however, he succeeded his mentor Thurlow Nelson as head of the Oyster Investigation Laboratory in the New Jersey Agricultural Experiment Station, and for many years thereafter devoted most of his research efforts to protecting and enhancing the oyster resource of Delaware Bay. Although he later became deeply involved in acquiring data on, and developing a management plan for, offshore surf clams, his heart and mind never strayed far from oysters and Delaware Bay. From his early efforts to institute harvest limits on the depleted natural seed oyster beds, through the devastation brought by the MSX parasite, to providing management data when populations later rebounded, Hal considered the Bay's oysters to be his personal responsibility. He brought to this and other tasks a unique combination of intelligence, scientific integrity, and the ability to work with people from all sides of a problem. He never shirked from controversy, but he was always armed with reams of data, which he carried in whiskey boxes in the back of his car, to backup his point of view. Hal took pains to make the data understandable to both the regulators and the fishermen. He spoke his mind, albeit diplomatically, and he rarely lost a battle.

One ongoing stuggle, which he inherited from Thurlow Nelson, was maintaining freshwater flow into the Delaware estuary. In this battle against diversions and dams, he had the enthusiastic participation of his wife, Peg, whom he had met when she was a recent graduate of Smith College and he was a graduate student at Harvard. The two of them eventually became a formidable team fighting for rational water management in New Jersey, particularly concerning those policies affecting Delaware Bay and its oyster populations.

Although he ran a large research laboratory, Hal devoted much of his time to teaching. As a young assistant professor, he taught mainly undergraduate courses in general biology, limnology, animal physiology, and invertebrate zoology. Somewhat later, he developed graduate courses in coastal oceanography, estuarine ecology, and malacology. Most of the graduate students in the Rutgers Zoology Department took at least one of these courses at some point in their academic careers—and never forgot them. Hal did not confine his teaching to the classroom, nor did he limit it to official students. He delighted in showing anyone the anatomy of a shucked oyster or talking about the intricacies of an oyster community. His audience might be a businessman or an oyster grower—it didn't matter—his enthusiasm captivated them all. Anyone who was associated with Hal in any capacity always wound up considering himself or herself a student. And Hal, himself, never stopped being a student.

Hal retired in 1984 but he remained active long thereafter. During his nearly 50-year career, he touched many people—students, colleagues, university and government officials, and shellfish producers. More than 200 of them gathered at the Haskin Shellfish Laboratory on September 28, 2002 to remember him. People came from all along the eastern seaboard and from as far west as Colorado to tell stories, share memories, renew acquaintances, look at old photographs, and eat good food—including freshly shucked oysters farmed at the Cape Shore near the Haskin cottage.

His first and last graduate students were there, as were a host of students in between. They recalled how taking one of his courses had been the stimulus to go into marine science or shellfish biology. Several remarked on how tough a questioner he was during thesis defenses and how his criticisms were right on the mark, sometimes requiring a return to the bench to do a critical experiment. Although Hal was remembered most for applied research that directly benefited the shellfish industry, his intellectual curiosity was profound. He insisted that applied research conform to the standards of basic research. Further, how could one provide sound scientific advice for management without understanding fundamental biological and ecological principals? Woe to any student or colleague who failed to convince Hal that he or she knew the basic scientific principles underlying a concept.

Students remembered his Saturday courses and that he worked well into the night on Friday, and often into the early morning hours of Saturday, preparing. The classes officially ran from 8 in the morning to 5 in the evening, but leaving at 5 was viewed with a highly disapproving eye. Several students remarked on his indifference to physical discomfort on the field trips—and that he was equally indifferent to discomfort of the students. The discomfort usually took the form of "cold and wet" or "seasick", but on one occasion it was much more serious. On an oceanography class field trip, Hal lacerated his hand severely on the pulley wheel of an outboard motor that he was attempting to start. The deep cut ran along the base of his fingers and down the outside of his palm. Flapping fingers indicated severe damage to his hand, but he merely wrapped it in a handkerchief and was fully prepared to continue the trip. At the overwhelming insistence of his students, however, he reluctantly canceled the excursion in favor of a trip to the hospital and several hours of microsurgery to rejoin the tendons leading into two fingers.

Neighbors, who grew up with the Haskin children at the Cape Shore, and whose fathers were businessmen and auto mechanics, couldn't figure out what Hal did for a living. He was like a kid in an adult body who actually got paid for mucking about on the tide flats playing with oysters. But he could answer all the questions they had about the organisms they found in the bay and along the shore.

Hal was an advocate of simplicity. He was not interested in "building an empire" because he felt that he would then have to spend all his time supporting and defending it—certainly much less stimulating to him than the hands-on field and lab activities that he relished. Colleagues and students remembered him as a quiet, low-keyed person who was a good listener. He was thoughtful and one knew that he had truly reflected upon a question or an issue before he gave advice.

One of the fondest memories, shared by nearly all the students, was of the biannual "tray moves". These events took place each spring when trays of selectively bred oysters had to be moved from winter quarters, where they were protected from ice damage, onto the tidal flats in front of the Cape Shore Laboratory where they were exposed to disease pressure and could be easily tended. Each fall, the reverse move took place. All able hands—students, faculty, technicians, friends—were marshaled for the event because the oysters in each tray—and there were often more than 100 trays—had to be counted, samples removed, and the oysters had to be placed in freshly prepared trays. The weather was usually cold and miserable, and ones fingers quickly became numb. Tying lines on the trays so that they could be hung in the marina that served as winter quarters was especially challenging under these conditions. Hal would check every single knot (four per tray, half-hitches, not bowlines) and retie most, while being silently cursed by the small group of students standing around on the dock—cold, wet, tired, and anticipating the reward that awaited them at the Haskin cottage where Peg was preparing the traditional turkey dinner and a fire was blazing in the wood stove. Fifteen, twenty, occasionally up to thirty famished people would arrive. The first order of business was the preparation and distribution of gin and tonics, and if Hal made them, they contained plenty of gin. People pitched in to set the table, make the salad, and cook the peas, but certain tasks were Hal's own province: making the gravy, mashing the potatoes, and carving the turkey. These jobs had to be performed in a very specific fashion, with Hal describing to anyone within earshot his way to successful gravy or mashed potatoes. The evening ended with homemade (by Peg) pie—cherry, pumpkin, blueberry, and pecan—along with ice cream, coffee and tea, and very muted memories of the earlier discomforts. The tray moves were planned to end on Saturday night when the turkey dinner was held. Sunday morning one could sleep late, but not so late as to miss the "flapper" breakfast—again at the Haskin cottage with Hal busy making blueberry pancakes. The tray moves eventually became very popular events that attracted ex-students and often, their friends, back to the Cape Shore for a weekend of work and good fun.

Hal's publication record was modest and belies his research accomplishments. He was totally disinterested in maintaining a CV. In fact, it was difficult to locate citations, among his own files, to list in this remembrance. His exacting standards applied to writing—both style and content—and to his own as well as that of others. He had difficulty with the concept of publishing a paper that didn't tell a complete story, and he usually felt that he needed more data than he had. This was particularly true for field studies, even though his data sets extended for years, and, in some cases, for decades. Although Hal always analyzed the results and used them in meetings or to advise management agencies, formal reporting was less interesting than starting a new project or going on a field expedition. Students recalled late night sessions in which everyone pitched in to help copy and assemble reports at the very last minute—typically well after the deadline. Nevertheless, Hal had little difficulty obtaining funds to run his laboratory because grant managers knew the quality of the data would be high—when they eventually received it.

When he wasn't working, which often seemed like never, Hal had three great recreational passions: woodcutting, sailing, and growing lilacs. For years, Hal and Peg heated their house in southern New Jersey and their Cape Shore cottage with wood stoves. Their house in Piscataway had multiple fireplaces. Hal always carried a chain saw and splitting wedges in the trunk of his car in case he had an hour or two free to cut wood. Friends recalled that he cut down only dead or dying trees and knew exactly when they should be cut to maximize dryness and minimize decay.

The principal Haskin sailboat was a 17 ft Thistle that was anchored on the tidal flats in front of the summer cottage, and sailed as often as possible at high tide with Hal at the helm and a boat full of family, friends, and students from the Cape Shore Laboratory, just down the beach. Annual beach parties were a chance for sailboat races between the Thistle and any other sailboat that could be pressed into service.

More than 100 lilac bushes representing 70 different varieties, formed a fragrant hedge around the Piscataway house. Hal knew all the varietal names and delighted in escorting visitors around the hedge, "introducing" them to each plant and pointing out its unique characteristics. Each May when the lilacs bloomed, he would bring buckets full of blossoms into the lab to distribute among the staff and faculty. He stored them in the cold room, which temporarily at least, smelled delightfully of lilacs rather than aged oysters.

The memorial service included tributes from representatives of numerous agencies, organizations, and institutions that Hal served, including the National Shellfisheries Association. He joined NSA in the late 1940s and rarely missed a meeting for almost 50 years. He was Vice President in 1966–67, and President during 1967–69. He became an Honored Life Member in 1979 and, most precious to him, was given the David Wallace Award in 1984.

In addition to Peg, Hal is survived by five children, Kathleen Haskin of New York City, Jean Haley of North Kingstown, RI, Elizabeth Haskin of Cape May Court House, NJ, Frederick James Haskin of Piscataway, NJ, and Mary D. Haskin of Washington, DC; and four grandchildren, Harold Haskin II, a student at Rowan University, Allegra and Elijah Penny, of Washington, DC, and William Schroer of Cape May Court House, NJ.

Hal, alone and with Peg, received numerous awards over the years (see Kraeuter and Ford, 1999. J. Shellfish Res. 18: 337–339), but one of the finest was presented at the memorial service: The New Jersey Nature Conservancy named a portion of its Delaware Bayshores Tract near the Cape Shore cottage "The Harold and Margaret Haskin Nature Preserve." It was an entirely fitting honor for a lifetime of dedicated service to environmental teaching and preservation.

Jay Donald Andrews
Honored Life Member

Jay Andrews, affectionately known as "Andy" by his many friends and colleagues, is widely respected for his fundamental research on the ecology of the major oyster pathogens in the Chesapeake Bay, *Haplosporidium nelsoni* and *Perkinsus marinus*. Less well known, but equally important, are his 22-y dataset on oyster spatfall patterns in the Chesapeake Bay and the disease management strategies he developed for industry.

Andy was born on September 9, 1916 in Bloom, Kansas. He grew up on a wheat and cattle farm in western Kansas south of Dodge City during the Depression and drought of the 1930s. Andy attended high school in Bloom and was the top student in a class of 10. Studies were apparently easy for him and he spent much time reading Zane Gray wild-west stories and following baseball scores and players. When Andy graduated from high school in 1934, the nation was in full depression, and the western plains were in a severe ten-year drought that was making farming very difficult, if not impossible. Lack of moisture prevented raising wheat or fodder for cattle. Over time, Andy remembers, pastures of the family farm were filled with annual weeds, prickly pear cactus, and an explosion of jackrabbits. After graduation, Andy's father took him to a bank in Dodge City, borrowed $100 and sent him to Kansas State College in Manhattan. College opened a new world for Andy, and he worked hard. In addition to classes, he worked 40 hours each month in the state 4-H Club for 25 cents an hour and participated in the ROTC, which paid $15 a month. He was designated the top agricultural student and obtained a degree in agriculture in 1938, but farming in western Kansas was not an attractive proposition for Andy. Instead, he began graduate study at the University of Wisconsin in Madison, where he obtained a teaching assistantship in biology. He earned a salary of $600 a year and had money for extracurricular activities for the first time. His love of opera developed during these years. Andy earned an M.S. in 1940 and continued on for his Ph.D.

Andy's graduate studies were interrupted by World War II; he was called up in January 1941 and spent four years in the infantry. He saw action in the South Pacific at the battle of Leyte Gulf and the battle of Bataan and survived multiple kamikaze attacks on his troop ship. In 1946, he returned to Madison to finish his degree, which he earned in 1947. In the spring of 1946, Andy and fellow student, Willard Van Engel, attended a fisheries meeting in St. Louis, where they met the Director of the Virginia Fisheries Laboratory in Yorktown, VA (the precursor of VIMS), who offered them jobs that they both accepted. Van Engel was requested to work on blue crabs, and Andy was asked to concentrate on oysters. A few months later, he was advised by a visiting professor from Yale not to work on oysters, because there was already a large literature and "everything had been done already." Thankfully, Andy ignored the advice. When Andy and "Van" arrived in Virginia in the fall of 1947, they learned that the three scientists who had been at the laboratory had left that summer for positions at Texas A&M. They had been working with mussels on some compound important to the war effort. The three scientists were John Mackin, Sewell Hopkins, and Winston Menzel.

Shortly after he arrived in Virginia, Andy began monitoring oyster spatfall patterns in the tributaries. After years of monitoring, it became clear that setting patterns could be easily separated into two distinctive types. The large tributaries and the Chesapeake Bay proper require very large stocks of brood oysters to acquire regular spatfall because of the large tidal exchange and flushing. Only the upper James River estuary met this requirement and that was because of its special circulation patterns and the large beds of transplanted oysters in the lower James being grown by private industry. Such other large rivers as the York, Rappahannock, and Potomac never had enough broodstock to produce regular spatfall, but occasional large sets did occur. The small tributaries, with low runoff, exhibit a completely different setting pattern than the large tributaries. These coastal plain subestuaries have moderate annual setting patterns, even though oyster populations are low because of high larval retention caused by the winding channels and shallow flats. Uncharacteristically, Andy never published these data on spatfall patterns. Beginning in 1950, Andy tried to persuade managers in Virginia to use the small estuaries to produce seed oysters for transplantation to larger tributaries, but this advice was ignored until long after he retired. When the reef restoration strategy was initiated in Virginia in 1996, the first few reconstructed oyster reefs were placed in these small tributaries because of the larval retention patterns that Andy had documented.

Andy's research on oyster diseases began when John Mackin visited VIMS from Texas to determine if *Perkinsus marinus* (Dermo disease) was present in Chesapeake Bay oysters. The discovery of this pathogen in an area lacking oil drilling confirmed that oyster mortality in the Gulf of Mexico was the result of *P. marinus*, not the oil industry. Andy produced fundamental papers on the epizootiology of Dermo disease during the 1950s, and his 1988 review on the pathogen is a classic paper still widely read and cited. When *Haplosporidium nelsoni* (MSX disease) appeared in the Chesapeake Bay in 1959, Andy immediately began conducting research on this organism and produced many seminal papers on the ecology of this pathogen as well as on *Haplosporidium costale*. One of Andy's most important traits was that he published his results in a timely manner. In 1960, Andy initiated a monitoring program for *H. nelsoni* at VIMS using imported susceptible oysters. This program continues to the present day and provides a 42-year database on *H. nelsoni* prevalence and intensity that has proved invaluable for examining climate effects on pathogen abundance. Because of his broad training and experience and his inquisitive nature, Andy was very insightful. For example, he was the first to hypothesize, in 1980, that *H. nelsoni* was an introduced pathogen. It wasn't until 2000 that molecular data were obtained that support his supposition.

Andy worked hard and expected hard work of others. You arrived on time, and you didn't leave early. Andy loved the rigors of fieldwork and scoffed at suggestions for an easier way to do things. He hauled oyster trays by hand and cleaned them by throwing countless buckets of water that he dipped by hand. After such trips he returned to the campus at VIMS wet, covered with mud, shirtless, in shorts, and barefoot. He surely startled more than one unsuspecting graduate student.

Andy is internationally recognized for his fundamental research on oyster diseases, but he was also a long-time educator. During his career at VIMS he taught Ichthyology, Field Biology, Taxonomy and Systematics, Marine Ecology and Biologic Oceanography.

Andy was a capable and energetic volleyball player. In the "interesting" lunch time volleyball games at VFL/VIMS he played with gusto, spiking near net-balls down the throats of opposing players with great vigor and glee. Road trips with Andy were always an experience. Once, while driving north for a meeting, Andy spied a walnut tree along the road. He pulled over and took an old pair of coveralls out of the trunk. He tied off the end of each leg, walked over to the tree and began filling the legs with walnuts that had fallen to the ground, commenting that he hoped we would not be shot by the owner.

Andy is an avid vegetable gardener and has a large plot near VIMS. He can still be seen hauling countless old milk jugs full of water in his old truck during drought periods and undoubtedly still cursing the varmints that take half his crop.

Andy is a long-time member of the National Shellfisheries Association and served as President and Editor. He was elected Honored Life Member in 1983. In 1998, he received the David Wallace Award in recognition of his career-long efforts to use science for the betterment of shellfish management and a sustainable industry.

Neil F. Bourne
Honored Life Member

Neil was born August 11, 1929 in London, Ontario, Canada. He began his elementary school education there, and it was in London, mainly through the influence of his father, that he became interested in natural history and particularly bird watching, a hobby and passion that have continued to the present. It was this interest in natural history that eventually led him to become a biologist. The family moved to Hamilton, Ontario in 1939, where he completed his elementary and high school education. By the time he moved to Hamilton, he had over 150 bird species on his life list! He entered McMaster University in Hamilton in 1948 and graduated with a BSc in biology in 1952. In 1953, he completed a MSc degree at McMaster under an Ontario Research Scholarship and in 1953–54 spent a year in Germany, where he undertook studies in limnology at the Freshwater Institute in Ploen and marine biology at the University of Kiel. He returned to Canada in 1954, entered the University of Toronto, and graduated from there with a PhD in 1959. His thesis was entitled, "Determination of carbon transfer from *Chlorella vulgaris* Beyerinck to *Daphnia magna* Strauss using radioactive carbon (C14) as a tracer." Three years of his studies were supported by National Research Council of Canada scholarships.

On completion of his PhD in March 1959, Neil joined the staff of the Fisheries Research Board of Canada at the Biologic Station in St. Andrews, New Brunswick working under the direction of the late Dr. J. C. Medcof, a former Honorary Member of NSA. At St. Andrews, he was in charge of the sea scallop investigation that included investigations of the basic biology and ecology of sea scallops, dynamics of sea scallop populations on Georges Bank and in the Bay of Fundy, scallop gear efficiency trials, and exploratory work to locate sea scallop resources in other areas along Canada's Atlantic coast. While at St. Andrews, Neil spent two weeks at Dr. V. Loosanoff's laboratory in Milford, Connecticut studying bivalve breeding technology. Thus began a life-long commitment to shellfish aquaculture. He used knowledge gained at the Milford laboratory to begin initial attempts to culture sea scallops and was successful in conditioning and spawning adults and raising larvae to the mature stage.

In 1965, Neil transferred to the Pacific Biologic Station in Nanaimo, British Columbia, first working for the Fisheries Research Board of Canada and later with the Department of Fisheries and Oceans. Initially, he worked with the late Dr. Dan B. Quayle, another former Honored Member of NSA, and remained at the Pacific Biologic Station until his retirement. During his career at the Pacific Biologic Station, Neil undertook research studies on a wide range of molluscan subjects, including the basic biology of several Pacific coast molluscan species, population studies of commercially important clams, harvesting gear efficiency, and studies to develop techniques to culture several species. He developed techniques to predict Pacific oyster spatfall accurately for the industry, a service he continues to provide. He undertook extensive surveys of bivalve resources in B.C. and, in particular, followed the dispersal of Manila clams northward along the coast. As a result of these studies, a fishery for Manila clams became established in the central coast of B.C.

As a result of previous work and the influence of his stay at the Milford laboratory, Neil remained intensely interested in bivalve culture and continued studies in this field. Initial studies were undertaken to investigate the potential of butter and littleneck clams and abalone. He undertook studies with Manila clam culture that were important in establishing the Manila clam culture industry that exists in B.C. today.

From 1981 to 1991 Neil led a program to investigate the feasibility of scallop culture in B.C. Several species were studied, but the decision was made to work with the Japanese scallop, *Mizuhopecten yessoensis*, and methods were developed to produce juveniles in a hatchery and raise them to commercial size within a period of two years. Much of the information culminated in the publication, *A Manual for Scallop Culture in British Columbia*, which continues to be used by many to the present day. Results of the work led to a private company building a scallop hatchery and beginning commercial scallop culture in B.C. He continues to serve as an advisor to this industry.

Neil has been active in foreign aid work, assisting at Universities and has been involved with several scientific societies. He worked for the Canadian International Development Agency for 1 1/2 years in Fiji, where he served as Director of a Fisheries Training Program at the University of the South Pacific in Suva. He undertook an assessment of the Cuban oyster industry for the Department of Fisheries and Oceans and advised on a joint Canada–Cuba program to expand oyster culture in Cuba. He worked for the United Nations Food and Agriculture Organization in the Peoples' Republic of China and continues to serve as a volunteer advisor to the Canadian Executive Service Organization. He served on the Aquatic Resources Subcommittee of the Science Council of British Columbia from 1987–2002 and was chairman from 1991 to 2002.

He is an affiliate professor at the University of Washington, School of Fisheries and has been a committee member for over 20 graduate students, mostly at the University of Washington, but also at the University of Victoria, the University of British Columbia, and Simon Fraser University.

Neil served on the executive boards of the Canadian Society of Zoologists, the World Aquaculture Society, the Aquaculture Association of Canada, serving as President of the latter Society from 1987–1988. He joined the National Shellfisheries Association (NSA) in 1961 and has been active in the affairs of the society since then. He served on the Executive Committee of the Association from 1974–1983, including tenure as President in 1981–1982; he was the first Canadian to serve as President of NSA. He has been a member of the editorial board of the *Journal of Shellfish Research* for many years. He was made an Honored Life Member of the Association in 1990 for his exemplary service to NSA and the profession. In 1991, he received the David H. Wallace award for promoting understanding, knowledge, and cooperation among industry members, the academic community, and all levels of government and for his outstanding success in bringing together shellfish scientists and industry officials for the benefit of shellfisheries.

Neil received an Award of Merit from the Department of Fisheries and Oceans in 1993 for an exceptional and distinguished contribution to the effectiveness and efficiency of the Public Service and the Department, particularly for contributions to the aquaculture industry of British Columbia. Neil retired from the Department in March 1994.

In May 2000, Neil was presented with an Honorary Lifetime Achievement Award from the Aquaculture Association of Canada. The selection board cited long-time service to the Association, the research community, industry, and young scientists as exemplary examples of the goals of that organization. He was the first recipient of this award.

Neil lives in Nanaimo and continues to work at the Pacific Biologic Station as a volunteer Scientist Emeritus, publishing results of past and current work and encouraging young scientists in their careers. He still has time to enjoy his grandchildren, hike, work around the house, and undertake other activities. He is keenly interested in golf and is a rabid bird watcher with the distinction of having birded on all seven continents. One activity in his retirement is to compile his bird life list, he believes he has seen about 2,500 species of birds! Those who have golfed with him have noted that he never lets golf interfere with birding although the opposite has occurred on occasion.

Victor G. Burrell
Honored Life Member

Dr. Victor (Vic) G. Burrell, Jr. has been a member of the National Shellfisheries Association (NSA) for over 30 years and served as its president from 1982–1983. He was born in Wilmington, NC in 1925 and served in the U.S. Navy during WW II from 1943–1946. He received a B.S. degree in English from the College of Charleston in 1949. In 1965, after 15 years in his family's meat-packing business, he went on to earn both Master's Degree and a Ph.D. Degree in Marine Science from the College of William and Mary in 1968 and 1972, respectively. In large part, this interest may have been kindled through his experiences operating a charter boat in South Carolina and working part time in the commercial oyster industry. While a student at Virginia Institute of Marine Science (VIMS), he served as the liaison to the fishing industry, especially with oystermen. At that time, he developed a method of denaturing the red algal-derived seasonal color of oysters using the blower system.

In 1972, he left the staff of the VIMS and returned to the Carolinas as an Associate Marine Scientist with the then just established Division of Marine Resources in Charleston. He spent from 1972 to 1991 at the Marine Resources Research Institute (MRRI) of the Division of Marine Resources, South Carolina Department of Natural Resources (then the Wildlife and Marine Resources Department). He served as the Institute's Director from 1974 to 1991, "retiring" in 1991. Since then, he has continued to take an active role in South Carolina's marine resources, including co-authoring numerous scientific and lay review publications for NOAA and the DNR as an emeritus director and scientist at Fort Johnson. In total, he has published over 65 scientific papers on zooplankton ecology, shellfish biology, and oyster culture. These include a series for NOAA in 1996–1997 entitled "The History, Present Condition, and Future of the Molluscan Fisheries of North and Central America and Europe, Volumes 1–3, with Clyde Mackenzie and others. In 2000, he authored a DNR educational report entitled "The Recreational Fishery in South Carolina: the Little River Story," reviewing the first organized offshore recreational fishing industry in South Carolina. He is also currently writing a history of South Carolina's oyster industry for publication.

During his leadership at MRRI, Dr. Burrell saw the staff double to about fifty professional individuals, including eleven Ph.D-level marine scientists. In addition to his active participation in the NSA, Dr. Burrell served also as president of the Southeastern Estuarine Research Society (SEERS) and was named an honorary life member of SEERS. He served as president of the College of Charleston Alumni Association and was honored as the college's Alumnus of the Year in 1963. He also saw the development and construction of the SC Aquarium serving on the executive board of the aquarium as a founding member.

He is listed in Community Leaders of America, Personalities of the South, American Men and Women of Science, International Directory of Distinguished Leadership, Who's Who in the South and Southwest, Who's Who in America, and Men of Achievement. He recently moved to new digs and we will miss him walking along the road tipping his hat and waving his hand as he traveled daily to MRRI from his James Island house. However, we still expect to see him almost daily in his office (when he is not taking a vacation cruise) chatting with everyone and being the gentleman that he is. He is an aficionado of big band swing and jazz, particularly that from the Depression era through post-war periods. We remember his enjoyment of Ken Burn's "Jazz" and discussed with him the pros and cons of Burn's choice of influential "characters," such as Louis Armstrong. He's knowledgeable enough about the music and musicians of that era to do a creditable history. He's been an active member of St. James Episcopal on James Island for many years, serving as Junior and Senior Warden on several occasions.

Vic and his wife Katherine have four children, eight grandchildren, and four great-grandchildren.

Original works of art surround the artist and NSA Honored Life Member, Herb Hidu, at his home in Alna, Maine.

Herbert Hidu
Honored Life Memeber

Herb has traveled an unusual and convoluted path to distinction in American shellfisheries science. He was born in 1931, the son of a German immigrant and a 2nd generation Hungarian farmer and estate manager. The family never had the slightest inclination for academia. He spent his youth hunting, fishing, and observing the pleasantries of living on a Connecticut rich man's estate as a cottage inhabitant. He joined the army in 1951 and for 2 years was a paratrooper with the 82nd airborne division, which gave him his mindset for later years. After his hitch, his drinking buddy made him aware of Korean G.I. Bill eligibility. Entering the University of Connecticut, he majored in fisheries management and forestry (B.S., 1958). Along the way he had the opportunity to resume his parachuting paranoia, working a summer as a smokejumper at the United States Forestry Service base in Winthrop, Washington, during which time he made four fire jumps.

At UConn, Dr. Slater of the Entomology Department convinced him to pursue a graduate degree in the biological sciences. He received a MS degree in Zoology in 1960 from Penn State University, working under the tutelage of Dr. Edwin L. Cooper on population structure of largemouth bass in a farm fish pond.

Then, for some unexplained reason, Herb accepted a job in the alien science of shellfisheries biology, working for Dr. Victor Loosanoff at the U.S. Bureau of Commercial Fisheries shellfish laboratory in Milford, Connecticut. His position entailed conducting bioassays with shellfish larvae. The 3-year experience taught him the intricacies of shellfish hatchery culture and, perhaps more importantly, perseverance. Indeed, having endured the extremely confining environment created by the very intense Russian scientist Loosanoff, the world was now Herb's oyster and the oyster was now Herb's world.

The Mid-Atlantic MSX oyster mortalities of the mid-1960s provided Herb an excellent avenue for advancement. Rutgers University and Dr. Harold Haskin were in great need of workers (students) who were versed in hatchery techniques. Efforts were concentrated on the production of experimental disease-resistant stocks. This became Hidu's "bread and butter" as a graduate student, where for over 3 years he begat many of Rutgers' experimental oysters stocks at the Cape May laboratory. He used the abundant larval stocks to conduct his study on laboratory behavior and field recruitment of Delaware Bay oysters. His 1967 Ph.D thesis is cited to this day as the definitive study on Delaware Bay oyster recruitment.

After Rutgers, Hidu became a shellfisheries research biologist at the Chesapeake Biological Laboratory (CBL) in Solomons, Maryland. It was hoped that he would fill the shoes and carry on the traditions of the late Francis Beavin, the "dean" of Chesapeake Bay oyster science. With four older veteran shellfisheries biologists, he pursued, for 3 years, field shellfish surveys of Chincoteague Bay and the effects of power plant effluent on the early life history stages of Chesapeake Bay oysters. He developed the natural feeding method for shellfish hatcheries in Maryland and stimulated an early commercial hatchery (Frank Wilde, Shadyside, MD). However, he was miscast in the position at CBL, which he viewed as a mixture of research and personnel management. As an advocate of hatchery production of shellfish to augment recruitment, he locked horns with the Maryland public oyster fishery. Furthermore, his lack of contact with students at the University of Maryland's College Park campus, 100 miles distant inland, created for Herb an untenable situation and he decided it was time to move on. His lifetime break came in 1970 when the University of Maine's Darling Marine Center entered the Federal Sea Grant Program with a "Coherent Areas" grant entitled "Culture of Resources in a Cold Water Marine Environment". Hidu was offered and accepted a position that required shellfish hatchery expertise and, more importantly to Herb, allowed access to excellent students who would pursue M.S. and Ph.D degrees in Oceanography while accomplishing the Sea Grant aquaculture research.

The 15+ graduate students Hidu sponsored at the University of Maine won a record 5 NSA Thurlow Nelson Awards and contributed significantly to the shellfisheries literature: blue mussel biology, R. Lutz, L. Incze, G. Podniesinski; triploid shellfish, S. Allen, M. Lee; intertidal shellfish capacity adaptations, R. Gillmor; hatchery pathology and techniques, L. Plunket, M. Logue–Keller, R. Clime, and others. In the 1970s Hidu developed the nation's first mariculture course. That field course and the associated aquaculture extension effort helped stimulate a significant new Maine industry in oyster grow-out and hatchery production. For this, in 1990, he received the

University of Maine's Presidential Public Service Award and, in the eyes of those of us who know Herb well, he took his place as Maine's "father of aquaculture".

His own research resulted in over 75 papers, with topics ranging from hatchery techniques to field recruitment of oysters, gregarious setting, biological fouling control, triploid shellfish, air winter storage of shellfish seed, blue mussel field recruitment, effects of pollutants on shellfish larvae, and behavior of shellfish larvae. He ran the gamut of offices in the National Shellfisheries Association (NSA), becoming President in 1980. He won the NSA David Wallace award in 1991 and became an NSA Honored Life Member in 1994. Herb retired in 1992 and is now Professor Emeritus of Animal and Veterinary Science at the University of Maine.

In retirement, Herb has gravitated toward his old roots with a move from aquaculture to horticulture, maintaining a small farm in Alna, Maine at which he raises commercial Hosta plants. In fact, his farm bears a remarkable resemblance to a certain Connecticut rich man's estate, with extensive trimmed pine hedges and espaliered trees. In 2001 he was a retired smokejumper volunteer in the Bob Marshall Wilderness Area of Western Montana working trails and helping build a wilderness bridge. He is active in golf, watercolor art, and woodlot management. He has been married 47 years to Judith and has 3 children and 4 grandchildren, all of whom live in Maine. He is the man to whom the author of this biography owes his career—thanks, Herb.

Sandra E. Shumway
Honored Life Member

Sandra "Sandy" Shumway was born March 29, 1952 in Taunton, Massachusetts. She attended Mulcahey Grammar School before going on to Taunton High School, where she graduated as Salutatorian in 1970. A tomboy as a youngster, she was more interested in cowboys and Indians, football and baseball than dolls. She began piano in the second grade, but it was not her instrument. In fourth grade, she took up the clarinet and later bass clarinet and played first chair in the All-State Band twice. While continuing to play throughout college, music was for fun and science would win out. From the time that school let out until Labor Day, summers were spent at the family summer home in Portsmouth, Rhode Island. She dug her first clam by the age of three, and as she got older she fished, sailed, and tended a few lobster pots. She spent countless hours collecting marine life and cataloging it (unlike other normal children). She began a small science project by the 5th grade and was involved in science fairs thereafter. She regularly won local and regional fairs and took first place at the Massachusetts State Science Fair at MIT during her junior year. In her senior year, she was named a Ford Future Scientist of America and to the NASA Youth Science Congress. She credits her parents and several tolerant and progressive teachers for nurturing her scientific interests.

Thus, her love of the sea and its creatures has carried over into her adulthood, and it is not surprising that she majored in this field in college. Sandy graduated *Summa Cum Laude* in 1974 with a B.S. in Marine Science/Biology from Southampton College, Long Island University. From there, she went on to the University College of North Wales in Bangor, Gwynedd, Wales as a Marshall Scholar, where she received her Ph.D. in 1976 and later a D.Sc. in 1992. As a post-graduate she continued at the Marine Science Laboratories in Menai Bridge, Gwynedd, North Wales, then at the University of Otago in Dunedin, New Zealand and with the Department of Ecology and Evolution, State University of New York at Stony Brook.

In addition to her investigations in Wales and New Zealand, Sandy has also conducted research in laboratories in Brazil and numerous states including Georgia, Maine, Washington, and North Carolina. Her formal teaching experiences have been limited to several levels at Southampton College, but she teaches constantly wherever she goes, and she has served on thesis committees at the University of Maine, the College of William and Mary, University of Washington, College of Charleston, North Carolina State University, University of South Florida, University of Maine, University of Connecticut, and Rutgers University. She has served as an External Examiner for Ph.D. candidates at various universities in Australia, Canada, England, India, New Zealand, and South Africa.

Her travels have taken her far and wide. After returning from abroad, where she spent 1974–1980 in Wales, New Zealand and Brazil, Sandy spent two years at Stony Brook and then moved north to the Maine Department of Marine Resources as a Research Scientist from 1983 to 1993 and an adjunct scientist at the Bigelow Laboratory for Ocean Sciences. After this, she moved back to Southampton College and spent the next seven years as a Professor of Marine Science and Biology. In 2001, she moved to the Department of Marine Science at the University of Connecticut in Groton, where she is presently an Adjunct Professor in Residence.

Sandy's research covers more than 27 years in shellfish biology, filter feeding, and physiological ecology of marine invertebrates. She pioneered the study of impacts of harmful algae on shellfish and introduced the use of flow cytometry to determine particle selection in filter-feeding invertebrates. A primary focus has been on problems associated with the shellfish industry: for example, distribution of toxins in shellfish tissues, detoxification rates, and timing and extent of toxicity between shellfish species with the goal of establishing species-specific closures and helping the industry to prosper in the presence of harmful algal blooms. She has recently worked with scientists at North Carolina State University to determine the impacts of *Pfiesteria* spp. on shellfish and public health. Two of these collaborators, Drs. JoAnn Burkholder and Howard Glasgow, recently named a new species of dinoflagellate, *Pfiesteria shumwayae*, in her honor. Sandy has a permanent illustration of it with her at all times.

Sandy has authored 120 publications, edited two books, and co-authored a shellfish cookbook. She has served as editor of the National Shellfisheries Association's *Journal of Shellfish Research* since 1986 and also edits the *Journal of Experimental Marine Biology and*

Ecology. In addition, she serves on the editorial boards of several other journals. Although this takes an incredible amount of time, she finds it satisfying to see the results in print and says it also gives her a fantastic overview of the fields of shellfish biology and experimental marine biology. The number of manuscript submissions to JSR from foreign countries has increased dramatically in recent years, and Sandy enjoys helping scientists from underdeveloped countries get their work published. She recently launched a new journal with Elsevier, *Harmful Algae*, co-edited by Ted Smayda.

Sandy has been responsible for much of the recent growth of the National Shellfisheries Association. When she became Editor of the *Journal of Shellfish Research*, the publication was often behind schedule and barely 100 pages a year. Since then, the JSR has averaged 600–700 pages annually and reached a new level with the publication of five issues and more than 1,700 pages in 1998. She was the first woman president of NSA, serving in 1991–1992, and was re-elected in 2002 to serve again in 2003–2004. She has worked to increase membership in the association and has played an important role in the annual meetings of NSA with her organizational skills, her management of students for registration, sales, and as AV operators, and for the student auctions, which she initiated in 1993. These auctions raise money for the Student Endowment Fund, which helps defray the costs of students who attend the annual meetings. She has good-humoredly dressed for these occasions in various costumes, including a court jester, a blue quahog, a geoduck, and a lobster. On another occasion, she made her own bikini top, with the help of a hotel employee, from a pair of sea scallop shells, and has actually sold the shirt(s) off her back. In her never-ending effort to nurture students, in 1992, Sandy began the Recruits, the organization of student members of NSA. The Recruits now have their own forum on the NSA website, a nonvoting representative on the EXCOM and write articles for the Newsletter.

Sandy has also held several offices in the World Aquaculture Society and was the push that NSA needed to become a sponsor of the Aquaculture Triennial Meetings, first as an affiliate sponsor of Aquaculture '86 and then as a full sponsor of Aquaculture '89 in Los Angeles. These meetings have allowed NSA members to meet with members of the World Aquaculture Society, the American Fisheries Society Fish Culture Section, and many other smaller societies. Since that first meeting, NSA has enjoyed the intellectual and financial advantages that these larger meetings provide, and Sandy has been a major part of the organization and production of each of these including San Diego, Las Vegas, two in Orlando and the upcoming AQ '04 in Hawaii.

Despite her seemingly endless efforts with students, journals, scientific meetings, and the shellfish industry, Sandy still has time to spend with her miniatures which she began building in 1982. She is a nationally recognized miniaturist, yet many of the people who know her are unaware of her love of the small. Students are particularly surprised to find out that she devotes time to things other than science. Her buildings have been featured in several magazines including *Miniature Gazette, Nutshell News, International Dollhouse*, and *Miniature Collector*. "Sandra Shumway's Sea-Born Treasures" by Mary Kaliski in the April 1998 issue of *Miniature Collector* is a wonderful example. At one time, she ambitiously wanted to build an entire village in miniature (1 inch = 1 foot), but she has had to settle for less because of lack of time and space. Thus far, however, she has created a general store, two fishing shacks, a bordello, a bakery, a drug and candy store, a barber shop, a school house, and a funeral parlor (all complete with people).

Sandy is also an avid pool player. She began when she was in college, but became more serious about it when she moved to Maine. She not only loves the game for what it is, but for the opportunity it provides to interact with fishermen. She organized local tournaments for years and has a number of trophies to show for her efforts. Often after a day of paper sessions and a dinner at the annual NSA meeting, she will find a local pool hall to unwind. Of all the honors and awards she has received over the years, one of her most prized recognitions came from a well-seasoned, cynical fisherman in a local bar who, when asked "Who's the broad at the pool table?" replied "She's a scientist, but she's okay."

Sandy was awarded NSA's highest honorary citation, the Honored Life Member award at Aquaculture '01 in Orlando, Florida on January 18, 2001 following the eloquent remarks of Dr. Melborne R. Carriker, who stated that "it is her warm outgoing personality, genuine interest in people, and readiness to extend an unselfish helping hand to those in need that has endeared her most to so many of us."

EVALUATION OF MIST ALERT™ RAPID TEST KITS FOR THE DETECTION OF PARALYTIC AND AMNESIC SHELLFISH POISONING TOXINS IN SHELLFISH

F. H. MACKINTOSH AND E. A. SMITH*
Fisheries Research Services, Marine Laboratory, P.O. Box 101, Victoria Road,
Aberdeen, AB11 9DB, United Kingdom

ABSTRACT Rapid test kits (MIST Alert™) for the detection of paralytic shellfish poisoning (PSP) and amnesic shellfish poisoning (ASP) toxins in shellfish have recently been developed. In this study, these kits have been evaluated for their potential use in shellfish toxin-monitoring programs and by the shellfish industry. These antibody-based tests were used to assess the presence of shellfish toxins qualitatively in a variety of shellfish species (mussels, scallops, oysters, cockles, razor fish) while routine methods of detection were simultaneously used to quantify any toxin present. All shellfish extracts found to contain PSP toxins at the regulatory limit of 80 μg saxitoxin equivalents (STX eq) 100 g^{-1} shellfish flesh using the mouse bioassay (MBA) were confirmed as positive by MIST Alert for PSP. Shellfish farmers and other professionals in the industry also used these test kits successfully, with all positive samples being correctly identified, clearly demonstrating its potential application in shellfish harvest management and end product testing. MIST Alert for ASP also detected toxin in all monitoring samples containing the regulatory limit for amnesic shellfish poisoning (ASP) toxins, 20 μg g^{-1} shellfish flesh, as determined by high-performance liquid chromatography (HPLC). In addition, among samples in which HPLC did not detect toxin, the kit agreed in 99% of tests. Overall, these results suggest that MIST Alert™ for PSP and ASP could be used as part of routine monitoring programs.

KEY WORDS: paralytic shellfish poisoning toxins, amnesic shellfish poisoning toxins, MIST Alert, shellfish monitoring, mouse bioassay, high-performance liquid chromatography

INTRODUCTION

Recently we have reported on the use of a commercial antibody-based rapid test kit (MIST Alert™ for PSP) for the qualitative (yes/no) detection of paralytic shellfish poisoning (PSP) toxins in shellfish (Mackintosh et al. 2002). These potent neurotoxins are produced by certain algal species and can accumulate in filter-feeding shellfish. Current European legislation requires that shellfish are monitored for these toxins, and if they are detected in shellfish flesh above the regulatory limit of 80 μg saxitoxin equivalents (STX eq) 100 g^{-1} shellfish flesh, restrictions on shellfish harvesting are imposed (Gallacher et al. 1998). The initial study (Mackintosh et al. 2002) highlighted that the MIST Alert for PSP kit could be used in monitoring programs as a prescreen for toxin-negative samples and in end-product testing and thus warranted further investigation.

Since our preliminary assessment of MIST Alert for PSP a further antibody-based qualitative test for amnesic shellfish poisoning (ASP) toxins has also been developed (MIST Alert™ for ASP). This kit utilizes sheep antibodies developed by Garthwaite et al. (1998) for the detection of neurotoxic domoic acid (DA), the principal compound of ASP toxins, produced by several species of the diatom *Pseudo-nitzschia*. MIST Alert for ASP utilizes the same working principals of immunoflow chromatography used in MIST Alert for PSP (Fig. 1).

The first recorded outbreak of human ASP, following consumption of contaminated mussels, was recorded in 1987 (Wright et al. 1989). Subsequently, many countries implemented monitoring programs for the detection of ASP toxins in shellfish with a regulatory level of 20 μg DA g^{-1} shellfish flesh adopted. In the UK, the Scottish shellfishery has been particularly adversely affected by ASP toxin contamination of king scallops which was responsible for widespread harvesting closures during 1999 and 2000 (Campbell et al. 2001, Gallacher et al. 2001).

To date, the main tools for PSP and ASP toxin-monitoring programs have been the mouse bioassay (MBA) and the high-performance liquid chromatography (HPLC) method of Quilliam et al. (1995) with UV diode array detection, respectively. The use of mice for the detection of PSP toxins is considered ethically questionable, and the assay is known to be susceptible to matrix interference (Schantz et al. 1958, Park et al.1986). Chemical analysis for ASP toxins is expensive and requires skilled operators. Hence, the requirement for simple, cheap, quick, and accurate detection methods for PSP and ASP toxins in shellfish have been widely discussed (Gallacher et al. 1998, Garthwaite 2000, Llewellyn et al. 2001).

The aim of this study was to evaluate further the use of MIST Alert for PSP in regulatory monitoring, as a harvest management tool, and end-product test by the shellfish growing and processing industries and to assess the potential of MIST Alert for ASP in routine shellfish monitoring.

MATERIALS AND METHODS

Assessment of MIST Alert for PSP During Routine Shellfish Monitoring

Throughout 2001, the MBA was used for the quantitative assessment of PSP toxicity (μg STX eq 100 g^{-1} of shellfish flesh) in acidic (0.1 M HCl) shellfish extracts (n = 547) as part of the Scottish shellfish-monitoring program. Simultaneously, MIST Alert for PSP test kits (Jellett Biotek Ltd., Nova Scotia, Canada) were used for the yes/no detection of PSP toxins and results compared with those from the MBA in four categories: not detected, <40; 40 – <80; and ≥80, μg STX eq 100g^{-1}· as previously described (Mackintosh et al. 2002).

Investigation into the Use of MIST Alert for PSP in Shellfish Harvest Management and End-Product Testing

MIST Alert for PSP test kits were supplied from Fisheries Research Services (FRS) to eight participants to evaluate its po-

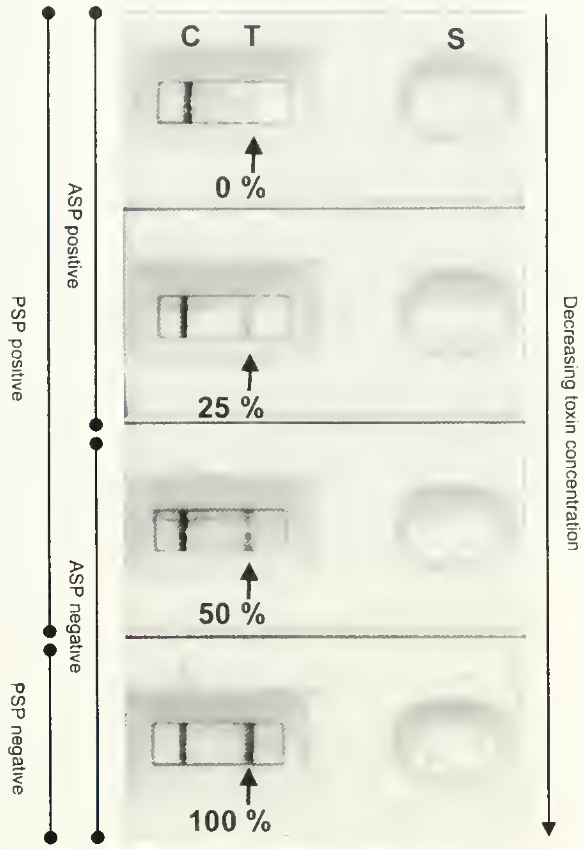

Figure 1. The MIST Alert™ test kit. Test kit strips consist of an absorption pad (S), a membrane striped with a mixture of toxin analogs (the "T" line), and an antibody detection reagent (the "C" line), a sample pad, and a conjugate pad containing the antibodies. A visible "T" line indicates absence of toxin in the sample and no line indicates the presence of toxin. The "C" line indicates that the sample fluid has sufficiently resuspended and mobilized the antibody color complex. As the level of toxin increases, the "T" line progressively disappears. Remnant "T" lines are scored as having 50, 25, or 0% of color intensity relative to the "C" line. MIST Alert for PSP™—samples are considered positive if the 'T" line is 50% or less the intensity of the "C" line. MIST Alert for ASP™—samples are considered positive if the "T" line forms only a faint shadow (i.e., less than 25%) or is completely absent.

tential for field use. Participants comprised shellfish farmers, processors, and environmental health officers (EHOs). Each participant was supplied with either 50 (farmers) or 100 (processors and EHOs) test kits and the equipment/chemicals necessary to perform acidic shellfish extraction as described by the manufacturer. Before the study, each participant received training in sample extraction and kit use. Subsequently, each participant assessed the presence/absence of PSP toxins in shellfish extracts using the test kits. An aliquot of each shellfish extract analyzed, the test kit, and the participant's interpretation of the result were returned to FRS. The kit result was reinterpreted by laboratory personnel and extracts reanalyzed by MIST Alert for PSP by an experienced user within the laboratory. Positive samples were further analyzed by the MBA. If this was not possible (e.g., if the sample volume supplied from the participants was too small), samples were diluted 1:1 in a negative shellfish extract and retested using MIST Alert for PSP.

Assessment of MIST Alert for ASP During Routine Monitoring

Shellfish samples (500) from the 2001 Scottish shellfish-monitoring program were extracted in aqueous methanol, [50:50 (v/v) water:methanol] according to the extraction procedure of Quilliam et al. (1995) and as detailed in Hess et al. (2001). Extracts were concurrently analyzed by MIST Alert for ASP (Jellett Biotek Ltd., Nova Scotia, Canada) and HPLC (Quilliam et al. 1995). MIST Alert for ASP is performed as for MIST Alert for PSP, but samples are only considered positive if the "T" line is completely absent or appears only as a faint shadow (i.e., less than 25%) (Fig. 1). The qualitative presence of ASP toxins by the test kits was compared with the quantitative analysis of these toxins (DA + epi DA = total amnesic shellfish toxins: AST) by HPLC categorized into five groups: not detected, the limit of detection (lod) that is about 2.5 μg AST g^{-1} shellfish flesh, >lod – <6, 6 – <20, and ≥20 μg AST g^{-1} shellfish flesh.

Reproducibility of MIST Alert for ASP

Fifty aqueous methanol extracts obtained from a variety of different shellfish species (mussels, *Mytilus edulis*; cockles, *Cerastoderma edule*; queen scallops, *Aquipecten opercularis*; Pacific oyster, *Crassostrea gigas*; king scallop, *Pecten maximus*—whole animals, gonad, adductor, residual tissue—gut, hepatopancreas, gills) were tested in triplicate using MIST Alert for ASP to investigate the reproducibility of the test kits. Extracts contained varying concentrations of AST, as determined by HPLC, and were chosen to contain levels within the five categories above.

RESULTS

Use of MIST Alert for PSP in Routine Shellfish Monitoring

Results from 547 shellfish extracts tested by MIST Alert for PSP were compared with results obtained using the MBA (Table 1, Fig. 2). All extracts ($n = 77$) determined to contain toxin concentrations above the regulatory limit (80 μg STX eq 100 g^{-1}) by the MBA were also found to be positive for PSP toxins by MIST Alert for PSP. In addition, test kits gave a positive result for 97% (131/135) of samples in which the MBA detected toxin below the regulatory limit (grouped as 40 – <80 and <40 μg STX eq 100g^{-1} in Fig. 2). The kit did not detect toxin in two mussel extracts (*Mytilus edulis*), a king scallop gonad (*Pecten maximus*), and a European oyster (*Ostrea edulis*) extract, the mussel extracts both being in the <40 μg STX eq 100 g^{-1} category.

The MBA did not detect toxin in 335 shellfish extracts. Using MIST Alert for PSP, 97 of these samples gave a positive result (29%) giving an overall "false-positive" rate of 18%. Of these samples, king scallop extracts (both gonad and whole animal) gave a higher proportion of MIST Alert PSP positive results (35 and 53%, respectively) than mussel extracts (25%), the most commonly tested species in the PSP toxin monitoring program.

Field Trials of MIST Alert for PSP

Results from 259 shellfish extracts from eight field trial participants are shown in Table 2. In general, participants and FRS agreed in the positive or negative interpretation of the test kit results. In one case, Participant 8 recorded a negative result, but FRS considered it positive. A positive result was confirmed when this extract was re-analyzed by MIST Alert for PSP at FRS. However, when further tested by the MBA, toxin was not detected. All but one Participant recorded positive results when using the kit.

TABLE 1.

Comparison of MIST Alert for the detection of PSP in shellfish extracts with the MBA.

Tissue Type	No. Tested	MBA ≥80[a]	MIST +	MIST −	MBA 40 – <80	MIST +	MIST −	MBA <40	MIST +	MIST −	MBA ND[b]	MIST +	MIST −

% compliance		100%			97.6%			96.1%			71.0%		

[a] MBA (μg STX eq 100 g^{-1}).

[b] ND, not detected.

[c] G, gonad.

[d] W, whole animal.

Only one sample was found to contain levels over the regulatory limit when analyzed by the MBA.

Interpretation of "T" Line Intensity

The majority of disagreement in results between participants and FRS were attributable to differences in "T" line intensity rather than whether a sample was considered positive or negative (Table 2). Participant 2 seemed to misinterpret kit instructions and in some cases, read the "C" line as a percentage of the "T" line. Despite this, positive and negative samples were correctly identified. Some trial participants attempted to read the kit too precisely; for example, rather than scoring the "T" line as 0, 25, 50, or 100% (see Fig. 1), results were reported as 5, 15, 30%, or so forth. Much of the difference in interpretation between FRS and Participants 6 and 7 was attributable to this "overinterpretation," but results were still correctly read as positive or negative.

Reanalysis of Shellfish Extracts

When shellfish extracts were retested at FRS, there was over 90% agreement with the positive or negative result previously obtained by Participants (Table 2). On four occasions when FRS reanalyzed extracts (from Participants 3, 6, and 8) by MIST Alert for PSP, the result changed from negative (on-site) to positive (at FRS). In one extract from Participant 3, (a king scallop gonad) a low level of toxicity (31 μg STX eq 100 g^{-1}) was detected by the MBA. In the extract from Participant 8, the MBA gave a negative result, while insufficient extract volume was available for further MBA testing from Participant 6, but when diluted and tested by MIST Alert for PSP, the result was considered negative. Two extracts from Participant 7 changed from a positive to negative score when reanalyzed by the kit, but because the "T" line intensity was close to 50% (see Fig. 1), the response was considered difficult to interpret.

Previous studies using HPLC showed that PSP toxin profiles of stored Association of Official Analytical Chemists (AOAC) acidic shellfish extracts do not change significantly over a five-day period (data not shown). It was, therefore, considered that during transportation of shellfish extracts from participants to FRS toxin levels remained unchanged.

Use of MIST Alert for ASP in Routine Shellfish Monitoring

MIST Alert for ASP was used to test 500 shellfish extracts, and the results were compared with the HPLC analysis routinely used in the ASP toxin shellfish-monitoring program (Table 3 and Fig. 3). All samples over the regulatory limit (20 μg AST g^{-1}), as determined by HPLC, were scored positive by MIST Alert for ASP (n = 162). In samples (n = 114) that were below the regulatory limit but above the HPLC lod (2.5 μg AST g^{-1}), MIST Alert for ASP detected toxin in 93 (81.5%). The kit also detected toxin in 10.6% (13/123) of samples at the HPLC lod and a further sample (king scallop gonad) that was negative by HPLC. Of 39 samples falling into the range >lod – <6 μg AST g^{-1} 24 yielded a positive result by the kit (61.5%). Of the commonly tested species, mussels yielded the fewest positive results at the lod.

Reproducibility of MIST Alert for ASP

Overall, 90% of samples tested gave three identical "T" line responses (Table 4). In samples wherein toxin was not detected, at

the lod or ≥20 μg AST g^{-1} by HPLC, the kit gave three identical responses in agreement with HPLC results. Eight extracts in the range >lod – <6 μg AST g^{-1} gave three identical responses—two negative and six positive. The remaining two samples each gave two identical responses—one, two negatives, and a positive; and the other two positives and a negative. Ten samples in the 6 – <20 μg AST g^{-1} category all gave three positive results, but only seven samples gave three identical results (Table 4).

DISCUSSION

MIST Alert for PSP in Routine Monitoring

Using MIST Alert for PSP, a positive result was recorded for all shellfish extracts, from a wide range of tissue types, known to contain ≥80 μg STX eq 100 g^{-1} as determined by the MBA, indicating that shellfish considered a threat to public health would be detected by this method during routine PSP toxin monitoring in Scotland (Table 1, Fig. 2). In addition, approximately 97% of samples containing toxins below the regulatory limit (by the MBA) were also found to be positive by MIST Alert for PSP, suggesting the kit has a similar sensitivity to the MBA (about 33 μg STX eq 100 g^{-1}), an important factor when considering its potential use. MIST Alert for PSP failed to detect toxin in four samples in which the MBA detected toxin below the regulatory limit (33, 38, 47, and 60 μg STX eq 100g^{-1}). MIST Alert for PSP detects the amount of toxin based on the ability of the antibody mixture on the test kits to detect different STX analogs. It has been reported that the test kit is less sensitive to neo-STX derivatives and requires levels close to the regulatory limit to give a positive result (Laycock et al. 2001).

Differing sensitivities of MIST Alert for PSP to different toxin profiles may also account for the observed "false- positive" results (i.e., MIST Alert recorded a positive result; whereas, the MBA indicated a negative result) observed in this study. For example,

extracts containing high levels of low-toxicity toxins (e.g., some C toxins) (Oshima 1995) may yield a negative result by the MBA but a positive result by MIST Alert for PSP (Laycock et al. 2001). This may be considered an advantage of the kit, because these toxins can be readily converted to other more potent PSP toxins during shellfish consumption. Shortcomings of the MBA must be taken into account when considering inconsistent results. The MBA is known to underestimate toxicity with an associated error of 20% (60% near the detection limit) (Park et al. 1986).

Use of MIST Alert for PSP in the Field

Results from data obtained by shellfish farmers, processors, and EHOs show very little difference in the interpretation of positive or negative results obtained by these lay persons with less experience of the test kits than staff at the routine monitoring laboratory (FRS). Similarly, in-house (FRS) and on-site (Participants) results from shellfish extracts were, for the most part, comparable (Table 2). In this study, variability in the interpretation of the "T" line response was observed. Previous trials (Mackintosh et al. 2002) also demonstrated variation in interpreting the "T" line response of MIST Alert for PSP by novice users. This trial suggests that this may not be a serious problem, because positive and negative samples were still correctly identified, and the manufacturer advises that if doubt exists because of "T" line intensity, a positive result should be recorded. It is also considered that this variable will be reduced with more extensive use of the kit.

Importantly, an extract determined to contain over 80 µg STX eq 100 g^{-1} by the MBA was correctly identified by a participant. A further positive extract that was not retested by the MBA (attributable to insufficient sample volume) was diluted 1:1 in a negative shellfish extract and retested using MIST Alert at FRS. This extract produced a negative response, suggesting toxicity in this sample was <80 µg STX eq 100 g^{-1}, although this would have been dependent on the toxin profile of the extract.

Overall, even when considering misinterpretation of instructions (e.g., recording of the "T" line intensity), participants correctly identified positive and negative samples. Previously, we have shown that novice users can make errors in both use and interpretation (Mackintosh et al. 2002), emphasizing that careful attention to the instructions and interpretation of the results is essential.

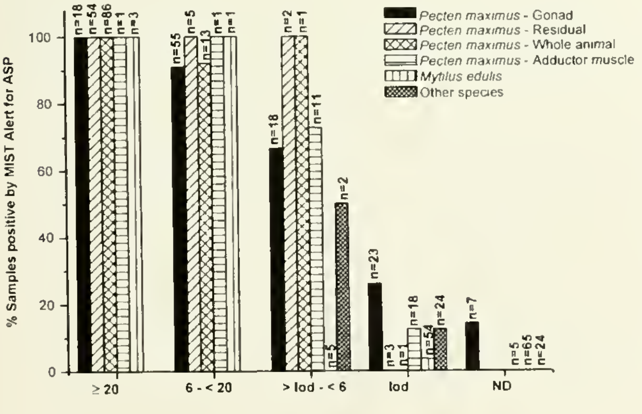

Figure 3. Percentage of samples found to be positive by MIST Alert for ASP when compared with HPLC results.

MIST Alert for ASP in Routine Monitoring

MIST Alert for ASP detected toxin in all samples containing the regulatory limit of ASP toxin (20 µg AST g^{-1}) and above, with good reproducibility observed between test kits (Table 3, Table 4, Fig. 3). Toxin was also detected in a high percentage (82%) of extracts containing between the regulatory limit and the lod of the HPLC method used. The manufacturer of MIST Alert for ASP reports a detection limit of between 8 and 12 µg AST g^{-1} (Jellett et al. in press); our results show that the kit will detect toxin at lower levels, particularly in king scallops. In Scotland, the contamination of king scallops with ASP toxins has adversely affected the offshore scallop fishery (Campbell et al. 2001, Gallacher et al. 2001); whereas, other shellfish species remain relatively unaffected. Results from routine monitoring of Scottish king scallops demonstrate that the proportion of scallops that currently do not contain ASP toxin as determined by HPLC is about 30% (J. Petrie pers. comm.). This implies that the majority of scallop extracts tested by MIST Alert for ASP will give a positive result, regardless of whether the scallops contain toxin below the regulatory limit, and would still be marketable.

Overall, results from this study indicate that MIST Alert for ASP is currently too sensitive to screen out low- toxicity king scallop samples in routine monitoring programs, but it may be suitable for other shellfish species (e.g., mussels). However, the requirement for an alternative method to the current HPLC technique for ASP toxin detection in shellfish is not considered paramount, because the ethical concerns surrounding the MBA do not need to be considered. It has been reported that MIST Alert for ASP and PSP can be performed using the same extract; that is, AOAC extract (sample homogenate extracted in 0.1N HCl). Before this study, AOAC acidic extracts were examined by MIST Alert for ASP and PSP (data not shown). It was found that, unless these extracts were used immediately, they were unsuitable for ASP testing because of the instability of DA in HCl, suggesting a single extraction protocol would not be feasible. In addition, acidic extracts are unsuitable for HPLC analysis if further investigation were required.

CONCLUSION

In conclusion, the MIST Alert for PSP has been successfully used during two monitoring seasons (Mackintosh et al. 2002) to determine the presence/absence of PSP toxins in Scottish shellfish. The test kits confirmed the presence of PSP toxins in samples considered to contain toxin at and above the regulatory limit (80 µg STX eq 100 g^{-1}). MIST Alert for PSP could be used in monitoring programs as a screen to eliminate negative and low PSP toxicity samples before use of the MBA for quantitative analysis of positive samples. For example, if MIST Alert for PSP had been used for this purpose during the study period in 2001, there would have been a reduction of 43% of the MBAs. Furthermore, field trial results indicate that the PSP kit has the potential to be used by shellfish farmers as a shellfish harvest management tool and by EHOs and processors in end product testing.

Results suggest that MIST Alert for ASP is too sensitive to use as a screen in the Scottish ASP toxin-monitoring program and in end-product testing for king scallops. A higher detection limit would be desirable to reduce the high number of MIST Alert for ASP positives observed at toxin levels <6 µg AST g^{-1} by HPLC. In contrast, it is possible that the kit may be used as a screen for ASP toxins in other shellfish species and this should be studied further.

ABSTRACT A serious diarrhetic shellfish poisoning (DSP) intoxication caused by the consumption of mussels harvested in the Gulfs of San José and Nuevo, Patagonia, Argentina occurred in March (autumn) 1999. This was the first observation of DSP toxins along the Argentine coast. Cells of the dinoflagellate *Prorocentrum lima* (Ehrenberg) Dodge were found in water samples, as were epiphytes upon macroalgae and in the stomach contents of the mussels *Aulacomya atra* (Molina) and *Mytilus edulis platensis* (d'Orbigny). Extracts from both mussel species were positive for DSP-like activity using the fluorimetric phosphatase inhibition assay. When the extracts were analyzed using liquid chromatography and tandem mass spectrometry, peaks of okadaic acid or dinophysistoxin 1 (DTX-1) were not observed in the nonhydrolized samples. DTX-1 was detected in hydrolized extracts of *Mytilus* and *Aulacomya*. The *Mytilus* extract contained 21.2 ng DTX-1 per gram of the whole tissue; the *Aulacomya* extract contained 94.0 ng DTX-1 per gram.

KEY WORDS: Argentina; diarrhetic shellfish poisoning; okadaic acid; *Prorocentrum lima*, toxic dinoflagellate

INTRODUCTION

Harmful algal blooms have increased in geographic distribution, magnitude, and frequency during the last decades (Anderson 1989; Smayda 1990; Hallegraeff 1993). Diarrhetic shellfish poisoning (DSP), a severe gastrointestinal disturbance following the consumption of shellfish, is also an increasing problem. DSP results from the accumulation, in shellfish tissues, of polyether toxins produced by dinoflagellates belonging to the genera *Dinophysis* and *Prorocentrum* (Wright & Cembella 1998 and references therein). In his 1993 review, Hallegraeff recognized only the coast of Chile as being affected by DSP in South America. Ferrari et al. (1993) and Méndez and Ferrari (1994) later reported DSP incidents occurring in Uruguay. Proença and Rörig (1995) and Proença et al. (1998) documented DSP occurrences in southern Brazil. To date, only species of *Dinophysis* have been the causative agents of DSP cases reported from South America (Lembeye et al. 1993, Lembeye et al. 1996, Proença et al. 1998, Uribe et al. 2001).

Since 1995, oceanographic research along the North-Patagonian coast of Argentina has included phytoplankton investigation, microscopical observations of stomach content of mussels, and analysis of physical and meteorological data. Because of recurrent blooms of another toxic dinoflagellate, Alexandrium tamarense, in the area (Esteves et al. 1992, Carreto et al. 1998, Gayoso 2001), monitoring programs are conducted only for paralytic shellfish poisoning toxins in shellfish (mouse bioassay) by the local (Chubut) government, who is responsible for imposing bans on shellfish harvest. Although the known DSP producers, *Dinophysis acuminata* and *Prorocentrum lima*, are present (Esteves et al. 1992, Santinelli et al. 1994, Gayoso 2001), monitoring programs for DSP are not currently conducted in Argentina.

On March 20, 1999, shellfish harvested in the Gulfs of San José and Nuevo (Chubut) were served at a social event despite voiced concerns from one of us (A.M.G.) that toxic dinoflagellates other than *Alexandrium tamarense* were potentially present in the water column and in the shellfish digestive glands. More than 40 people suffered from gastrointestinal disorders after consuming the shellfish. Physicians from the Dr. Andrés Isola Public Hospital reported symptoms of diarrhea, nausea, and abdominal pain, consistent with the DSP syndrome. After the incident, samples were collected from the two north-patagonian gulfs for phytoplankton and epiphytic dinoflagellate identification, chemical analysis of mussel tissues, and microscopic examination of the stomach content of mussels was undertaken to document the causative toxin(s) and the responsible organisms. This work reports on the first recognized episode of diarrhetic shellfish poisoning on the Argentine coast.

MATERIALS AND METHODS

Water samples at two depths (surface and bottom) with a 2.5 L Van Dorn bottle and vertical and oblique hauls with a 25 μm mesh plankton net were taken at two stations: Puerto Madryn, situated on the west coast of Golfo Nuevo (42°46′S, 65°02′W) and San Román, located on the north coast of Golfo San josé (42°15′S, 64°15′W). Dominant macroalgae and mussels (*Aulacomya atra* and *Mytilus edulis platensis*) were manually collected from the bottom (ca. 18 m depth) at each station by scuba divers. The samples were collected twice a month from March to June 1999.

The identification of species was made using the net samples, a light microscope provided by Nomarsky illumination, and a scanning electron microscope. For quantitative analysis, subsamples (from the bottle samples) were settled in a chamber from a cylinder of 50 mL and counted with an inverted microscope. The species of macroalgae were analyzed separately, subsamples (2–6 g wet weight) were placed in a tube containing a solution of formaldehide-filtered seawater, the suspended epiphytic dinoflagellate populations were examined and their abundance, expressed as cells per gram wet weight of macroalga, was estimated from counts using a 1 mL Sedwick Rafter chamber. The mussel stomach contents were analized within 4 h of collection, the stomach content of at least six mussels was extracted with a Pasteur pipette, the contents were pooled, diluted with filtered seawater, and observed on a slide using a compound light microscope. Microalgae present were identified and their relative abundance was estimated.

Toxin Analysis

Toxin analysis was performed on the following two mussel samples: (1) *Aulacomya atra*, which were collected in Golfo Nuevo on March 18, 1999; and (2) *Mytilus edulis platensis*, which were collected in Golfo San José on March 25, 1999. Both were frozen whole until the time of analysis.

Sample Extraction

For each species, 5 g wet weight of whole mussels were homogenized in 80% methanol for 2 min using a Polytron. The resulting extract was filtered through a GHB glass fiber filter and the filtrate brought to a volume of 5 mL. To convert all metabolites to the parent okadaic acid (OA) or dinophysistoxin-1 (DTX-1), 2.5 mL of each sample were hydrolyzed by heating at 76°C for 40 min after addition of 250 μL of 2.5 N NaOH (Mountfort et al. 1999). Therefore, for each species two separate samples were analyzed for DSP-toxins.

Protein Phosphatase Inhibition Assay

The protein phosphatase inhibition assay was performed in a 96 well format using the procedure of Vieytes et al. (1997). The assay tests the ability of OA standard or unknown sample to inhibit activity of purified protein phosphatase 2A against a fluorimetric substrate, 6,8-difluro-4-methylum belliferyl phosphate (DiFMUP). All samples were diluted in reaction buffer (50 mM Tris HCl pH 7.0, 0.1 mM $CaCl_2$) at least 4-fold to reduce the methanol concentration to ≤5% in the assay. This step was to eliminate inhibition of the enzyme by methanol. For the assay, 10 μL of a 1:1 dilution of 40 mM $NiCl_2$ and 1 mL/mL bovine serum albumin, 17 μL of reaction buffer, 33 μL samples and standards (0.03–10 nM OA; NRC, Ottawa Canada) and 200 μL of purified PP2A enzyme (Upstate Biotechnology, Lake Placid, NY) were added to duplicate wells of a 96 well plate (Costar, Corning, NY). To start the reaction, 120 m DiFMUP (10 mM; Sigma, St. Louis, MO) was then added to each well and the reaction allowed to proceed for 1.5 h at 37°C, followed by 30 min at 4°C. Protein phosphatase activity was determined by fluorescence (360 nm excitation; 460 nm emission) in the wells using a fluorimetric plate reader (Fluostar, BMG Laboratory Technologies, Durham, NC). OA-like activity in the sample was quantified relative to the standard curve. The detection limit of the fluorimetric phosphatase inhibition assay was approximately 1×10^{-10} M okadaic acid equivalents.

Liquid Chromatography and Tandem Mass Spectrometry (LC-MS/MS)

Samples that displayed protein phosphatase inhibition activity were analyzed by LC-MS/MS using a Finnigan LCQ mass spectrometer. The methanolic extracts were injected on a C18 column (Zorbax 2.1 × 150 mm) and eluted with a gradient of 50 to 95% methanol/water containing 0.1% TFA at a flow rate of 0.2 mL/min. A splitter device was used to direct 10% of the column effluent to the electrospray source. The mass spectrometer was operated in positive ion mode. Toxins were analyzed by trapping [M+Na]+ species for each toxin and conducting selected ion monitoring experiments for distinctive fragment ions from the collisionally activated dissociation of the trapped parent ions. Chromatographic traces were acquired for the detection of the fragment ions and undissociated parent ions. The limits of OA and DTX-1 detection were approximately 1×10^{-7} and 1×10^{-8} M, respectively, as measured by LC-MS/MS.

RESULTS

P. lima (Fig. 1) was unequivocally identified in net samples from the gulfs of San José and Nuevo. The two main thecal plates (valves) of the specimens found were obovate (length 33–38 μm, width 22–24.2 μm, $n = 10$) and cellular morphologic features agreed with the descriptions given by Faust (1991) and McLachlan et al. (1997, as *Exuviaella lima*). A row of conspicuous marginal pores, scattered valve pores, and valve center free of pores were observed. The species was registered in water samples (cell densities less than 100 cells L^{-1}) on March 18, April 13 and June 29, 1999 (16.5–18°C). Its occurrence coincided with the autumn phytoplankton peak in which *Rhizosolenia setigera* Brightwell, *Chaetoceros curvisetus* Cleve, *C. diadema* (Ehrenberg) Gran, *C. didymus* Ehrenberg, and *Pseudo-nitzschia pungens* (Grunow ex Cleve) Hasle were most abundant, and *A. tamarense* (Lebour) Balech was also present. Dominant macroalgae in the gulfs San José and Nuevo, *Dictyota dichotoma* (Hudson) Lamouroux (Phaeophyceae), *Anotrichium furcelatum* (J. Agardh) Baldock, *Ceramium rubrum* (Hudson) C. Agardh (Rhodophyceae), and *Ulva rigida* (C. Agardh) Thuret (Chlorophyceae) showed an epiphytic assemblage of diatoms and dinoflagellates that included *P. lima*. Cell densities of *P. lima* varied from approximately 750 cells per g wet weight of macroalga at station San Román to 1782 cells per g wet weight at station Puerto Madryn.

Intact cells (with protoplasm) of *P. lima* were observed in the stomach contents of the mussels on March 18, May 18, and June 29, 1999. During the study period, the diet of *A. atra* and *M. edulis platensis* consisted mainly of diatoms, with benthic forms outnumbering pelagic species. *Prorocentrum micans*, benthic pennate diatoms, *Paralia sulcata*, and *Thalassiosira* spp. were the most abundant organisms found in the mussel stomachs.

Extracts of both mussel species were positive for DSP-like activity using the fluorimetric phosphatase inhibition assay. The *Mytilus* sample contained 33.5 ng of OA-equivalent activity per gram of whole tissue, whereas the *Aulacomya* sample contained 150 ng/g. The difference between hydrolized and nonhydrolized samples using this assay were not significant.

Extracts of the nonhydrolized samples analyzed using LC-MS/MS did not exhibit peaks corresponding to okadaic acid or dino-

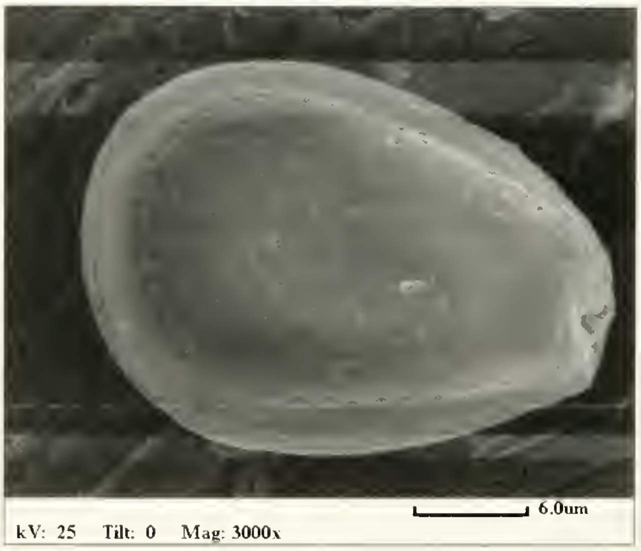

Figure 1.

physistoxin-1. However, dinophysistoxin-1 was detected in the *Mytilus* and *Aulacomya* extracts that had been hydrolized, yielding 21.2 ng DTX-1/g whole tissue and 94.0 ng/g, respectively.

DISCUSSION

Dinophysis acuminata is a frequent component of the phytoplankton in the area; its abundance can reach up to 1.9×10^3 cells L^{-1} (Gayoso 2001). However, no known gastrointestinal disorders have accompanied its presence. The episode of diarrhea following shellfish consumption observed in March 1999 appears to be related to the presence of *P. lima*. It is an important component of the epiphytic community associated with the dominant macroalgae in the gulfs. The species was also present in the mussel stomach contents and in the water samples.

Not only was *P. lima* present in mussel digestive glands, but DSP toxin activity was also detected in *M. edulis platensis* and *A. atra*, strengthening the causal relationship between *P. lima* and the gastrointestinal disorders of March 1999. If toxin regulations such as those implemented in the European Union had been in effect, the shellfish harvest would have been halted; most EU countries tolerate no DSP toxins above detection levels (Shumway et al. 1995).

LC-MS, a highly selective and sensitive method for detection of DSP toxins (Quilliam & Wright 1995), showed a peak corresponding to DTX-1 in hydrolyzed samples of *M. edulis platensis* and *A. atra*, whereas neither OA nor dinophysistoxin was observed in nonhydrolyzed extracts. This finding is indicative of the esterified nature of DTX-1 within the mussels; esterified DSP toxins (also called DTX-3 complex) are acyl derivatives that also possess toxic activity (Quilliam & Wright 1995). Upon sample hydrolysis, the esterified toxin converts to the active parent compound. Esterified DTX-1 is found to be the main DSP toxin in two other shellfish, the scallop *Patinopecten yessoensis* and the mussel *Mytilus galloprovincialis* (Suzuki & Mitsuya 2001). A significant difference was found in the toxin concentration of the two hydrolyzed samples: 21.2 ng DTX-1/g of whole *Mytilus* tissues versus 94.0 ng/g for *Aulacomya*. This finding may be explained by the time of collection (1 week apart for the two species), different specific feeding and digestion behavior, and location of the two populations.

REDUCING NEUROTOXIC SHELLFISH POISON (NSP) IN PACIFIC OYSTERS (*CRASSOSTREA GIGAS*) TO LEVELS BELOW 20 MOUSE UNITS · 100 G^{-1}

GRAHAM C. FLETCHER,[1] BRENDA E. HAY,[2] AND MARGARET F. SCOTT[3]
[1]*New Zealand Institute for Crop & Food Research Limited, Private Bag 92169, Auckland, New Zealand;* [2]*AquaBio Consultants Ltd., P.O. Box 560, Shortland St, Auckland, New Zealand;* [3]*New Zealand Institute for Crop & Food Research Limited, Private Bag 11030, Palmerston North, New Zealand*

ABSTRACT Pacific oysters previously exposed to the algae *Karenia breve*, which produces neurotoxic shellfish poisoning (NSP), were held in experimental depuration tanks for up to 5 days prior to determination of their NSP levels by mouse bioassay. Although depuration reduced NSP levels in the oysters to around the regulatory limit (20 mouse units · 100 g^{-1}), levels below the regulatory limit could not be assured at temperatures of 15°C and 20°C and salinities of 24‰ and 34‰ with the standard bioassay used. Detoxification appeared less effective at 12°C. The use of an in-line filter to remove free algae or ozone to eliminate algae and toxins did not enhance detoxification. Use of a biological filter at 12°C in the tanks or feeding the oysters with *Isochrysis galbana* also did not assure NSP levels below the regulatory limit. Examination of NSP distribution in the shellfish tissues revealed that during depuration, the percentage of this lipid soluble toxin associated with the organs of the digestive system (gills and digestive viscera) decreased while levels increased in high lipid tissues, such as the gonads. We postulate that NSP is difficult to eliminate from oysters because it is incorporated into the lipid stores of the animal.

KEY WORDS: neurotoxic shellfish poison, Pacific oyster, *Crassostrea gigas*, detoxification

INTRODUCTION

Although the uptake of algal toxins by bivalve shellfish is a problem worldwide for shellfish producers, to date there have been very few successful strategies to mitigate the effects of toxic algal blooms. Current controls rely on growers monitoring toxin levels in shellfish and ceasing harvesting when levels exceed prescribed limits. This is in contrast to the situation when shellfish are exposed to bacterial pathogens. In this case growers may have the options of either relaying (moving shellfish to unaffected areas and harvesting again when the shellfish have naturally purified themselves after a period of weeks) or processing the shellfish in land-based depuration tanks where they will be cleared from bacterial pathogens within a few days (Roderick 1994). Similar strategies for the detoxification of shellfish from algal toxins are not commercially available.

The uptake and elimination of three of the four main algal toxin groups affecting shellfish have been investigated in laboratory studies: paralytic shellfish poison (PSP) (Bricelj & Shumway 1998), diarrhetic shellfish poison (DSP) (Cembella et al. 1998) and amnesic shellfish poison (ASP) (Wohlgeschaffen et al. 1992, Whyte et al. 1995). These studies suggest that land-based detoxification only appears to be feasible for ASP. Relaying to eliminate toxins could be developed but further research is required and there would be risks of introducing toxic algae to unaffected areas. Little work has been reported on detoxification of shellfish affected by the fourth toxin group, neurotoxic shellfish poisoning (NSP). Despite promising work that showed that NSP toxins were susceptible to oxidation in ozonated seawater (Schneider & Rodrick 1995) little work on the toxins within shellfish has been published (Fletcher et al. 1998). NSP occurs when people eat shellfish that have been subjected to dinoflagellate blooms composed of *Karenia* (syn. *Gymnodinium*) species. These blooms commonly occur in the Gulf of Mexico where the causative alga is *Karenia breve* (syn. *Gymnodinium breve, Ptychodiscus brevis*). One outbreak, caused by a *K. breve*-like species, has been recorded in New Zealand (Chang 1995). We have previously reported the results of six experiments designed to determine whether Pacific oysters (*Crassostrea gigas*) might be successfully detoxified of NSP toxins in a depuration system (Fletcher et al. 1998). We found that, although mean NSP levels could be reduced to levels below the regulatory limit of 20 mouse units · 100 g^{-1}, levels below this limit could not be assured in individual tests using the regulatory method (APHA 1970). This was regardless of whether ozone was used in the seawater. We now report on four experiments designed to confirm the previous results, investigate why levels below 20 mouse units were not consistently achieved and to evaluate other detoxification methods that may result in additional decreases in NSP levels.

MATERIALS AND METHODS

K. breve cells were grown in a medium derived from the GP medium of Loeblich and Smith (1968). The original GP medium contained 85% seawater, but because a higher percentage of seawater gave better growth rates for *K. breve* (unpublished data) we modified the GP medium in this study to the following composition: seawater (1 L), KNO_3 (200 mg in 2 mL H_2O), vitamin solution (1 mL), trace element solution (5 mL), and soil solution (5 mL). This medium was autoclaved (121°C, 15 min), and then K_2HPO_4 (8.7 mg in 4 mL autoclaved) was added aseptically. The vitamin solution contained thiamin HCl (100 mg), vitamin B_{12} (0.1 mg), biotin (0.2 mg) and H_2O (100 mL). The trace element solution contained Na_2EDTA (6 g), $FeCl_3.6H_2O$ (0.29 g), H_3BO_3 (6.85 g), $MnCl_2.4H_2O$ (0.86 g), $ZnCl_2$ (0.06 g), $CoCl_2.6H_2O$ (0.026 g), and H_2O (1 L) adjusted to pH 7.9 with NaOH. The soil solution was the supernatant after filtering (Whatman No. 2 filter) a mixture of soil (1 kg) and H_2O (2 L) that had been autoclaved (121°C, 60 min).

Oysters were supplied with *K. breve* cells at rates of 10 to 25 × 10^6 cells.oyster^{-1} (Table 1) and left for 24 h to ingest the cells and take up the NSP toxin, as described previously (Fletcher et al. 1998). This feeding regime gave initial toxin levels from 29.6 to 70.7 mouse units · 100 g^{-1} (Table 2).

Four detoxification experiments (designated Experiments 1 to 4) were carried out in the experimental tanks described previously (Fletcher et al. 1998). Briefly the tanks consisted of two closed systems: one of four 50 L tanks plumbed in parallel to a tempera-

ture controlled sump and the other of a single 50 L tank maintained at the same temperature. Both systems had in-line 5 μm cartridge filters (FilterPure 5PW10, Contamination Control, Auckland) and ultraviolet lamps (Steriflo 369P, Contamination Control, Auckland) available. Ozone could be supplied to tanks 1-4 by a corona discharge generator (CD1000, Novozone, Auckland) using oxygen as the source gas. When applied, water was ozonated using an electronic controller to provide a reading of 350 ± 20 mv (redox electrode MC241Pt, Radiometer) in the shellfish tanks, which converts to an Eh of 549 mv using the correction factor of +199 mv applicable to the Ag/AgCl, KCl reference electrode (Vogel 1961). Additionally, in Experiments 3b and 4c, oysters were placed in a 1000-L biofilter tank (12 ± 0.5°C) where recirculating water was purified by passing it through a sand and shell-based biologically active filter.

Ozone and ammonia levels in the seawater were measured using Palintest Photometer 5000 methods (Anon. 1994) and salinity was determined using a refractometer (Atago). NSP levels in the oysters were measured using the APHA method (APHA 1970). Each NSP test was carried out on at least 100 g drained meats from 10–12 oysters. One or two such pooled samples were tested from each treatment on each testing occasion with the two samples being taken from separate tanks when the treatment was spread over more than one tank (details of timing and numbers of samples taken are recorded in Fig. 1). The NSP method can detect toxin levels down to about 10 mouse units · 100 g^{-1}, depending on the size of mouse used (18–22 g). Where toxicity was observed but the relevant mice did not die, the toxin level was scored at half the minimum detectable level. Crude lipid levels were determined from the weight of lipid extracted in the ether extraction during the NSP extraction procedure.

The experimental conditions under which the oysters were made toxic and maintained during depuration are presented in Table 1. The depuration conditions in Experiments 1 and 2 were designed to complement the half factorial design used in previous work (Fletcher et al. 1998), increasing the replication for each

factor (ozone or ultraviolet light sterilization, in-line filtration to 5 μm or no filtration, water temperatures of 15°C or 20°C and salinities of 24‰ or 33‰). Also, in Experiment 1, three batches of oysters were separately fed different levels of *K. breve* (Treatments 1a, 1b, and 1c), and then subjected to identical detoxification conditions. Experiment 3 compared UV sterilization at 20°C (Treatment 3a) with the use of the biofilter at 12°C (Treatment 3b). Experiment 4 also compared UV sterilization (Treatment 4a) with the use of the biofilter (Treatment 4c) but all oysters were held at 12°C. Additionally, (Treatment 4b) oysters were held in the same conditions as Treatment 4a except that they were fed with 10 million cells *Isochrysus galbana* per oyster on days 2 and 3. Treatment 4d was a control where oysters that were not toxic were placed in the same tanks as Treatment 4a oysters and tested at the end of the experiment (after 5 days) to see whether detectable levels of toxin had been accumulated during the trial.

Nonlinear regression analysis was used to fit exponentially declining detoxification curves of the form:

$$Y = a + b.r^X \tag{1}$$

where Y was the mean NSP level for a treatment on a given day and X was the number of days since the beginning of the experiment. The parameter a is the asymptote of the curve (the level to which NSP approaches after some large number of days); $a + b$ is the initial NSP level; and r is related to the speed of approach to the asymptote. The model was constrained with $r < 1$ and $a \geq 0$. Accumulated analysis of variance was used to compare the fitted curves. Analysis of variance (ANOVA) was applied to the mean NSP levels after day 2 (exclusive) and on parameter a in Equation 1 to determine whether any of the experimental factors had statistically significant ($P < 0.05$) effects on the outcome of detoxification for 6 experiments providing a balanced set of factors (Runs 1 to 4 of previously published work (Fletcher et al. 1998), with Experiments 1 and 2 of the current work). Residual Maximum Likelihood (REML) statistics were similarly applied to compare the effect of treatments in all experiments.

At the end of Experiment 2 (day 4) and at the beginning and end (days 0 and 5) of Experiment 3a, the distribution of toxin in various tissues was determined as well as the NSP levels in two pooled samples of 10 oysters. To determine toxin distribution, 100 oysters were dissected [see Quayle (1969) for a description of *C. gigas* anatomy] into mantle (up to the junction between the mantle and gill, adductor muscle, gill, labial palps, gonad (i.e., the white colored tissue surrounding the digestive organs) and digestive tissues (remaining visceral mass). The tissues from the 100 oysters were pooled, tested for NSP, and the results were related to the total NSP level found in the pooled samples of the 10 whole oysters.

RESULTS

The NSP results for the 4 detoxification experiments are presented in Figure 1 and Table 2. Initial toxin levels ranged from 29.6 (Experiment 3) to 70.7 (Experiment 1 Treatment c) mouse units g^{-1} with considerable variation in levels recorded from identical conditions of uptake (Table 1). As observed previously (Fletcher et al. 1998), there was a period of rapid detoxification followed by a period of no significant changes in toxin levels (from Days 3 to 5 inclusive). The results of fitting these data to Eq. 1 are shown in Table 2. As separating the 3 batches of shellfish in Experiment 1 did not improve the goodness of fit the NSP results were analyzed as a single treatment. Statistical analyses of Experiments 3 and 4 did not demonstrate significant differences in NSP levels between treatments, with or without an in-line biofilter or with or without feeding with *I. galbana*. Treatments with an in-line biofilter did not result in increased ammonia levels in the water with time while treatments in the smaller tanks did, as reported previously (Fletcher et al. 1998). Adding the extra replication of factors provided in Experiments 1 and 2 to the previously reported (Fletcher et al. 1998) half factorial experiment (Runs 1–4) effectively reduced the confounding effect of shellfish weight and initial NSP level from the analysis and allowed valid ANOVA. However, this still showed no significant differences between the four factors evaluated: temperature (15°C, 20°C), salinity (24‰, 34‰), in-line filter (5 μm, absent), disinfection agent (UV, ozone). Further, REML analysis of all the experiments also showed no significant effects ($P > 0.05$), although detoxification from treatments at 12°C was possibly less effective than from those at 15°C ($P < 0.10$).

Results from the analyses of different tissues in Experiment 2 and Experiment 3 Treatment a are presented in Table 3. Immediately after toxification (Day 0, Experiment 3), the toxin was concentrated in organs associated with ingestion and digestion (gills, palps, digestive tissues) while at the end of the detoxification

[1] Weighted contribution of the tissue to total amount of toxin for all tissues.

experiments (Day 4 of Experiment 2 and Day 5 of Experiment 3) the remaining toxin was located in the palps, digestive tissues and gonads, all tissues with high levels of lipid.

DISCUSSION

The fit of data to Eq. 1 (as indicated by the R^2 statistic) ranged from a very good fit for Experiment 2 to poor for Experiment 4 Treatment a. However, the poor fits can be explained by the large variability between results from pooled samples of identically treated oysters on a given day rather than the inappropriateness of the exponential model. Similar results were found when fitting the previously published data (Fletcher et al. 1998) from Runs 1 to 6 with the R^2 statistic ranging from 0.565 to 0.999 and the a parameter from 5.21 to 18.29. In New Zealand's only confirmed NSP event, NSP stopped being recorded in shellfish (including Pacific oysters) shortly after the causative organism disappeared from the water column (Chang et al. 1995). In an open system where fresh seawater was continually supplied to the oysters it could be expected that parameter a in Eq. 1 would be zero (i.e., given sufficient time the oysters would completely purify themselves of the toxin as happened in the wild). In fitting the curves this only proved true for two treatments: Experiment 3 Treatment b where the oysters were in large tanks filtered through a biofilter and Experiment 4 Treatment b where oysters were fed with algae during the detoxification experiment. The levels of NSP after 3–5 days for these two treatments were no lower than other experiments, so detoxification was not more rapid in these treatments, but the value of 0 for parameter a suggests that complete detoxification would occur with time. The overall results suggest that the closed tank system is fundamentally limited in its ability to totally detoxify oysters of NSP.

Practical requirements for bacterial depuration of shellfish allow that salinity can vary from ambient by up to 20% without affecting performance (e.g., Interstate Shellfish Sanitation Conference 1997). In our work, reducing salinity from an ambient of 34 to 24‰ (30% reduction) did not have a significant effect on toxin loss, so a similar parameter could be applied for NSP detoxification. Previous work showed that bacterial depuration of Pacific oysters was more effective at 15°C–20°C than at temperatures below 14°C (Fletcher et al. 1991). The current work confirms that a similar pattern applies for NSP detoxification in this species with some evidence of reduced detoxification at 12°C, but no differences in detoxification effectiveness at 15°C and 20°C. Inclusion of an in-line 5 μm filter did not improve the effectiveness of detoxification, suggesting that uptake of NSP associated with particles in the water (e.g., whole algal cells) is not important in this system. As the products of ozonating seawater break down NSP toxins (Schneider & Rodrick 1995) it was expected that NSP detoxification would be more effective for oysters in ozonated water. However, the results did not show any such effect, probably due to the relatively low levels of ozone we were able to add to the water, levels that produced a change in redox potential in seawater from the ambient of around 450 to 550 mv. This level was used because, in preliminary trials, Pacific oysters were observed to close their shells and cease pumping at redox potentials of over 600 mv. Thus, ozonation did not appear to be beneficial in reducing NSP toxin levels within oysters.

In the initial work, we observed that the levels of ammonia in the water increased substantially during the detoxification experiments. We postulated that these levels of ammonia and other metabolic byproducts might have inhibited oyster function, thereby preventing detoxification after the first 2 days of the experiments. Holding oysters in the larger tank where water was filtered by the biological filter in Experiments 3 and 4 was designed to test this. Although there was no build-up of ammonia in this tank, there was still no significant detoxification after the first 2 days (Fig. 1) and rates and levels of detoxification were not significantly different to those oysters in the experimental tanks without the biological filter. Similarly, feeding the oysters did not result in any marked improvement in detoxification. Although these treatments may have slightly improved detoxification, the differences were not sufficient to assure the production of oysters below the regulatory level within the 5-day period.

The location of toxins in the different oyster tissues goes some way towards explaining the failure to achieve complete detoxification. The locations of the NSP toxin at the start of Experiment 3 support the hypothesis that the toxin is associated with algal particles that are in the process of being ingested or digested. However, during the detoxification period the toxin was eliminated from the gills and appeared in the gonad tissues. After detoxification, although the total levels of NSP were reduced, the remaining toxin only appeared in high lipid tissues at the end of Experiments 2 and 3. This suggests that while some of the algal particles may have been passed out in feces others have been digested and some of the lipid-soluble toxin has been transferred to the animals' lipid stores. Subsequent detoxification, therefore, will be a much slower process, reliant on the oysters' need to metabolize their lipid stores.

The considerable variability in toxin levels in oysters held under identical conditions is of concern. The method we used is the one accepted by regulatory authorities and the laboratory is approved under FDA protocols for this test. Although considerable variability is expected when testing individual shellfish (e.g., Scotti et al. 1983, White et al. 1993), pooling 10 to 12 oysters should limit the effects of oyster-to-oyster variability on the results. In some experiments (e.g., Experiment 2) the results of replicate samples were acceptably close, but in others using the same test procedures (e.g., Experiment 1) wide variances were observed. The control in Experiment 4 Treatment d was designed to test whether some of this variability might be due to the uptake of toxins excreted by other oysters. However, this did not appear to be the case, as the non-toxic oysters in this treatment did not accumulate toxin to detectable levels. The observed variability is critical in a regulatory environment where the test is usually carried out on a single pooled sample of 10 to 12 oysters from a given area. For example, in Experiment 1 Treatment c on Day 4 one sample was below the regulatory limit while another was well above (Fig. 1a). Due to the variability in results, an argument could be made that it would be better to base the regulatory limit on the mean of a number of samples rather than a single pooled sample. In this case many of our experiments would have met the regulatory limit. The extra testing required to obtain mean values would place an extra cost on the industry when the current regulatory limit has been effective in preventing NSP illness. There is little knowledge of the human dose-response curve for NSP but a 100-g sample is a reasonable reflection of an average serving for a consumer.

CONCLUSIONS

The levels of NSP in Pacific oysters were reduced to levels near the regulatory limit of 20 mouse units · 100 g^{-1} in 2–3 days when held at temperatures between 15°C and 20°C and salinities between 24‰ and 34‰. However, no treatment consistently produced levels below the regulatory limit within the 5-day trials. This failure can be explained by the hypothesis that toxins migrate from the readily accessible surfaces of digestive tissues and are incorporated into the animals' lipid stores. The level of variability encountered with the standard APHA test procedures suggests that they need to be reviewed to confirm their suitability for assuring safe levels of NSP toxins in shellfish.

RECIRCULATION OF DINOFLAGELLATE CYSTS BY THE MUSSEL, *MYTILUS EDULIS* L., AT AN AQUACULTURE SITE CONTAMINATED BY *ALEXANDRIUM FUNDYENSE* (LEBOUR) BALECH

F. M. HARPER,* E. A. HATFIELD, AND R. J. THOMPSON

ABSTRACT Holding suspension-feeding bivalves at an aquaculture site may facilitate the maintenance of toxic dinoflagellate populations by concentrating transient vegetative cells or resuspended cysts. To examine the role of the mussel, *Mytilus edulis*, in recirculating cysts within an aquaculture site contaminated with the dinoflagellate *Alexandrium fundyense*, sediment cores and fecal samples were collected in September and October 1996. In the interim period, a bloom of *A. fundyense* vegetative cells began. Mussels egested similar concentrations of dinoflagellate cysts (*Scrippsiella* sp., *A. fundyense*, and an unknown Grey species) regardless of the location of the mussel sock in the site, or the position of the mussel in the water column. In September, more putative *A. ostenfeldii* cysts were egested in feces collected from the bottom of two socks than in those from the top. One sock was located at greater depths near a barrier island and the other in a shallow northeastern cove. Within each dinoflagellate species, there were no significant differences between cyst concentrations in sediment throughout the site, the exception being the high concentrations in September of putative *A. ostenfeldii* beneath the sock located near a barrier island (182 cysts·cm^{-3}). Post-bloom, there were significantly fewer *A. fundyense* cysts in the sediment underlying the sock near a barrier island. In contrast, there were significantly more putative *A. ostenfeldii* cysts in the sediment in the shallow northeastern cove (580 cysts·cm^{-3}). The daily replenishment rate of *A. ostenfeldii* cysts in bottom sediments by mussel fecal deposition was estimated as 2×10^5 cysts m^{-2} d^{-1}, or about 8%. This may be a considerable contribution to the maintenance of this dinoflagellate species in a mussel aquaculture site, but further studies are required to compare other inputs and outputs of cysts to establish the relative importance of bivalve aquaculture.

KEY WORDS: dinoflagellate, *Alexandrium*, cysts, mussel, aquaculture, PSP

INTRODUCTION

Accumulations of resting cysts (or hypnozygotes) of benthic dinoflagellates have been observed in various marine environments: offshore trenches and depressions, fjords, and the shallow coastal embayments often selected for shellfish aquaculture operations (Dale 1976, Dale et al. 1978, Anderson & Morel 1979, White & Lewis 1982). Certain locations that accumulate cysts as a result of selective deposition due to hydrographic and sedimentary processes can act as "seed beds", producing motile cells that then initiate blooms (Steidinger 1975, Anderson & Morel 1979, Tyler et al. 1982). More than 80 species of marine dinoflagellates are known to produce cysts (Matsuoka et al. 1989), including species of the toxic dinoflagellate *Alexandrium* (Halim) Balech (formerly classified as *Gonyaulax* spp. or the *Protogonyaulax catenella/tamarensis* species complex). In many parts of the world, *A. tamarense* (Lebour) Balech has been responsible for incidents of paralytic shellfish poisoning (PSP; see review by Hallegraeff 1993).

PSP is a serious public health risk that threatens the commercial harvest of both wild and cultured bivalve populations. Potent neurotoxins can accumulate in bivalves through ingestion of vegetative cells of toxic dinoflagellates during suspension feeding (Shumway et al. 1987, Shumway 1990). Cysts formed at the end of *Alexandrium* blooms have also been implicated as vectors of PSP toxin transfer to bivalves (Dale et al. 1978, White & Lewis 1982). There has been some debate concerning the toxicity of the cysts relative to the motile vegetative cell (Dale et al. 1978, Yentsch & Mague 1979, White & Lewis 1982, Cembella et al. 1990), although there is a consensus that *A. tamarense* cysts contain PSP toxins. The abundance of *A. fundyense* (Lebour) Balech cysts in sediments has been positively correlated with maximum-recorded levels of PSP toxins in the blue mussel, *Mytilus edulis* (Schwinghamer et al. 1994). Mussels ingest *A. tamarense* cysts and pass them in fecal pellets (Anderson 1984), but whether bivalves can extract the toxins from cysts and assimilate them remains to be established.

Bivalves inhabiting areas with bottom sediments contaminated with toxic cysts cannot avoid encountering these cells during resuspension events. Dense concentrations of suspension-feeding bivalves in areas such as aquaculture sites may facilitate the maintenance of a seed bed of toxic dinoflagellate hypnozygotes by concentrating transient vegetative cells or resuspended cysts and depositing these cells onto the underlying sediment in the form of pseudofeces or feces.

Mussel aquaculture is an expanding industry in Newfoundland: production has increased from 320 tonnes in 1991 to over 1700 tonnes in 1999 (Statistics Canada 1999). Surveys of coastal sediments around the Province have revealed contamination by *A. fundyense* cysts in many areas (McKenzie 1993, McKenzie 1994, Schwinghamer et al. 1994). One former mussel farm, located in Barred Island Cove, Notre Dame Bay, is permanently closed to aquaculture due to persistent PSP contamination, and has been the focus of ongoing research (Fig. 1). Sediment analysis at this site, a cove with two barrier islands and a shallow sill, has revealed *A. fundyense* cyst concentrations ranging from 20 to >1,000 cysts·cm^{-3} (McKenzie 1993, McKenzie 1994, Schwinghamer et al. 1994). This site experiences frequent sediment resuspension as the result of strong winds.

The objective of this study was to examine the role of the mussel, *M. edulis*, in recirculating dinoflagellate cysts and maintaining *Alexandrium* populations within an aquaculture site. The dinoflagellate cyst composition of feces collected from mussels from the tops and bottoms of socks was determined to test the hypothesis that mussels suspended further away from the contaminated sediment egest fewer cysts. To facilitate comparisons be-

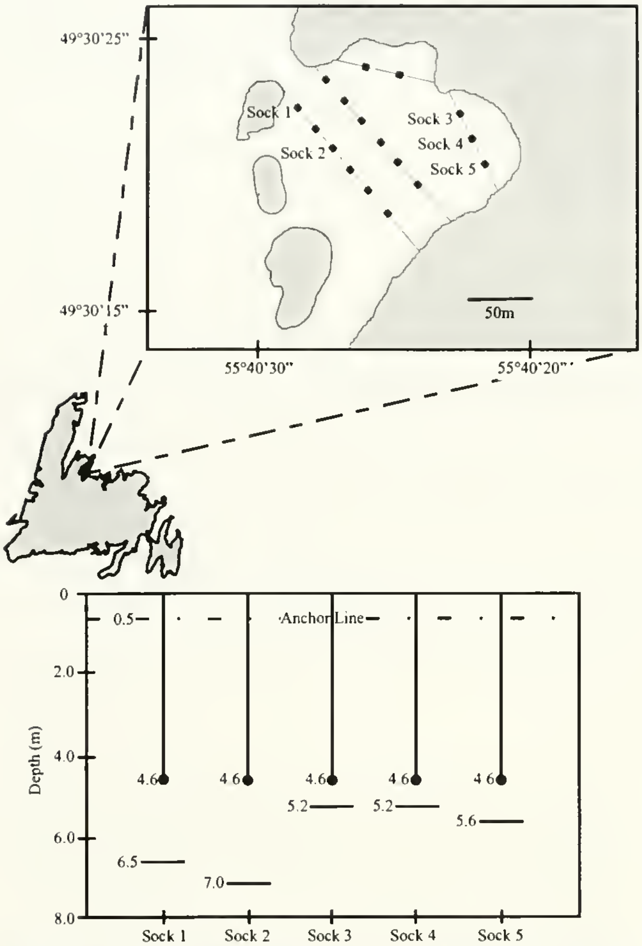

Figure 2. Location of mussel long-lines (—) and socks (◆) at the study site, Barred Island Cove, in Notre Dame Bay, Newfoundland. Lengths of socks and sediment sampling depths are depicted for specified socks (insert).

tween different sampling locations in the site, the concentrations of cysts in the sediment beneath the mussel socks were determined. The biodeposition rate of dinoflagellate cysts in fecal pellets was then calculated to estimate the rate at which cultured mussels returned resuspended cysts to the sediment surface.

MATERIALS AND METHODS

Collection and Examination of Mussel Fecal pellets

Mussels were sampled in September and October 1996 from the tops and bottoms of mussel socks previously established at the study site, Barred Island Cove, Notre Dame Bay, Newfoundland (see Fig. 1). Wind speed and tide stage, factors that could induce heavier sediment resuspension, were similar for the two sampling periods. Sediment traps deployed in September and retrieved in late October contained *Alexandrium* cells in various stages of encystment, suggesting a mid- to late-October bloom (McKenzie et al. 1998). Socks (4.6-m length) were selected based on results of earlier studies conducted at this site, which demonstrated that the highest cyst concentrations occurred in the shallow sediment at the northeastern edge of the cove (McKenzie 1994, Schwinghamer et al. 1994). Socks 1 and 2 were located near the barrier islands; socks 3–5 were situated in the northeastern cove (see Fig. 1).

On September 24, 1996, five mussels (*Mytilus edulis*, mean shell length 63.5 mm ± 10.2 SD) were collected from the top and five from the bottom of each of socks 1, 2, and 4. Two species of mussels, *M. edulis* and *M. trossulus*, co-exist in Newfoundland; those used in this study were identified as *M. edulis* based on size and morphologic characteristics (Freeman et al. 1992). Furthermore, over 95% of mussels in this part of the coast of Newfoundland are *M. edulis* according to genetic markers used by Innes and Thompson (unpublished data).

Mussels were transported on ice (8 h) to the Ocean Sciences Center, Logy Bay; no mortalities occurred. On arrival, mussels were scrubbed free of epibionts and placed in individual 1-L containers with 700 mL UV-sterilized, filtered (1.0 μm) seawater (FSW) at 15°C. Mussels were removed after a 15 h incubation period and the fecal pellets carefully collected and stored in the dark at 4°C. No preservative was necessary, as low storage temperature (4°C) and darkness do not stimulate germination of cysts (Perez et al. 1998). Preliminary trials indicated that the gut retention time of dinoflagellate cysts was approximately 9 h, therefore 15 h was considered adequate time for complete digestion and/or egestion; Scarratt et al. (1993) proposed that 12 h would be sufficient time to purge cysts from mussels. Since the mussels remained closed during transport, there was no egestion of feces. Prolonged retention of the material within the digestive tract during transport did not appear to affect the egestion of intact dinoflagellate resting cysts, although some cysts may have been digested so that the values for cysts egested may be underestimates.

On October 29, four mussels (mean shell length 43.6 mm ± 6.7 SD) were sampled from the top and bottom of each of socks 1, 2, 3, and 5. Fecal pellets were collected on-site: after being scrubbed free of epibionts, individual mussels were placed in plexiglass cylinders (diameter = 70 mm; height = 75 mm) filled with surface water. Cylinders were sealed with a rubber stopper, leaving an air pocket, and submerged for 19 h at 7°C. Fecal material was then collected and transported to the laboratory for processing. No pseudofeces production was ever observed.

Fecal contents were disaggregated by repeated aspiration through a micropipette tip, followed by gentle sonication for thirty minutes in an ice-water ultrasonic bath (Cole Parmer 8851). In preliminary testing of methods for disaggregating fecal pellets, gentle sonication in the bath did not destroy any cysts and resulted in a homogeneous suspension of fecal material (Harper 1997). Sonication by microprobe and by ultrasonic bath has no significant negative effects on germination of *A. tamarense* cysts collected from sediment (Perez et al. 1998). Cysts in each sample were counted (triplicate samples) with an Utermöhl settling chamber. Dinoflagellate cysts were identified and enumerated by direct cell counting using phase and epifluorescence microscopy. Although this approach is laborious and time-consuming, it yields the most accurate information about the composition of the phytoplankton and the condition of the cells (Sakshaug 1990). An electronic particle counter could not be used for enumeration of the cells in the fecal material as the cysts of each species were approximately the same size (40 μm diameter) and shape, and thus cysts of any given species could not be distinguished from those of other species.

To facilitate comparisons between mussels from different locations and of different sizes, cyst abundance values were expressed per mg total dry weight (DW) and per mg ash-free dry weight (AFDW) of feces. Duplicate samples of 0.7–1.2 mL homogeneous fecal suspension were retained on preweighed, precombusted (450°C) Whatman GF/C filters (25 mm) under gentle vacuum, then rinsed with 10 mL 3% ammonium formate to remove salts. Filters were oven-dried to constant dry weight at 60°C, then combusted at 450°C for 12 h, cooled in a desiccator and reweighed to determine the AFDW of feces. Weights were determined within 1 μg with a Mettler UM3 microbalance.

Collection, Concentration, and Examination of Cysts from Sediment

On each of the sampling dates, four sediment cores were collected by hand by SCUBA divers within a 1-m^2 area beneath mussel socks 1–4 in September and socks 1–5 in October. The sediment was composed of small rocks, fine gravel and silt. The top 6–8 cm of sediment and 2–3 cm of overlying water was collected using a 50-mL polycarbonate centrifuge tube (cross-sectional area 5.92 cm^2) with the conical tip removed (McKenzie 1993, McKenzie 1994; McKenzie & Schwinghamer 1994). Cores were transported on ice in the dark to the laboratory where the top 3 cm of sediment and the overlying water were transferred to clean 50-mL tubes, then stored in the dark, unpreserved, at 4°C. Dinoflagellate cysts were enumerated in the top 3 cm of sediment rather than just in the flocculent surface layer (Anderson & Wall 1978, Dale et al. 1978, Lewis et al. 1979). As many *Alexandrium tamarense* (*Gonyaulax excavata*) cysts can be present in the top 3–4 cm of sediment as are found at the surface (White & Lewis 1982).

To ensure adequate dispersal of detritus, sediment samples were sonicated with two bursts (each 45 sec., power level 4) of a Branson 250 Probe Sonifier. Samples were then fractionated to separate and concentrate dinoflagellate cysts following the density-gradient technique of Schwinghamer et al. (1991). In brief, after sonication the sediment was sieved through 80- and 20-μm Nitex nylon sieves, retaining the material on the 20-μm sieve. A step gradient was then formed by slowly injecting "light" and "dense" solutions of a non-toxic, aqueous colloidal silica suspension (Nalco 1060), made isosmotic with seawater (salinity 32‰) using sucrose, beneath the sieved cyst suspension in a 50-mL centrifuge tube. The tubes were then centrifuged at 1,500 g for 30 min at 4°C and the concentrated layer of dinoflagellate cysts at the interface between the light and dense layers removed for examination.

The dinoflagellate cyst composition of each sediment core was determined in triplicate by examining the concentrated cyst layer with phase and epifluorescence microscopy. Each count was performed on 100–200 μL of the homogenous cyst slurry, the volume settled for each core being adjusted to yield a total of 100–300 cysts per slide (Venrick 1978, with reference to Lund et al. 1958). Results were expressed as the number of cysts·cm^{-3} sediment.

Dinoflagellate Cysts in Feces and Sediment

The cysts of four dinoflagellate species were enumerated in fecal and sediment samples: *Scrippsiella* sp. (Stein) Loeblich, *Alexandrium fundyense*, and two unknown species. Cysts were identified using morphologic characteristics: the shape of the cyst body and its ornamentation, cyst size and diameter, wall structure, and the presence of food reserves and pigmented bodies (Matsuoka & Fukuyo 1995). The first unidentified form resembled the resting stage of *A. ostenfeldii* (Paulsen) Balech et Tangen, a toxic dinoflagellate that has been observed in the Gulf of St. Lawrence (Levasseur et al. 1996), and in Nova Scotian coastal embayments (Cembella et al. 1998, Cembella et al. 2000). These cysts matched the description of the *A. ostenfeldii* cyst provided by MacKenzie et al. (1996): a spherical cell (~40 μm diameter) containing one or two red-brown pigmented granules and areas of condensed, golden-brown pigmentation radiating from the center of the cell towards the periphery. Identification of the vegetative cells that emerged from these cysts was not possible, as repeated attempts at establishing cultures were unsuccessful, but these vegetative cells had the typical gonyaulax form (Hallegraeff 1995), although they did not survive more than 48 h. These cysts are referred to here as putative *A. ostenfeldii* pending further germination studies.

The second unidentified cyst is referred to as the Grey cyst because of its appearance in phase microscopy. It is possible that these cysts were partially digested *A. fundyense* cysts as they were approximately the same dimensions and clearly contained a red pigmented body, but all were tapered at one end, in contrast with the two rounded ends of cylindrical *A. fundyense* cysts. Grey cysts did not germinate under culture conditions and currently remain unidentified.

Statistical Analyses

The concentrations of the dinoflagellate cysts in feces from mussels collected from the top and bottom of each sock were analyzed by two-way analysis of variance with the sock and the position of mussel on the sock as fixed factors and the individual mussel as the unit of analysis. Separate analyses were performed for the abundance of each dinoflagellate species present in mussel feces, expressed per mg DW and per mg AFDW feces. September and October data were treated separately as only socks 1 and 2 were sampled in both months.

The concentrations of the four species of dinoflagellate cysts in the sediment beneath the socks were analyzed by one-way analysis of variance with the sock as the fixed factor. Analyses were performed separately for September and October data, and for each cyst type, expressed as the total number present·cm^{-3} sediment.

A two-way analysis of variance was performed to compare pre- and post-bloom concentrations of the cysts in the sediment beneath socks 1–4. Month and sock were fixed factors in the analysis; the individual cores were the experimental units.

Where the F value exceeded the critical value at $P = 0.05$, planned comparisons were made using Fisher's LSD method (Milliken & Johnson 1984). The criterion for statistical significance in all analyses was $P \leq 0.05$.

RESULTS

Concentrations of Dinoflagellate Cysts in Mussel Feces

The concentrations of dinoflagellate cysts egested were highly variable between individual mussels (Fig. 2, Fig. 3). In September (see Fig. 2), the concentrations of *Scrippsiella* cysts egested were low, ranging from 0–142 cysts·mg^{-1} DW and 0–98 cysts·mg^{-1} AFDW feces. Few *Alexandrium fundyense* cysts were egested, from 0–28 cysts·mg^{-1} DW and 0–846 cysts·mg^{-1} AFDW feces. Concentrations of the unknown grey morphotype were also low, ranging from 0–71 cysts·mg^{-1} DW and 0–474 cysts·mg^{-1} AFDW feces. There were no significant differences in the concentrations of *Scrippsiella* sp., *Alexandrium fundyense*, and Grey cysts between mussel feces collected from the tops and bottoms of socks.

More putative *Alexandrium ostenfeldii* cysts were found in the mussel feces collected in September (see Fig. 2) than any of the

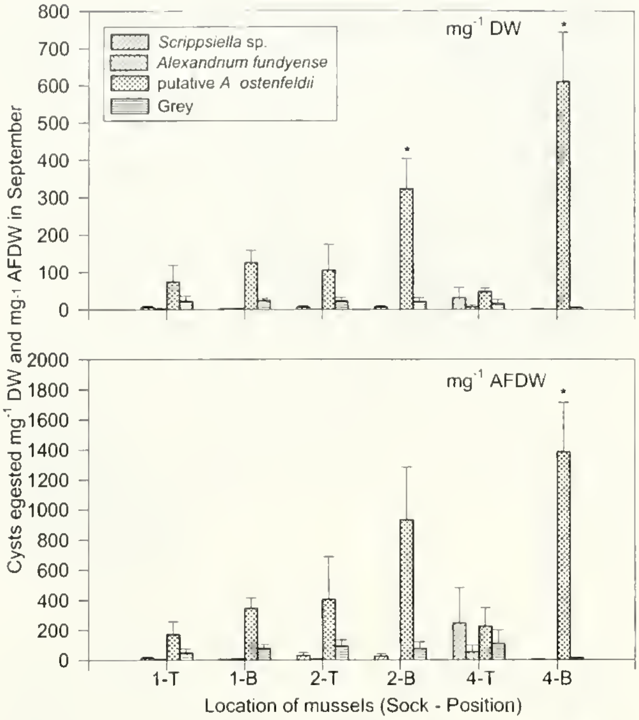

Figure 2. Concentrations of dinoflagellate cysts egested in mussel feces collected from the tops (T) and bottoms (B) of socks in September. Values are standardized per mg dry weight of feces and per mg ash-free dry weight. Each bar is the mean ± standard error ($n = 5$). The asterisk (*) indicates significant differences (P 9 0.05) between the concentrations of a dinoflagellate species in feces collected from the top and bottom of a specific sock.

other dinoflagellate cyst types quantified. Putative *A. ostenfeldii* concentrations varied from 10 to 846 cysts·mg^{-1} DW and 18 to 2,190 cysts·mg^{-1} AFDW feces. Significantly more of these cysts were found in mussel feces collected from the bottom of sock 4 than from the top ($P = 0.0001$ for values expressed in terms of DW; $P = 0.004$ for AFDW) and from the bottom of sock 2 than from the top ($P = 0.039$ for DW). Sock 4 was located in the northeastern cove; the bottom of the sock was only 0.6 m above the sediment. Socks 1 and 2 were located near the barrier islands and were further from the bottom, 1.9 and 2.4 m from the sediment respectively (see Fig. 1).

In October (see Fig. 3), there were no significant differences in the concentrations of any of the dinoflagellate species between fecal samples from mussels collected from the tops and bottoms of the socks. The concentrations of *Scrippsiella* sp. egested were similar to those found in September, ranging from 0–90 cysts·mg^{-1} DW and 0–216 cysts·mg^{-1} AFDW feces (see Fig. 3). *Alexandrium fundyense* cysts concentrations in the mussel feces remained low, varying from 0–170 cysts·mg^{-1} DW and 0 to 181 cysts·mg^{-1} AFDW feces. Concentrations of putative *A. ostenfeldii* cysts egested ranged from 0–130 cysts·mg^{-1} DW and 0 to 325 cysts·mg^{-1} AFDW feces. Grey cyst concentrations were also low; consistent with amounts egested in September, ranging from 0 to 130 cysts·mg^{-1} DW and 0 to 325 cysts·mg^{-1} AFDW feces.

The error in counting cysts in the fecal suspension was estimated from five replicate counts of a single sample containing 494 cysts (putative *A. ostenfeldii*). The coefficient of variation (CV) was 18% mg^{-1} DW and mg^{-1} AFDW feces. The error in this method is comparable to the 20% CV reported by Ishikawa and Taniguchi (1994) for enumeration of cysts of *Scrippsiella* sp. in sediment. The counting error (CV) for the sediment cores was 14%, estimated by five replicate counts of putative *A. ostenfeldii* cysts in one sediment core that contained 156 cysts·cm^{-3}.

Concentrations of Dinoflagellate Cysts in Sediment Beneath Mussel Socks

On both sampling dates, concentrations of *Scrippsiella* sp., *Alexandrium fundyense* and Grey cysts did not differ significantly within each species between sediment samples collected throughout the site ($P > 0.05$, Fig. 4). In September, *Scrippsiella* sp. cysts numerically dominated the sediment with a mean concentration of 596 cysts·cm^{-3} (±335.6 SD) compared with the mean *A. fundyense* concentration of 89 cysts·cm^{-3} (±88.7 SD). Grey cysts were scarce (mean 4 cysts·cm^{-3} ±6.8 SD). In October, mean *Scrippsiella* sp. concentrations were 306 cysts·cm^{-3} (±144.2 SD), *A. fundyense* mean concentrations were 142 cysts·cm^{-3} (±137.3 SD), and very few Grey cysts were found (mean 0.6 cysts·cm^{-3} ±1.3 SD).

In September, there were significantly more putative *A. ostenfeldii* cysts in the sediment beneath sock 1 than elsewhere in the site ($P = 0.008$). In October, however, there were no significant differences in putative *A. ostenfeldii* cyst concentrations in the sediment beneath the mussel socks ($P > 0.05$).

Sediment trap data collected in October as part of a concurrent study (McKenzie et al. 1998) suggested that an *A. fundyense* bloom began during mid- to late-October. Post-bloom, there were significantly fewer *A. fundyense* cysts·cm^{-3} beneath sock 1 than

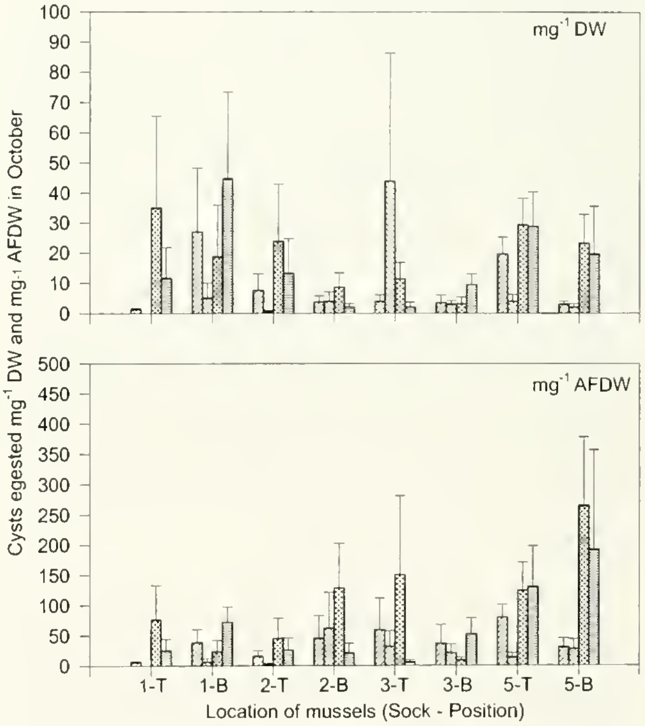

Figure 3. Concentrations of dinoflagellate cysts egested in mussel feces collected from the tops (T) and bottoms (B) of socks in October. Values are standardized per mg dry weight of feces and per mg ash-free dry weight. Each bar is the mean ± standard error ($n = 4$). Legend as in Figure 2.

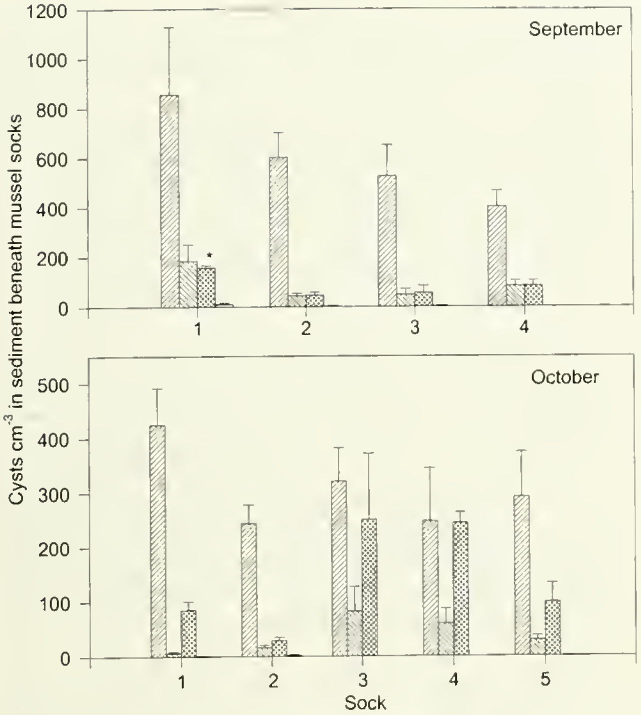

Figure 4. Concentrations of dinoflagellate cysts per cm^3 in the sediment beneath mussel socks sampled in September and October. Sock numbers refer to designations on Figure 1. Each bar is the mean ± standard error ($n = 3$). The asterisk (*) indicates a significant difference between the concentrations of putative *A.ostenfeldii* cysts beneath sock 1 and concentrations beneath socks 2–4 in September ($P = 0.008$). Legend as in Figure 2.

elsewhere ($P = 0.001$). In contrast, there was significantly more putative *A. ostenfeldii* cysts beneath socks 3 and 4 in October than there were in September ($P = 0.006$ and $P = 0.02$, respectively).

DISCUSSION

Significance of Mussel Position in the Water Column with Respect to Cyst Contamination

Vertical repositioning of mussels in the water column may limit their exposure to toxic dinoflagellate cells (Desbiens et al. 1990). To reduce PSP contamination, Desbiens and Cembella (1993) placed mussels near the bottom of the water column (13–15 m deep) during a bloom of vegetative *Alexandrium excavatum* cells and raised the mussels close to the surface when *A. excavatum* was concentrated near the bottom of the water column. Mussels placed near the bottom were the least toxic for most of the exposure period.

In this study, we hypothesized that mussels suspended close to the sediment would egest more dinoflagellate cysts than mussels suspended near the top of the water column. We found that this depended on the location of the mussel sock in the site and the sampling time. In September, mussels collected from the bottom of socks near a barrier island and in the northeastern cove of a former aquaculture site at Barred Island Cove, Newfoundland, egested more putative *A. ostenfeldii* cysts than mussels collected from the top of the socks. In October, however, similar numbers of *A. ostenfeldii* cysts were egested regardless of the proximity of the mussels to the underlying sediment and their location in the site. No differences were found in either sampling date within the concentrations of *Scrippsiella* spp., *A. fundyense* or Grey cysts in feces from mussels collected from the tops and bottoms of the socks.

It is not possible to establish a direct relationship between the concentration of cysts beneath a mussel sock and the concentrations in feces egested by the overlying mussels. Mussels may have been ingesting cysts from other sources (e.g., horizontal advection, newly formed cysts in the water column resulting from encysting vegetative cells), or cells may have encysted within the digestive tract. For example, Grey cysts were numerous in mussel feces collected in October, but few were present in the underlying sediment. Samples from the water column are needed to determine the source of the egested cysts, but it is clear that suspending cultures near the top of the water column does not reduce the exposure of mussels to cysts at this site.

The depth of sediment erosion may be a factor in the resuspension of dinoflagellate cysts, depending on the depth distribution of the cysts of each species. White and Lewis (1982) demonstrated that there are as many *A. tamarense* (*Gonyaulax excavata*) cysts in the top 3 cm of sediment as in the flocculent surface layer, but it is not known whether there are vertical gradients in the abundance of other types of cysts within the sediment. There is no clear relationship between the density of dinoflagellate cysts directly beneath the mussel socks and the number of cysts passing through the overlying mussels.

Distribution of Dinoflagellate Cysts in Bottom Sediments

Concentrations of *Scrippsiella* sp., *Alexandrium fundyense* and Grey cysts did not differ significantly within each species throughout Barred Island Cove. Sediment core samples collected in November and December of 1992 showed the highest concentration of *A. fundyense* (1,130 cysts·cm^{-3}) in the shallow sediment on the eastern edge of the site (McKenzie & Schwinghamer 1994). In October 1993, the highest concentration of *A. fundyense* (118 cysts·cm^{-3}) was detected near the barrier islands (McKenzie 1994). In September 1996, the highest concentration of *A. fundyense* cysts was found beneath sock 1, near the barrier islands (371 cysts·cm^{-3}); in October, the highest concentration was found in the northeastern edge of the cove beneath sock 3 (214 cysts·cm^{-3}). Similarly, the highest concentrations of putative *A. ostenfeldii* were found in the sediment beneath sock 1 in September (182 cysts·cm^{-3}) and beneath sock 3 in October (580 cysts·cm^{-3}). The distribution and concentrations of dinoflagellate cysts in the sediment are clearly variable both temporally and spatially within this site.

Between September and October 1996, concentrations of *A. fundyense* cysts either did not change or significantly decreased in sediments beneath the mussel socks samples. In contrast, there were significantly more putative *A. ostenfeldii* cysts beneath socks in the northeastern cove in October than there were in September. In the interim, a bloom of *Alexandrium* vegetative cells began (McKenzie et al. 1998). Although this bloom was attributed to a proliferation of *A. fundyense* cells, it is possible that it may have been caused by both *A. fundyense* and *A. ostenfeldii* blooming concurrently, triggered by the same environmental conditions; *A. ostenfeldii* does not tend to form monospecific blooms (Cembella et al. 1998). Vegetative cells of *A. fundyense* and *A. ostenfeldii* are difficult to distinguish under the light microscope, the method used by McKenzie et al. (1998). In material fixed in Lugol's iodine, Hansen et al. (1992) were unable to distinguish between the two species.

Blooms of motile, cyst-forming dinoflagellate species can increase cyst deposition in the underlying sediments. For cysts to accumulate, the deposition rate must exceed the rates of loss through regeneration, excystment and transport (Cembella et al. 1988). In this study, we did not observe a post-bloom increase in cyst concentrations of *A. fundyense* in the surface layer of the sediment, but there was an increase in putative *A. ostenfeldii* that may have been the result of transport of cysts within the site or encysting of vegetative cells. Vegetative cells were still in the process of encysting in the water column, as various encystment stages of *A. fundyense* were observed in sediment trap samples (McKenzie et al. 1998).

Previous studies at this site enumerated only those cysts that appeared exactly like *A. fundyense* (McKenzie 1993, McKenzie 1994, McKenzie & Schwinghamer 1994). In 1996, putative *A. ostenfeldii* cysts were as abundant as *A. fundyense* in the sediment. The vegetative cells of *A. ostenfeldii* have been documented in the St. Lawrence Estuary and Gulf (Levasseur et al. 1996) and in coastal Nova Scotia (Cembella et al. 1998). This species has not been recorded in Newfoundland, possibly because it is difficult to identify. Maximum concentrations of *A. fundyense* (371 cysts·cm^{-3}) and putative *A. ostenfeldii* cysts (580 cysts·cm^{-3}) in the sediment from this site are comparable with values from other identified cyst beds in eastern Canada. Sediments in the lower St. Lawrence estuary can contain 400–1,500+ *A. excavatum* cysts·cm^{-3}, depending on the time of the year (Cembella et al. 1988, Cembella 1990). The southern Bay of Fundy, particularly to the east and northeast of Grand Manan Island, is rich in *A. fundyense* (*G. excavata*) cysts, ranging from 2,000–8,000 cysts·cm^{-3} sediment (White & Lewis 1982). In Newfoundland, sediments at Harbour Grace, Conception Bay, contain between 30–150 *A. fundyense* (*G. excavata*) cysts·cm^{-3} (White & White 1985).

Estimated Biodeposition Rate of Cysts from Suspended Mussel Cultures

The replenishment rate of bottom sediments by putative *A. ostenfeldii* cysts egested by mussels can be estimated from the rate of biodeposition, the process by which feces and pseudofeces settle to the bottom (Haven & Morales-Alamo 1966). Since this study was not designed to investigate the biodeposition rates of dinoflagellate cysts, mussels were not continuously exposed to the cells of interest. Values from the following calculations later may, therefore, underestimate the actual rates of biodeposition since the mussels collected in this study were isolated from the seston and were not permitted to feed continuously.

Over the 15 h incubation period in September, mussels (n = 30) egested an average of 333 putative *A. ostenfeldii* cysts·mg^{-1} DW feces. In October, mussels (n = 32) egested an average of 2.4 cysts·mg^{-1} DW feces over 19 h. Navarro (1983, as cited in Navarro & Thompson 1997) reported that biodeposition rates of ~53 mm shell length *Mytilus chilensis* ranged from 10–38 mg DW·mussel^{-1} d^{-1}. Using an intermediate value of 20 mg DW·mussel^{-1} d^{-1}, the biodeposition rate of putative *A. ostenfeldii* cysts by an individual mussel was 6,660 cysts·mussel^{-1} d^{-1} in September and 47 cysts·mussel^{-1} d^{-1} in October. Comparison of these values with the concentrations of cysts in the bottom sediments requires information on the stocking density of mussels. In Newfoundland, the average mussel farm has an estimated 30.9 mussels·m^{-2} bottom (C. Couturier, pers. comm.), therefore in September approximately 2.1×10^5 putative *A. ostenfeldii* cysts·m^{-2} d^{-1} were transferred to the sediment in the form of biodeposits. In October, approximately 1.5×10^3 cysts·m^{-2} d^{-1} were deposited on the bottom.

Mean concentrations of putative *A. ostenfeldii* cysts in the sediment, expressed as numbers·cm^{-2} integrated through the upper 3 cm, were 2.55×10^6 cysts·m^{-2} in September and 4.26×10^6 cysts·m^{-2} in October. Approximately 8% of the putative *A. ostenfeldii* cysts in the sediment were being replenished daily in September by fecal pellet deposition from the overlying mussel stocks. The replenishment rate in October was considerably lower, less than 1% of the cysts in the sediment being deposited in the form of mussel feces.

The egestion of putative *A. ostenfeldii* hypnozygotes by *M. edulis* in feces provides a mechanism for the recycling of dinoflagellate cysts to the sediment. An approximate daily replenishment rate of 8% may be a considerable contribution to the maintenance of cyst populations, and could alter the composition of the sediment over time. Before the contribution of mussel aquaculture to dinoflagellate cyst recycling within a site can be determined, the number of cysts in biodeposits must be compared with other inputs and outputs of cysts, such as horizontal advection or natural sedimentation during blooms. Future research should include the determination of concentrations of cysts and vegetative cells in the water column of aquaculture sites and comparison with appropriate reference areas. The hydrographic characteristics of each site must also be considered as these can clearly play an important role in distribution of cysts.

REPRODUCTIVE CYCLE OF THE CHOLGA PALETA, *ATRINA SEMINUDA* LAMARCK, 1819 (BIVALVIA: PINNIDAE) FROM NORTHERN PATAGONIA, ARGENTINA

RODRIGO GASPAR SORIA,* MARCELA SUSANA PASCUAL, AND VÍCTOR HUGO FERNÁNDEZ CARTES
Laboratorio y Criadero de Moluscos Bivalvos, Instituto de Biología Marina y Pesquera Alte. Storni. CC 104, (8520) San Antonio Oeste, Río Negro, Argentina

ABSTRACT *Atrina seminuda* (Bivalvia:Pinnidae) is distributed naturally along the Atlantic coast of America from North Carolina to the Valdés Peninsula. At the San Matías gulf (North Patagonia), its southern distributional limit, it inhabits subtidal areas of fine and coarse sandy bottoms, on depths ranging from 4 to 30 m. The reproductive cycle of a population of *A. seminuda* was studied from October 1999 to October 2000. Histologic samples of gonad tissue were obtained from adult individuals collected at Piedras Coloradas (40°53′S, 65°04′W). Six stages of gonad development were described on the basis of histo-morphologic characteristics: indifferent, early active, developing, mature, spawning, and spent. This study indicates that *A. seminuda* exhibits an annual reproductive cycle. Gametogenesis starts at the beginning of autumn and is prolonged during the winter. A high synchronism in maturation and spawning occurs at November and December. The spent stage begins at mid-summer and concludes at the end of that season. Muscle index (MI) fluctuates inversely to the gonad index (GI) along the reproductive season, suggesting that this species uses reserves stored in the adductor muscle for gonadic maturation. *A. seminuda* is a gonochoric stable species that exhibits, on a 1.05% of the individuals, two types of functional hermaphroditism

KEY WORDS: bivalves, Pinnidae, *Atrina seminuda*, reproductive cycle

INTRODUCTION

Species belonging to the family Pinnidae are commonly known as pen-shell, hacha, rompechinchorro, wing-shell, razor-shell, and locally as cholga paleta. They are distributed along sheltered sites of warm and temperate seas, at depths up to thirty meters.

The cholga paleta, *Atrina seminuda* Lamarck 1819, is a member of the Pinnidae family and is the only Pinnidae present at the Patagonian coast. This species is distributed from North Carolina, United States, to the San José Gulf, Argentina (Scarabino 1977, Lodeiros et al. 1999). *A. seminuda* has been cited by the synonyms *Pinna seminuda*, *Pinna listeri*, and *Atrina (Servatrina) seminuda* (Scarabino 1977).

At the San Matías Gulf (40°40′ S, 63°30′ W) (Fig. 1) this species inhabits sandy bottoms at depths ranging from five to thirty meters. The cholga paleta lives in a vertical position with the anterior portion of its body deeply buried on the substrata, to which it is attached by large and strong byssal threads.

The biology of *A. seminuda* had not been studied until present. However, several studies have dealt with other members of the family Pinnidae, focusing reproductive biology (Noguera & Gómez–Aguirre 1972, Coronel 1981, Yongqiang & Xiang 1988, de Gaulejac et al. 1995a, de Gaulejac et al. 1995b, Maeda–Martínez et al. (unpublished manuscript), Rodríguez–Jaramillo et al. 2001, Ceballos–Vázquez et al. 2000), ecology and population structure (Butler & Brewster 1979, Keough 1984, Butler 1987, Warwick et al. 1997, Richardson et al. 1999), fisheries, and aquaculture (Sung & Myong 1984, Cendejas et al. 1985, Bishui et al. 1987, Yoo & Yoo 1984, Yoo et al. 1988, Maeda–Martínez et al. 1996, Reynoso–Granados et al. 1996, Guo et al. 1999).

Studies on reproductive biology and gonadic cycle are important tools in fisheries and aquaculture management of valuable commercial species. Several methods can be used to estimate the reproductive cycle in bivalves (gonadal macroscopic appearance or frottis, dynamics of embryos and larvae in the plankton, timing of larval recruitment, physiologic indexes behavior, etc) being the histologic study of gonadal tissues the most reliable method.

In this study we describe the reproductive cycle of *Atrina seminuda* from Northwest San Matías Gulf (Patagonia, Argentina) through histologic analyses and the role of the adductor muscle as a storage organ of reserves used in gonad maturation.

MATERIALS AND METHODS

Samples were collected at Piedras Coloradas (40°53′ S, 65°04′ W), a site located on open waters of the NW coast of the San Matías gulf (see Fig. 1). The sampling site has bare bottom, composed of coarse sand and gravel, covered with sparse bivalve shell fragments. Tidal current speed is 0.3–0.5 $m.s^{-1}$, and tides are semidiurnal (average height: 6.31 m) (Servicio de Hidrografía Naval 1994). Monthly average sea surface temperature fluctuates between 10.4°C in August, and 19.8°C in February, and salinity varies between 34.1‰ and 35.1‰ (Fernández 1989).

Sampling was carried out from October 1999 to October 2000, on a monthly basis with the exception of the period October to February when samples were collected fortnightly. Individuals were randomly collected by diving along a straight transect, at depths ranging from 8–12 m. Surface seawater temperature was recorded at each sampling date.

Seventy individuals of sizes ranging from 150–250 mm total length were selected from the sampled lot for histologic treatment and to estimate muscle index (MI).

Histologic Treatment

The visceral mass of each individual was separated from the adductor muscle. A section of gonadal tissue (approximately 1 cm^3) from the posterior-dorsal area was excised from each individual. Each tissue section was fixed in Davidson's solution, stored in 70% alcohol and dehydrated in consecutive baths of ethanol and 1:1 mix of 100% ethanol and xylene. Tissue samples were embedded in paraffin (56/58°C). Five to seven μm sections

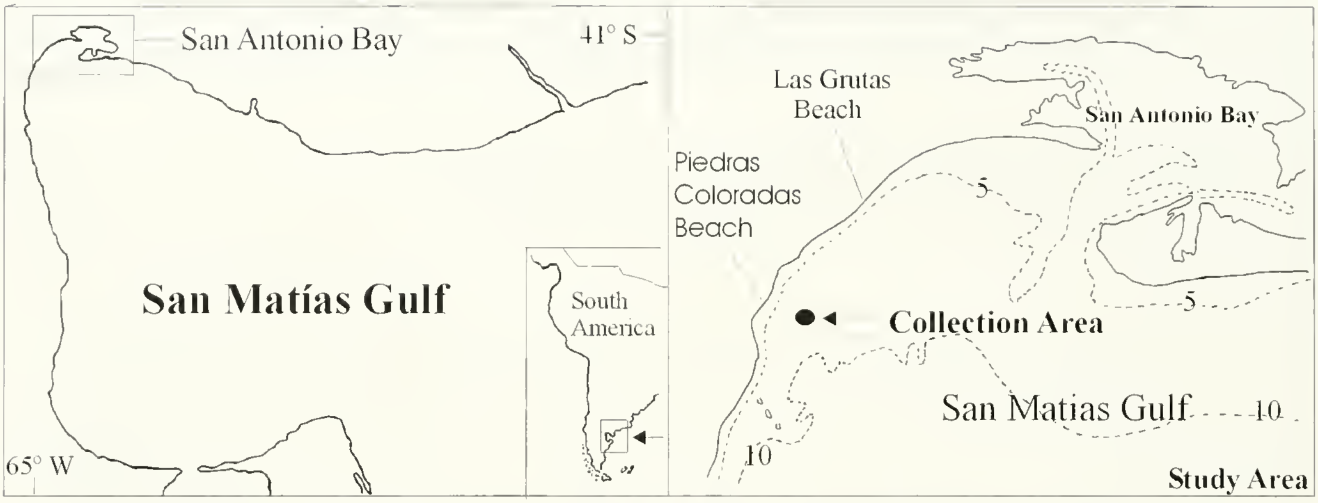

Figure 1. Location of the study area at the Northwest coast of the San Matías Gulf, (Patagonia) Argentina.

were made with rotary microtome and stained with hematoxilin and eosin.

Analysis of the Reproductive Cycle

Histologic sections were examined under light microscope. Sex was determined for each animal.

A scale of gonadal maturity was developed using as a basis a scale of maturity stages described for other Pinnidae, namely *Atrina maura* (Maeda–Martínez et al. unpublished manuscript) and *Pinna rugosa* (Noguera & Gómez–Aguirre 1972, Coronel 1981, Ceballos-Vázquez et al. 2000). Relative frequencies of gonadal developmental stages were obtained throughout the annual cycle. Sex ratio was estimated during the period over which mature and spawning individuals appeared. A *Chi-square* test was used to assess differences from the 1:1 sex ratio.

Frequencies Distribution and Mean Size of Oocytes

Oocyte size was determined from histologic sections using an eyepiece graticule calibrated with a stage micrometer (×400). Five to eight females were randomly selected from the lot sampled during each collection date, and at least 100 oocytes (among those with a clearly visible nucleoli) per female were measured through the longest axis, transverse to the nucleus. Individuals with scarce oocytes and extensive phagocytosis (spent and indifferent individuals) were not analyzed, following the criteria recommended by Grant and Tyler (1983a, 1983b).

Gonad Index

A gonad index (GI) that represents the reproductive activity was estimated using a numerical grading system based on the maturity stages described from each monthly collection data (Heffernan et al. 1989). Three categories were established on the basis of gonad development: 1 = Indifferent (I) + Spent (VI), 2 = Early Active (II) + Developing (III), and 3 = Mature (IV) + Spawning (V). The GI was estimated by multiplying the number of individuals belonging to each category by the category score (1 to 3), then summing the values and dividing the resulting value by the total number of animals in the sample.

Muscle Index

Dry weight of both posterior adductor muscle and remaining soft tissues from 40 individuals on each collection date was obtained using a drying chamber (85°C) until constant weight was reached (~72 h). Muscle index was estimated as MI = (adductor muscle weight/soft tissue weight) × 100. Mean values were calculated for each collection date.

RESULTS

Sex Ratio

A total of 378 individuals were studied (mean shell length = 194.37 mm; SD = 21.49 mm) of which, 175 were females (46.3%), 124 were males (32.8%), 4 were hermaphrodites (1.05%) and 75 (19.8%) could not be sexed (Fig. 2). Sex ratio during the spawning season (1.15 females: 1 male, *n* = 90) did not differ significantly ($P \geq 0.05$) from the expected 1:1 ratio.

Histologic Analyses

Macroscopic and histologic analysis of gonadal tissues, allowed the authors to establish the following stages according to the characteristics exhibited during development.

Indifferent

No evidence of gametic development, acini small with total absence of gametes. Connective tissue is abundant. In this stage it is not possible to determine sex (Fig. 3).

Externally the gonad is brownish, watery, and flaccid.

Females

Early Active: Acini irregular in shape containing oogonias, giving place to previtellogenic pear shaped oocytes (average = 7.6 μm SD = 3.2 μm) attached to the walls of acini. Interfollicle connective tissue decreasing (Fig. 4A).

Macroscopically, gametogenic activity is evidenced due to color and swelling changes. Gonad acquires a pale pink color in the region next to the digestive gland.

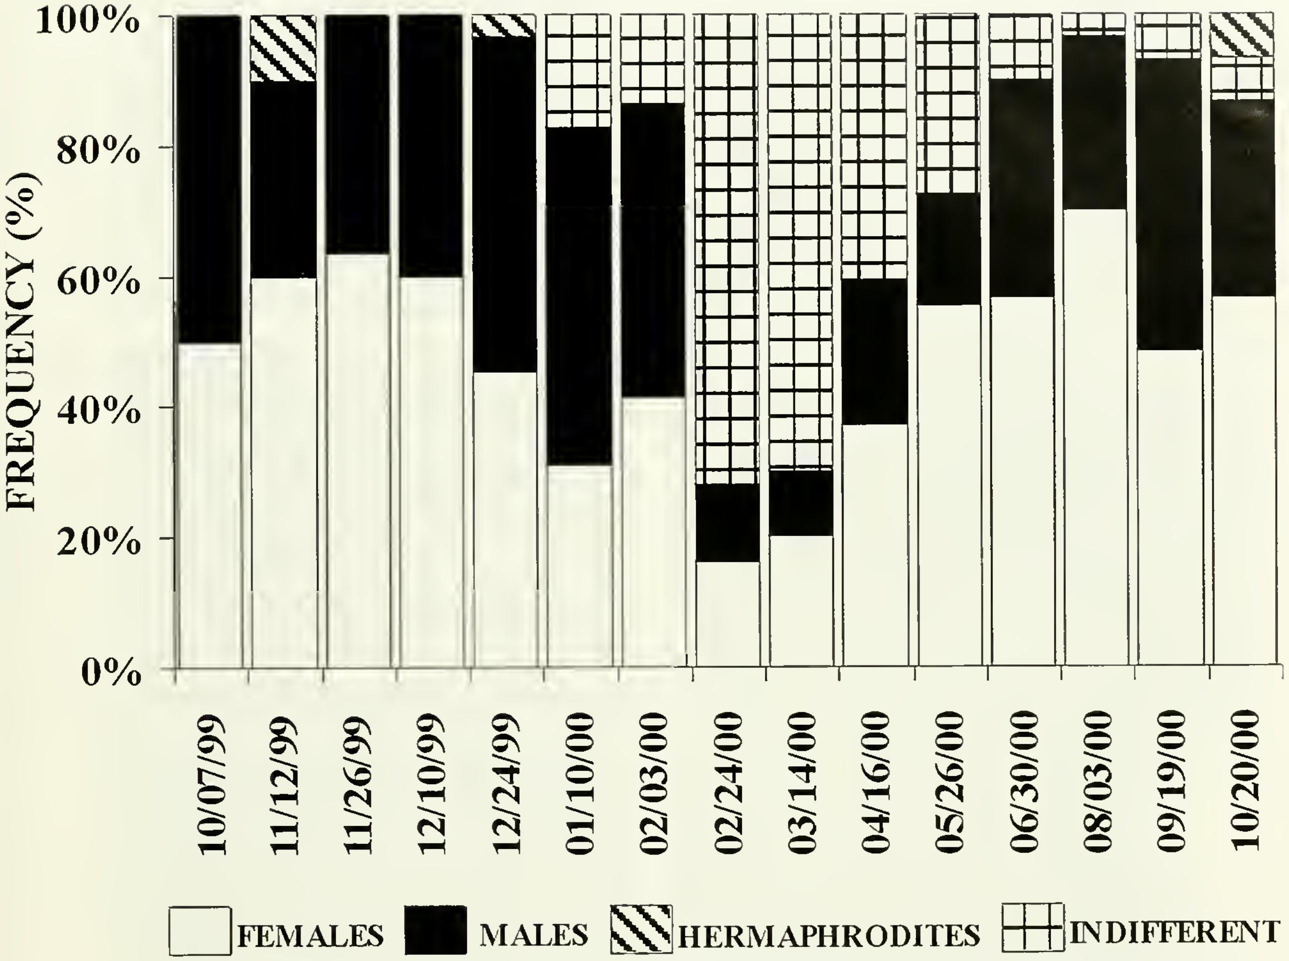

Figure 2. Frequency distribution of male, female, hermaphrodites and undifferentiate individuals of *A. seminuda* in the period October 1999 to October 2000.

Developing: Acini increase in size as a result of oocyte accumulation and growth. Previtellogenic oocytes are found attached to the wall of acini, also several vitellogenic oocytes can be found dispersed in the lumen (average = 31.43 μm, SD = 12.4 μm). Acini walls are well defined and interfollicle connective tissue has decreased (see Fig. 4B).

As gonadic tissue develops, it invades the digestive gland, extending towards the posterior region. Gonadal tissue becomes orange in color.

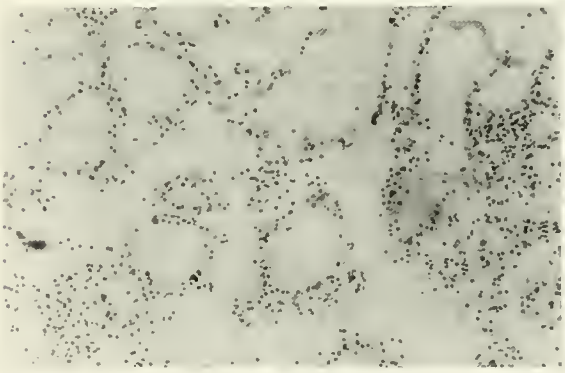

Figure 3. Photomicrograph of gonadal stages: indifferent stage; scale bar = 50 μm.

Mature: Acini are distended and fulfilled with ripe polygonal shaped oocytes (average = 45.6 μm; sd = 23.7 μm); some oocytes remain attached to the walls of acini. Intrafollicle area is reduced to a minimum. The boundary of acini is not distinguishable. Connective tissue is reduced or it is absent (see Fig. 4C).

Gonad reaches its largest area, gonadal tissue is swollen and is red colored.

Spawning: Acini partially spawned containing few oocytes that expand and lose the polygonal shape. Phagocytes are present. Little connective tissue is present. A new proliferation of oocytes attached to the walls of acini can occur (see Fig. 4D).

Externally the gonad exhibits red color, begins to decrease and loses swelling.

Spent: Acini are collapsed as a result of oocyte release. Residual oocytes are irregular in shape; are free in the lumen and begin to be absorbed. Phagocytes proliferate during this stage. Connective tissue abundant. A new proliferation of oocytes can occur attached to acini walls (see Fig. 4E).

Macroscopically, the gonadal tissue shows a pink-red color and watery aspect.

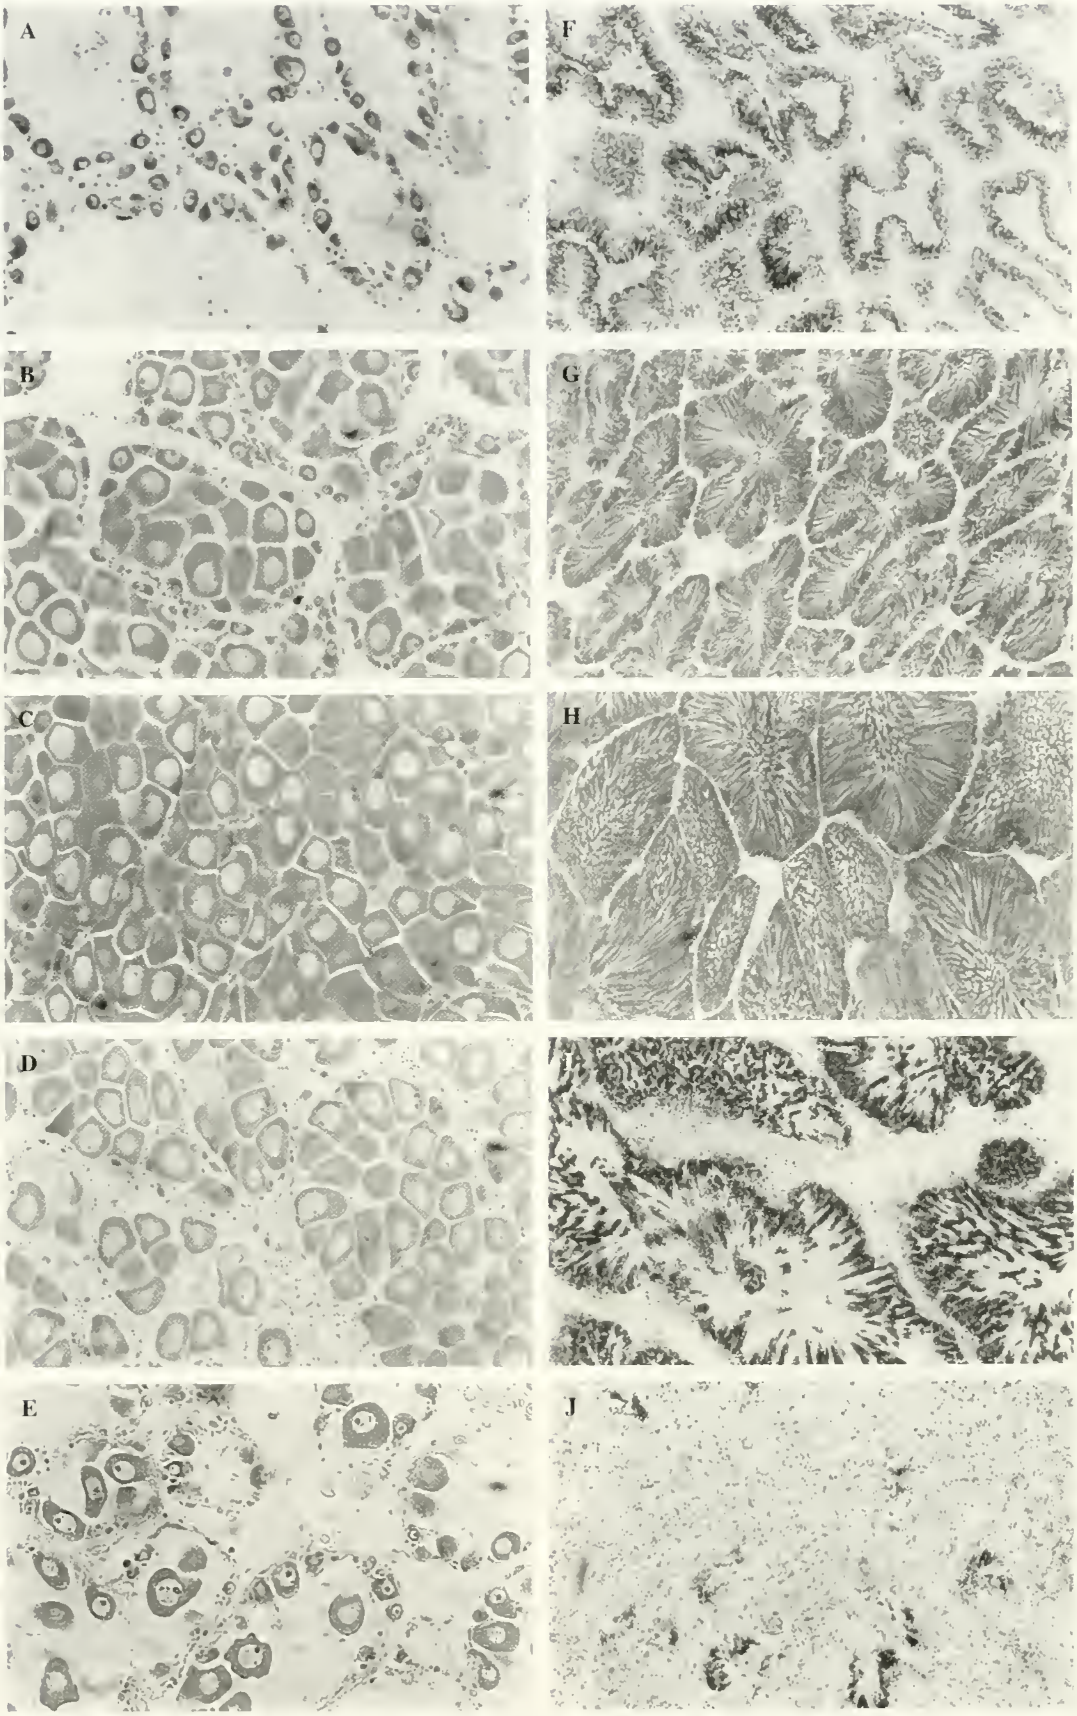

Figure 4. Photomicrographs of gonadal stages of *A. seminuda*. Females: (A) early active, (B) developing, (C) mature, (D) spawning (E) spent; and males: (F) early active, (G) developing, (H) mature, (I) spawning and (J) spent; scale bar = 50 µm.

Males

Early Stage: Several primary germinal cells are attached to the wall of the acini. A variable quantity of spermatogonia is located along the internal wall of the acini arranged in bands of several cells. Connective tissue is decreasing (see Fig. 4F).

Externally, this stage is evident due to color change and swelling of gonadal tissue. It acquires a grizzly white color.

Developing: Spermatogenesis exhibits a centripetal evolution from the internal wall towards the lumen. Spermatocytes and spermatids are free and filling the lumen. Connective tissue continues decreasing as gamete accumulation proceeds (see Fig. 4G).

Gonadal tissue grows invading the digestive gland, and extends towards the anterior area. Gonadal tissue acquires a whitish color.

Mature: Acini are distended, filled with spermatozoa with their tails pointing towards the acini lumen. Spermatocytes and spermatides conform a thick layer against the follicular walls. Connective tissue is absent. Boundaries between acini are not distinguished (see Fig. 4H).

Gonadal tissue is swelling and has a white color.

Spawning: Acini are partially empty, showing a marked decrease in the number of spermatozoa. Connective tissue is increasing (see Fig. 4I).

Externally, gonadal tissue begins to loose size and swelling, and has a grizzly color.

Spent: Acini collapsed with few residual spermatozoa, connective tissue is abundant. No evidence of active gametogenesis. Phagocytes proliferate during this stage (see Fig. 4J).

Gonadal tissue shows a watery aspect and a whitish-grizzly color.

Hermaphrodites

A. seminuda exhibits two types of functional hermaphrodites, both equally represented.

Type 1: Gonads exhibit separated female and male acini (Fig. 5A). Externally, it is possible to distinguish male gonadal tissue and clear reddish female "patches".

Type 2: Female and male gametes arranged inside the same acinus. Oocytes area located at the periphery of the acinus and spermatozoa in the center of the acinus (see Fig. 5B). This type was not detected macroscopically during sampling. The individuals exhibit the appearance of a typical female gonad.

Seasonal Change of Reproductive Cycle

During the period of study, superficial water temperature exhibited its highest value (21.2°C) in January 2000 and the lowest value (9.7°C) on September 2000 (Fig. 6).

The annual reproductive cycle of the total population of *A. seminuda* is summarized in Fig. 7a. In October 1999 only early active (12.5%) and developing individuals (87.5%) are represented. The highest proportion of mature individuals is found in late November (82%), sharply decreasing by middle December. Spawning peaks by the end of December (84%) while, in the following months, individuals at spent and indifferent stages gradually increase. From the end of February to March, the majority of the population is in the undifferentiated stage (72%). Gonad differentiation begins at middle March involving a small portion of the population. Intense gametogenic activity is evidenced through the winter with individuals showing early active and, in lower proportion, developing gonads. By October 2000, as opposed to the former year, the majority of the population has developing gonads (60%) (see Fig. 7a).

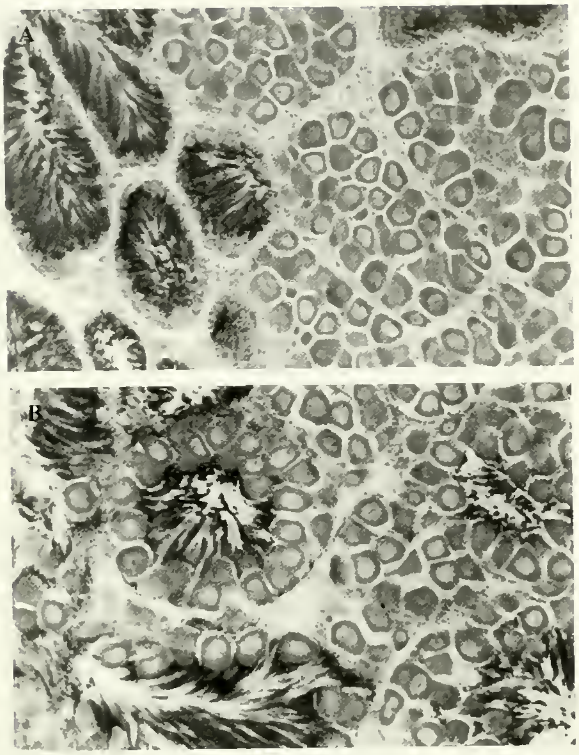

Figure 5. Photomicrographs of hermaphroditic individuals of *A. seminuda*. (A) type 1: separate male and female acini, (B) type 2: male and female gametes in the same acini bar = 50 μm.

Females

In October 1999 all females show developing gonads. The highest proportion of mature individuals is found at the end of November (86%), time at which spawning begins. Spawning peaks in December (86%) and extends through the summer involving low numbers of individuals (10% in January). Gonad proliferation begins in March, with gonads in early active and developing stages represented until October (see Fig. 7b).

Males

In October male gonads are mainly at the developing stage (75%), during November and December gonads at the stages developing, mature and spawning coexist in the population. Evacuation begins in November and, at the end of this month, 78% of mature individuals are detected. Spawning mainly occurs in December, even when spawning extends along the summer until May. Spent individuals are found from January to April. Gonads development begins on April and proceeds throughout the winter and spring months (see Fig. 7c).

Frequencies Distribution and Mean Size of Oocytes

In October 1999 mean oocyte diameter (MOD) was 27.07 μm (s = 11.63 μm). During November and December oocytes grow,

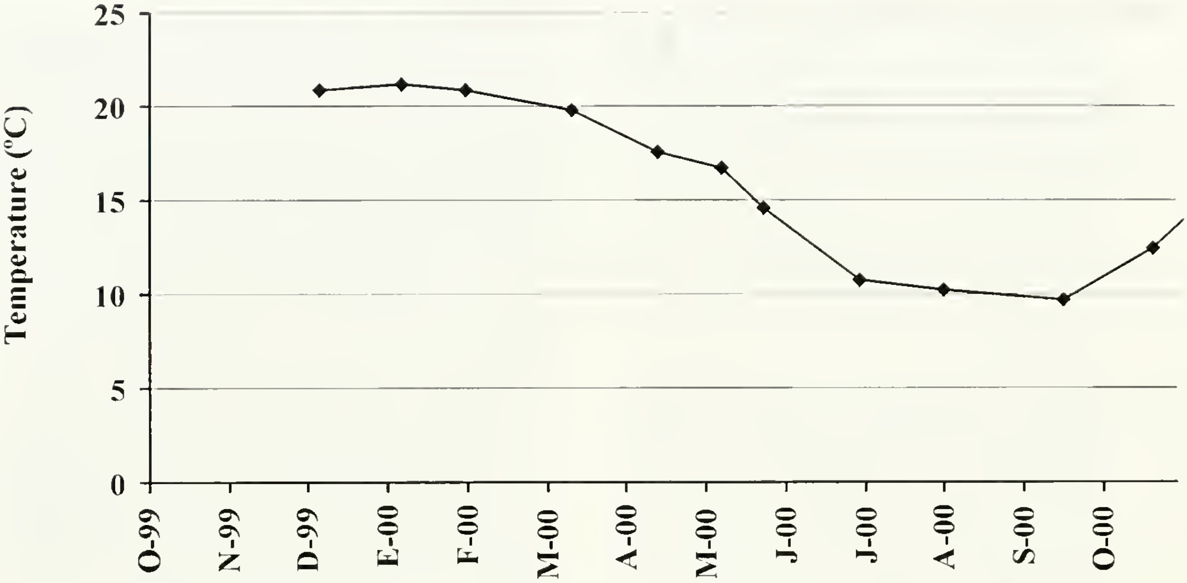

Figure 6. Surface seawater temperature recorded at each sampling date at Piedras Coloradas.

showing the maximal MOD on November 26 (45.63 μm; s = 23.74).

In early December oocytes ranging 35–65 μm decrease in numbers, while oocytes of sizes ranging 5–35 μm, increase. MOD decreases at this time, reaching 29.47 μm (s = 15.84). By the end of December the pattern inverts and the MOD again increases reaching 41.52 μm (s = 12 μm) on December 24. In January and February 2000 the mode represented by 35–65 μm oocytes have diminished markedly and simultaneously a new mode of proliferating oocytes arises in individuals showing spawning and spent gonads. This new proliferation is reflected by an abrupt decline in MOD values that reach 16.11 μm (s = 12.65) in January, and 14.4 μm (s = 12.55) in February. This new summer proliferation does not seem to culminate in a spawning event due to the fact that these oocytes do not reach the typical mature oocyte size in the season (Fig. 8). By the end of February there is a total absence of oocytes in the gonad.

At the beginning of March, MOD shows the minimal values of the annual cycle (mean = 8.08 μm; s = 3.98), and the low dispersion of the data shows the debut of gametogenic activity (see Fig. 8).

Gonad Index

Gonad index exhibits a marked seasonal pattern (Fig. 9). GI increases at mid spring reaching its highest values by the end of November and December as a result of the higher numbers of mature and spawning individuals. Minimal is found by the end of February when most individuals have undifferentiated gonads. GI increases again in March indicating the debut of gametogenesis (see Fig. 9).

Muscle Index

MI also exhibits a seasonal pattern, showing an increase of 73.6% from the end of November, when it has its lower value (20.64%), to August when it reaches its highest value (35.8%) (see Fig. 9). The MI shows, during the reproductive season (October to February), the opposite pattern to the GI, decreasing whilst this increases. This behavior is held until March when both indexes increase and remain stable during the winter months and the debut of spring.

DISCUSSION

A. seminuda exhibits an annual pattern of reproduction at the Northwest of San Matías Gulf. Gametogenesis initiates at the beginning of autumn, when surface seawater temperature (≈19°C) begins to decrease. A high synchronism in maturity and spawning is recorded. Spawning takes place during the end of spring (November to December) when seawater temperature is around 20°C. By the end of December, most of the population was spawning or had already evacuated their gonads. Females exhibit a higher synchronism in maturation and spawning than males. Oogenesis begins earlier in autumn and ends earlier in summer than spermatogenesis. This fact suggests that the small amount of undifferentiated individuals found from June to October can be mainly attributed to males whose spent stage is displaced on time compared with females.

The analysis of oocyte size supported and facilitated the interpretation of the reproductive cycle of *A. seminuda*. Oocyte proliferation and growth could be easily identified, suggesting that the first cohort (December oocytes) is released; meanwhile the new cohort of oocytes that proliferates during spawning or in spent individuals (February oocytes) does not reach maturity and is probably not released. These summer oocytes are most likely reabsorbed.

Gametogenesis is defined by exogenous (mainly temperature and food) and endogenous factors and the relation among them shapes the pattern of each reproductive cycle (Sastry 1979). *A. maura* from La Paz, Mexico, behaves as many tropical and subtropical species, maturing during the warmer months and spawning when temperature decreases (Maeda–Martínez et al. unpublished manuscript). On the other hand, *P. rugosa*, from Bahía Concepción, Mexico show the inverse pattern, with reproductive activity occurring during the warmer months (March to November) and reproductive inactivity in winter (November to February) (Ceballos–Vázquez et al. 2000). Both species show a protracted reproductive period. *A. seminuda* shows a similar reproductive pattern to that of *A. pectinata japonica* from Yoja Bay, Japan (Yoo & Yoo 1984), which shows a protracted developing period and a shorter spawning season that coincides with the warmer months.

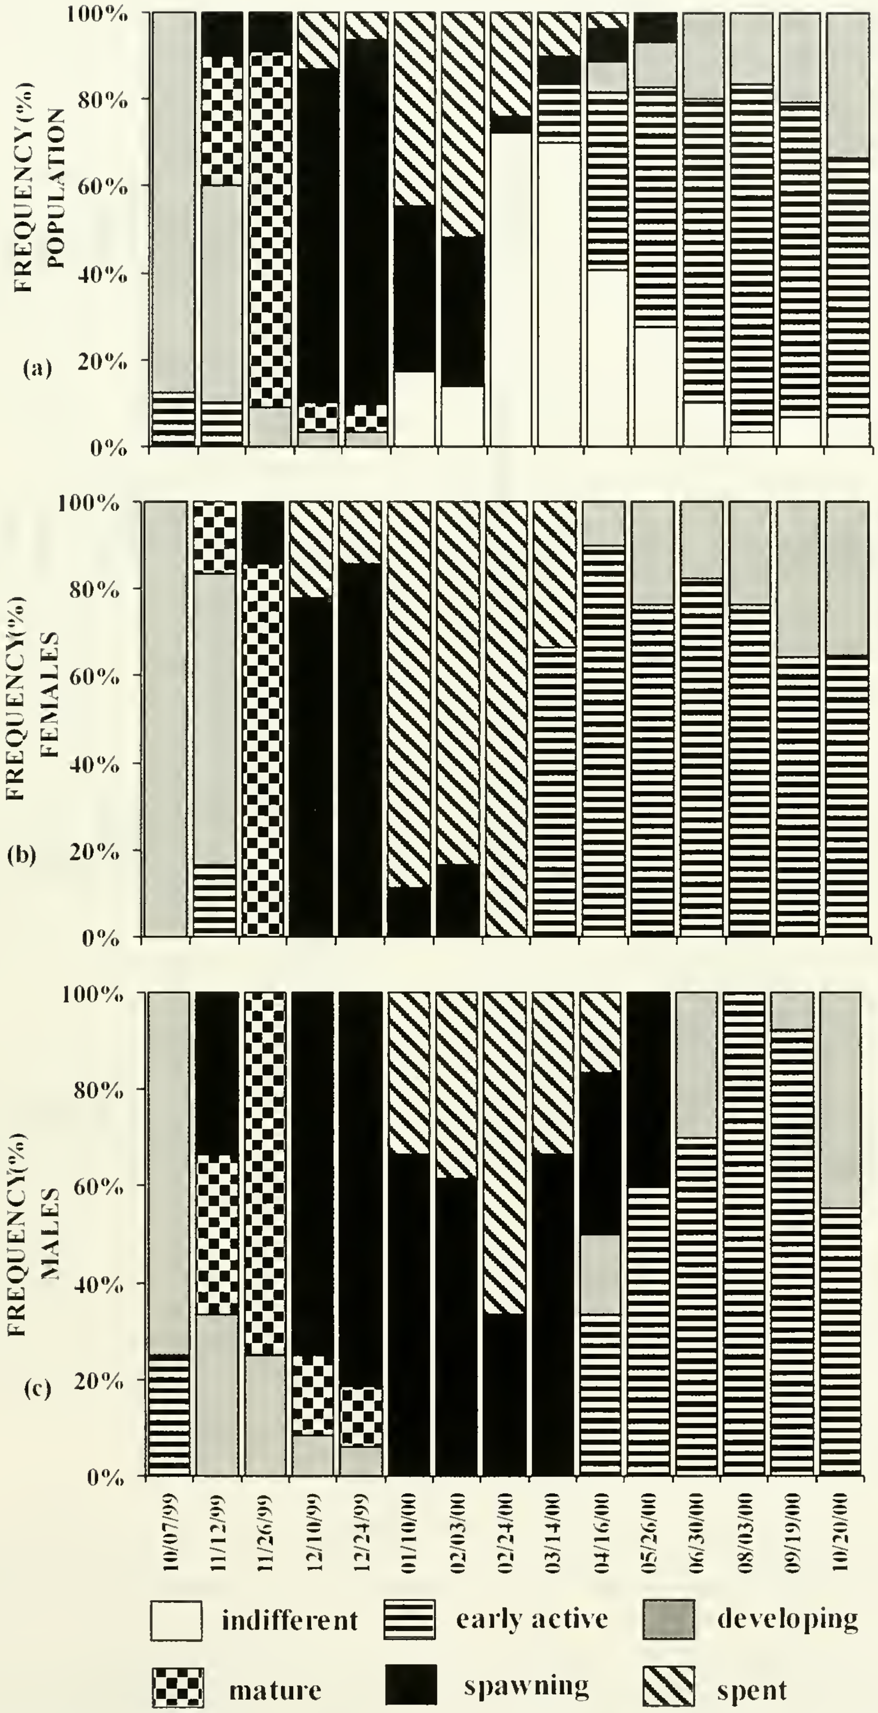

Figure 7. Reproductive cycle of *A. seminuda* at Piedras Coloradas. Relative frequencies of gonadal stages from October 1999 to October 2000. (a) Total population, (b) females, and (c) males.

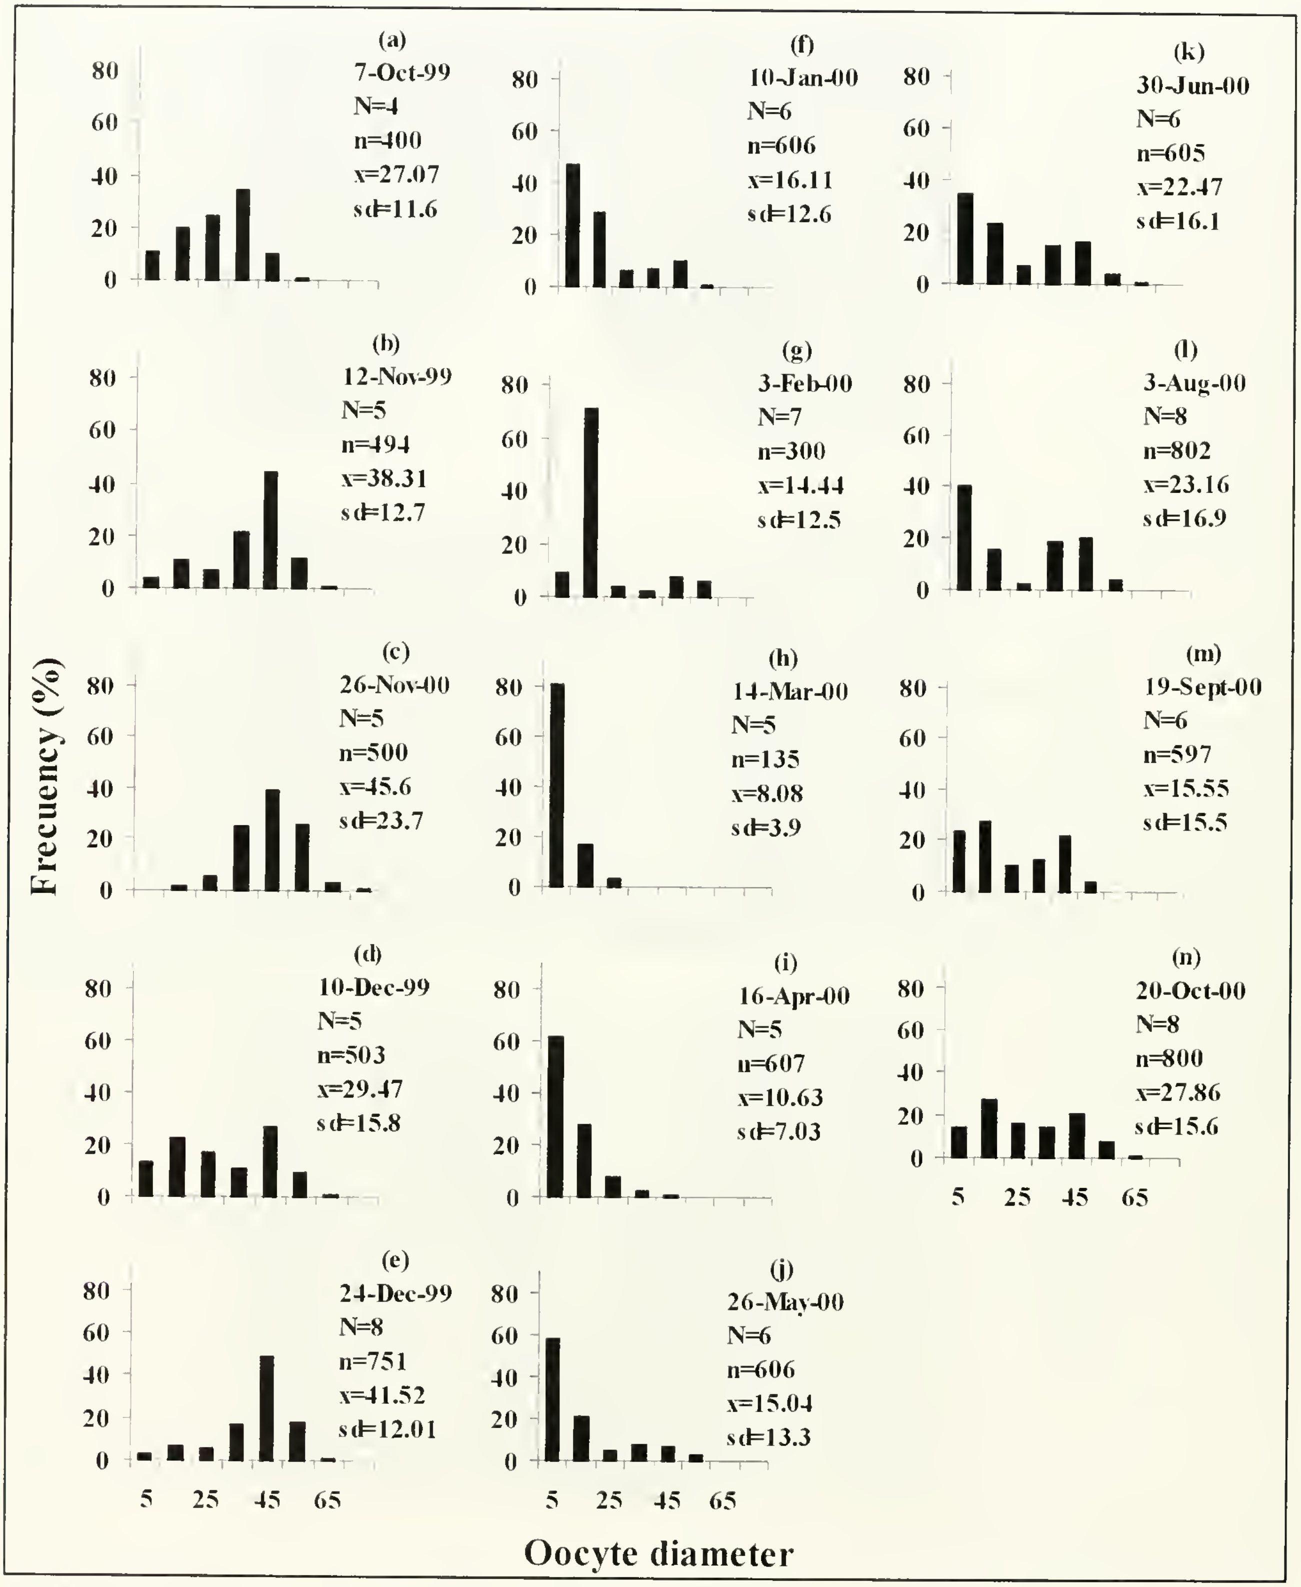

Figure 8. Frequency (%) distribution of oocyte diameter (μm). N = number of females; n = number of oocytes; x = mean oocyte diameter.

This pattern is also shared by other Northern Patagonian bivalve species, as *Amiantis purpurata* (Morsán 2000), *Aequipecten tehuelchus* (Narvarte 2001), *Mytilus edulis platensis* (Trancart 1978) and *Ostrea puelchana* (Morriconi & Calvo 1979).

The adductor muscle of *A. seminuda* (locally called "callo") shows marked seasonal changes becoming light in weight and watery after spawning. The MI sharply decreases during the start of the spawning season, suggesting that this specie uses for reproduction the reserves stored in the adductor muscle. As the proportion of non-spawned individuals in the population decreases, the

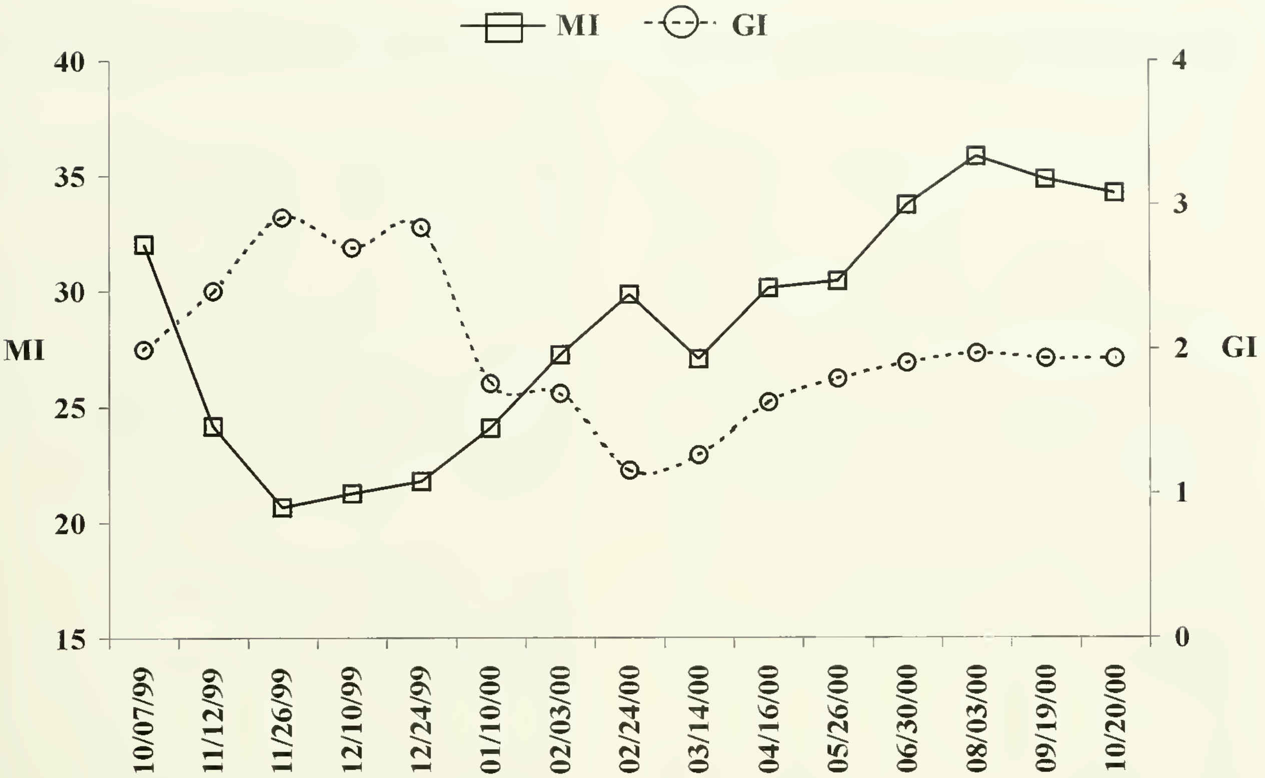

Figure 9. Variation of O = mean gonad index (GI), and □ = muscle index (MI) from October 1999 to October 2000.

MI initiates a gradual increase. This relation among the MI and the reproductive cycle has not been described for other members of the Pinnidae. Maeda–Martínez et al. (unpublished manuscript) found no relation between the MI and the reproductive cycle for *Atrina maura*, a warm temperate sea species that has a different reproductive behavior than *A. seminuda*.

Pelecypods exhibit a wide variation in the expression of their sexuality ranging from strictly gonochoric species to those that are invariably functional hermaphrodites (Sastry 1979). Hermaphrodite individuals are often found in normal gonochoric species. The cholga paleta *A. seminuda* is a stable gonochorist (Giese & Pearse 1974) that shows a low frequency of hermaphrodites (1.05%).

The most common form of hermaphroditism in pelecypods is "type 1" where separate female acini and male acini occur in the same individual (Sastry 1979), although the occurrence of both sexes in the same acini can also exist. The cholga paleta shows both types of functional hermaphroditism. In the case of "type 2" hermaphroditism, the male products are arranged in the lumen and the oocytes are arranged on the walls of acini, suggesting a protandric pattern of gonad development.

Ceballos–Vázquez et al. (2000) documented 20.9% of hermaphroditism in *P. rugosa*, and Butler (1987) reported 0.1% of hermaphrodites in *P. bicolor* from Australia. Coronel (1981) described for *P. rugosa* a similar "type 2" hermaphroditism as the described in our study. Hermaphroditism "type 1" was reported in *Aulacomya ater* (Tortorelli 1987), *Mytilus californianus* (Young 1941, Young 1945) and *Mytilus edulis* (Lubet 1959).

Hermaphrodites have not been reported for cogeneric species *A. maura* (Maeda–Martínez et al. unpublished manuscript), and *A. pectinata japonica* (Yongqiang & Xiang 1987).

ACKNOWLEDGMENTS

We are grateful to Instituto de Biología Marina y Pesquera Alte. Storni and the staff of the Laboratorio y Criadero de Moluscos Bivalvos (I.B.M.P. Alte. Storni), particularly to Cecilia Castaños and Myriam Elvira for support during this work. We also thank Norma Santinelli, Natalia Zais and Sebastián Leal for laboratory and field assistance, and one anonymous reviewer for suggestions made on the manuscript.

THE PHYSIOLOGICAL ECOLOGY OF BLACK-RIBBED MUSSELS, *SEPTIFER VIRGATUS* (WIEGMANN) (BIVALVIA: MYTILIDAE) ON A SUB-TROPICAL WAVE-EXPOSED SHORE IN HONG KONG

QIN-FENG GAO, KA-KEI MAK, AND SIU-GIN CHEUNG*
Department of Biology and Chemistry, City University of Hong Kong, Tat Chee Avenue, Hong Kong SAR, China

ABSTRACT Oxygen consumption and ammonium excretion by *Septifer virgatus* were measured *in situ* on an exposed rocky shore monthly from January to December 1999. Condition index and reproductive cycle were determined simultaneously. Spawning was diphasic, the first phase being recorded in spring (March to April). The second spawning was more prolonged (July to October), but less intense than the first. Oxygen consumption was temperature-dependent and demonstrated a seasonal pattern with a peak being recorded from summer to early autumn and with lowest values in winter. Seasonal variation in excretion rate was small with a major peak in summer, possibly associated with post-reproductive stress and high temperatures. O:N ratio reflected energy metabolism and utilization with a peak in spring and early summer (>30) when growth and gametogenesis were resumed. In late summer, spawning was initiated and temperatures rose high and became lethal. O:N decreased to minimum values.

KEY WORDS: *Septifer*, oxygen consumption, excretion, O:N ratio, mussels

INTRODUCTION

Numerous studies have been reported on the relationship between environmental variables and physiological processes of bivalves and corresponding mechanisms whereby the organisms are functionally acclimated to their environments (Bayne 1976, Gosling 1992, Dame 1993). Among various factors, exogenous ones such as food, temperature, and salinity, and endogenous ones such as size, age, and reproductive activity are important in controlling an individual's physiological processes (Bayne 1976, Bayne & Widdows 1978, Bayne & Newell 1983, Huang & Newell 2002).

Representatives of the Mytilidae are highly successful colonizers of intertidal habitats, playing a significant role in energy flow and nutrient cycling due to their dense populations and filter-feeding patterns (Smaal & Prins 1993, Gili & Coma 1998). Among various mytilids, northern temperate/boreal species of *Mytilus* have received most attention (Seed & Suchanek 1992). Black-ribbed mussels, *Septifer virgatus* (Wiegmann) are distributed throughout the Indo West-Pacific and dominate the mid-littoral zone, forming a continuous band on exposed rocky shores including Hong Kong (Iwasaki 1995, Morton 1995). As the ecological equivalent of *Mytilus edulis* and *M. galloprovincialis* on northern Atlantic shores and *M. californianus* on northwestern Pacific shores (Morton 1995), it is surprising that very little is known about this species. In Hong Kong, *S. virgatus* matures at a shell length of ~15 mm and lives for 4–5 y, although older individuals, possibly up to 12 y of age, occur as solitary organisms lower down the shore. Two groups of narrowly spaced growth bands are deposited annually, one during winter (December to March) and another in summer from July to October (Morton 1995, Richardson et al. 1995). Most adult individuals remain mature year round. Spawning is divided, however, into two phases, one in spring (February to March) and another in autumn (September to December). Such a diphasic pattern is suggested to be the result of intense stress in summer when high rock temperatures at mid-day coincide with low spring tides (Liu & Morton 1994, Morton 1995). Such conditions also cause mass mortalities of mussels, barnacles and limpets (Williams & Morritt 1995). In spite of the above research on *S. virgatus* in Hong Kong and elsewhere (Tsuchiya 1983, Iwasaki 1995), no systematic data have been reported upon seasonal variations in physiological responses and their relationships with exogenous and endogenous factors. The objectives of this study are to determine the seasonal changes in physiological responses (oxygen consumption, ammonium excretion) under ambient temperature and food conditions as well as body condition and reproductive cycle. The results provide interesting comparisons with data for other bivalves, particularly the ecologically equivalent mytilids from temperate/boreal regions.

MATERIALS AND METHODS

Sample Collection and Determination of Hydrographic Conditions

S. virgatus occurs as a continuous band in the higher intertidal zone of a wave-exposed shore at Cape D'Aguilar on the southeastern extremity of Hong Kong Island, Hong Kong. About 50 individuals of *S. virgatus* of shell lengths 14–66 mm were collected monthly from the shore from January to December 1999 (except in November when sampling was prevented by strong waves). Epibionts on the shells were removed and individuals were kept for three days in an outdoor fiberglass tank supplied with seawater pumped continuously from the study site.

Food conditions of the seawater, i.e., total particulate matter (TPM: mg l^{-1}), particulate organic matter (POM: mg l^{-1}), particulate inorganic matter (PIM: mg l^{-1}) and organic content (f), were determined using the filter and ash method. Six samples of seawater (200 ml each) were filtered through ashed and pre-weighed 25 mm glass fiber filter papers (Whatman GF/C), rinsed with isotonic ammonium acetate, dried at 90°C for 24 h, weighed to the nearest 0.1 mg, then ashed in a muffle furnace at 450°C for 6 h and reweighed. The concentrations of TPM and PIM were thus measured directly, POM was calculated by subtracting PIM from TPM and f was estimated as $f = POM/TPM$. Temperature (°C), dissolved oxygen (mg l^{-1}) and salinity (‰) were also measured during each visit.

Oxygen Consumption and Nitrogen Excretion

To determine oxygen consumption rate ($\dot{V}o_2$: μg h^{-1}), each *S. virgatus* was placed in a separate sealed perspex chamber (300–

---

*Corresponding author. E-mail: bhsgche@cityu.edu.hk

550 ml, depending on the size of the animal). For individuals smaller than 20 mm, four to six were put in a container and the calculated oxygen consumption was divided by their number. Two empty chambers were used as controls. The sealed chambers were bathed in a fiberglass tank supplied with seawater pumped continuously from the sea to reduce the effect of temperature on the respiratory activity of the contained animals. Each chamber was sealed for about 60 min, the time chosen according to a preliminary study such that the oxygen concentration declined neither too excessively to affect the normal respiration, nor too slightly to accurately determine variations in oxygen concentration (Wong & Cheung 2001). Initial and final dissolved oxygen values were determined with a YSI DO meter. The oxygen consumption rate was measured as $\mu g\ h^{-1}$ after correction with the control.

Ammonium excretion rate (V_N: $\mu g\ NH_4\text{-}N\ h^{-1}$) was determined using the phenolhypochlorite method (Parsons et al. 1984). Individual *S. virgatus* were maintained in separate glass beakers filled with 200 ml filtered seawater (GF/C) for 1 h and the initial and final concentration of ammonium measured. Similar to the oxygen consumption rate measurement, 4–6 individuals smaller than 20 mm were used and the calculated ammonium excretion rate divided by the number in each beaker. Two beakers without animals served as controls.

Oxygen consumption and ammonium excretion rates were transformed to atomic equivalents and the ratio of oxygen to nitrogen (O:N ratio) computed.

Condition Index and Size-Standardization

After determining respiration and excretion rates, the shell length of each individual was measured with vernier calipers to the nearest 0.01 mm. Body tissues were then dissected out and soma and gonad dried separately at 80°C to constant weight. Tissue dry weight was measured by an electronic balance to the nearest 0.1 mg. Body condition was represented by the condition index (CI) calculated from tissue (TDW: mg) and shell (SHDW: g) dry weights according to the equation CI = TDW/SHDW (Brown & Hartwick 1988). Dry gonosomatic index (DGSI), representing the reproductive cycle, was calculated as the ratio of gonad dry weight (GDW: mg) to total tissue dry weight (TDW: mg), i.e., DGSI = GDW/TDW (Lee 1985).

Respiration and nitrogen excretion rates were plotted against shell length and body weight following the allometric equation, $Y = aX^b$, where Y is the physiological parameters, X is body size, and a and b are coefficients. To facilitate comparisons of physiological rates in different seasons, physiological rates were size-standardized according to the following equation:

$$Y_S = (S_S/S_O)^b \times Y_O \quad \text{(Strychar \& MacDonald 1999)}$$

Where, Y and S were the physiological parameters and bivalve body size, respectively and standard and observed measurements refer to the subscripts 's' and 'o', respectively. Analysis of covariance (ANCOVA) indicated that the slopes of the monthly allometric equations were unequal, (i.e., no all-year pooled slope might be regressed) b, therefore, was the coefficient in the above allometric model derived from monthly data (Packard & Boardman 1987).

Physiological parameters were frequently standardized with body weight. One defect of body weight, however, was its seasonal flexibility compared with shell length, especially when large variations in the condition index occur (Navarro et al. 1996), to which the current study conformed. Moreover, it is widely accepted that ventilation rates, one of the factors regulating respiration, is dependent on ctenidial area, which is highly correlated with shell length (Jones et al. 1992, Hughes 1969; Bayne et al. 1976). We, therefore, used shell length instead of tissue weight to standardize the physiological parameters (Iglesias et al. 1996, Labarta et al. 1997). Physiological rates were standardized to a 40 mm individual of *S. virgatus*, the dominant size at the study site.

Statistical Procedures

To obtain functional relationships between physiological responses and environmental conditions, a set of regression equations was fitted to experimental data, following standard least-squares procedures. Regression analyses were performed by simple linear and non-linear procedures, depending on the most appropriate function to be fitted in each case (Zar 1999). Multiple regression analysis was conducted when physiological parameters were correlated with more than one environmental condition, and the collinearity between independents was tested with collinearity statistics of SPSS measured with tolerance value and condition index (Belsley et al. 1980, SPSS Inc. 1999a, SPSS Inc. 1999b). Independent(s) highly correlated with others was (were) eliminated from the independent list and the regressive model was reconstructed until all the intercorrelations between the independent variables were removed. Residuals were also analyzed to check normality, constant variance of predicted dependents and other necessary assumptions of the regression model. Data were transformed if necessary to meet the regressive requisites, (i.e., normality of datum distribution and homogeneity of variances).

Analysis of variance (ANOVA) or analysis of covariance (ANCOVA) was used, depending on whether covariance existed or not, for comparisons among the groups of data. Prior to analysis, raw data were diagnosed for normality of distribution and homogeneity of variances using the Kolmogorov–Smirnov test and Levene test, respectively. All statistical procedures were performed with software SPSS, release 9.0 (SPSS Inc. 1999a, SPSS Inc. 1999b, SPSS Inc. 1999c).

RESULTS

Hydrography

Seasonal variations in hydrographic parameters including seawater temperature, dissolved oxygen, salinity and seston characteristics are presented in Table 1. Temperature underwent seasonal variations with high values (~29°C) being obtained in summer, decreasing gradually to low ones (~17°C) in winter. Dissolved oxygen level was quite constant throughout the year (except in December 2000) and was centered around 6.5 mg l^{-1}. Salinity was fully marine throughout the year except in summer (June to August) when rainfall was highest and value fell to 26‰. Monthly changes in food concentration (TPM) were small but an exceptionally high value was obtained in January, which was six times that of the lowest value (5.11 mg l^{-1}) obtained in June and was probably caused by strong winter monsoon winds and consequent strong waves (Morton & Morton 1983). The value of f varied from 0.20 in April to 0.50 in October with higher values being obtained in summer to autumn (June to December).

DGSI and CI

Temporal variations in total tissue, soma, and gonad dry weight of a 40 mm mussel are shown in Figure 1 and DGSI and CI in

TABLE 1.

Seasonal variations in seston characteristics (±SD) including TPM (mg l^{-1}), POM (mg l^{-1}), PIM (mg l^{-1}), and f, and temperature, dissolved oxygen (DO) and salinity from January to December 1999.

Aug	6.75 ± 0.91	2.99 ± 0.79	3.76 ± 0.91	0.44 ± 0.09	28.6	6.87	27.0
Sep	6.47 ± 1.10	2.84 ± 0.97	3.63 ± 0.57	0.44 ± 0.07	28.0	5.61	32.5
Oct	6.89 ± 1.32	3.36 ± 0.75	3.52 ± 0.79	0.50 ± 0.05	25.7	6.25	32.0
Dec	7.21 ± 0.73	2.59 ± 0.29	4.62 ± 0.57	0.35 ± 0.05	17.6	9.90	33.0
Annual mean	9.47 ± 8.05	2.76 ± 1.79	6.71 ± 6.50	0.33 ± 0.11	24.3 ± 4.5	6.81 ± 1.13	31.3 ± 3.3

Figure 2. Soma dry weight remained constant throughout the year with a single peak in February. Two peaks, however, were identified for the gonad with a major one occurring from February to March and a smaller but extended one from May to September. Seasonal changes in the reproductive cycle were represented by DGSI for which two peaks were identified, one in winter and the other in summer (Fig. 2). DGSI was positively correlated with CI (Pearson correlation coefficient r = 0.442, *n* = 402, $P < 0.001$). CI was also correlated with both temperature (Pearson correlation coefficient, r = –0.265, *n* = 402, $P < 0.001$) and TPM (r = 0.054, *n* = 402, $P = 0.276$) but not f (r = 0.039, *n* = 402, $P = 0.436$).

Oxygen Consumption, Ammonium Excretion, and Oxygen: Nitrogen (O:N) Ratio

Allometric equations relating oxygen consumption ($\dot{V}o_2$) and shell length are presented in Table 2. $\dot{V}o_2$ was significantly correlated with shell length for all months. The slopes of the regressions were significantly different (ANCOVA, $F_{10,380} = 5.82$, $P < 0.001$) and varied from 1.30 in September to 2.68 in February. $\dot{V}o_2$ of a standard-sized (40 mm) *S. virgatus* varied significantly with time (ANOVA, DF = 10, 391, F = 34.51, $P < 0.001$) with high values in summer (May to September) and lowest one in January (Fig. 3). The regression analysis showed that $\dot{V}o_2$ was significantly affected by temperature and the relationship between respiration rate, temperature and shell length can be described by the following equation:

$$\dot{V}o_2 = 0.0177 \times SL^{1.948} \times e^{0.0780T}\ (r^2 = 0.726,\ F_{2,399} = 529.54,\ P < 0.001)$$

With temperature as the covariate, salinity did not significantly affect $\dot{V}o_2$ (ANCOVA, $F_{1,399} = 1.098$, $P = 0.295$). There was a negative correlation between $\dot{V}o_2$ and body condition with a Pearson correlation coefficient of –0.14 (*n* = 402, $P < 0.001$).

Allometric relationships relating ammonium excretion (V_N) and shell length are presented in Table 3. V_N was significantly correlated with shell length for all months with the slopes of the regressions varying significantly with months (ANCOVA, $F_{10,380} = 10.09$, $P < 0.001$). The regression coefficient ranged from 1.13 in September to 2.89 in January. V_N of a standard 40 mm *S. virgatus* varied significantly with time (ANOVA, DF = 10, 391, F = 33.13, $P < 0.001$) with the lowest value being obtained in April and a maximum one in September (Fig. 3). As compared with $\dot{V}o_2$, the correlation between V_N and temperature was weak ($P < 0.001$) with a Pearson correlation coefficient (r) of 0.21. Using temperature as covariate, salinity did not significantly affect V_N (ANCOVA, $F_{1,399} = 1.407$, $P = 0.237$). V_N, however, was positively correlated with $\dot{V}o_2$ (r = 0.138, *n* = 402, $P < 0.01$) and negatively with CI (r = –0.176, *n* = 402, $P < 0.001$).

O:N of a standard 40 mm *S. virgatus* varied significantly with

Dec	$\dot{V}o_2 = 0.011 \times SL^{2.55}$	19.168	4.031	$F_{1,37} = 175.96$	<0.001	0.83	142.5 ± 46.9

time (ANOVA, DF = 10, 391, F = 9.15, $P < 0.001$) with high values being obtained from April to August and low ones from September to March (Table 3, Fig. 4). The annual mean value of O:N was 24.0 with highest and lowest values being 36.1 and 10.5, respectively. O:N was significantly correlated with temperature (Pearson correlation coefficient r = 0.236, $n = 402$, $P < 0.001$) but not with salinity and food conditions.

DISCUSSION

Morton (1995) showed through histological studies that individuals of *S. virgatus* from the same site as the present study remained mature year round. Spawning, however, was limited to two periods in spring (February to March) and autumn (September to December). This matches with our data on DGSI for which the values decreased in March to April and July to October, showing that they reflect reproductive cyclicity satisfactorily. The increase in somatic growth in winter to spring was probably an artefact as the gonad in *S. virgatus*, like in other mussels, was not a discrete organ with gonoglands ramifying throughout the body. Complete separation of gonadal and somatic tissue, therefore, is impossible. This is further confirmed by the suspension of growth from December to March with a winter growth ring formed (Morton 1995). Lee (1988) also found the coupling of gametogenic event and DGSI for another local mytlid, the green mussel *Perna viridis*. The bimodal pattern of spawning and recruitment demonstrated in this study is common to other local mytilids (Morton 1991) and is correlated with seasonal changes in hydrography in Hong Kong of which high summer temperatures (possibly in conjunction with lowered salinities as a result of enhanced summer rain) dividing an otherwise single pattern of summer breeding into pre- and post-summer phases (Morton 1991, Morton 1995). Although DGSI showed two major peaks with similar amplitude, only one was identified for CI in February with a less obvious decrease being obtained from August to December. As growth was suspended in winter to spring (Morton 1995), a higher CI value indicated that reproductive output in spring was much higher than in summer. An extended spawning in summer may help alleviate the problem of post-reproductive stress and increase survival when high rock temperatures at mid-day coincide with low spring tides (Morton 1995). Similar observations were also documented for another locally dominant mussel, *Perna viridis*, inhabiting a sheltered harbor (Cheung 1993a).

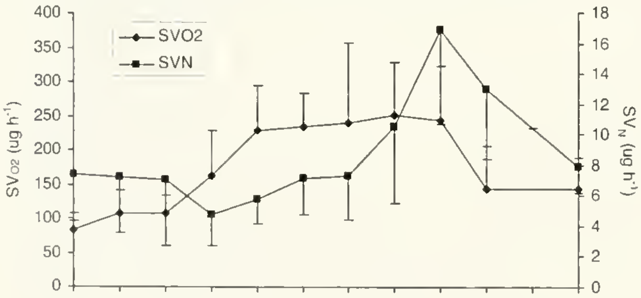

Figure 3. Monthly variations (±SD) of oxygen consumption (SV_{O2}: µg h^{-1}) and ammonium excretion (SV_N: µg h^{-1}) of a standard 40 mm *Septifer virgatus* from January to December 1999.

Food availability is a major factor determining gonadal growth and reproductive cycle (Bayne 1976, Newell et al. 1982, Kang et al. 2000). Food availability in this study was the lowest when the gonad was developing from April to July (Table 1). It was, however, also the time for body growth that was diphasic, with spring growth occurring from March/April to June and autumn growth from September/October to December/January (Morton 1995). A trade-off for limited resources between growth and reproduction may help explain a lower reproductive output in summer than autumn/winter when food availability was highest (October to February).

The oxygen consumption rate of *S. virgatus* demonstrated a seasonal pattern with peaks recorded from summer to early autumn and low values in winter. A similar seasonal pattern has been documented for a number of bivalves (Bayne & Newell 1983, Cheung 1993b, Hummel et al. 2000, Huang & Newell 2002) with temperature, food availability, and reproductive condition being the major determining factors (Babarro et al. 2000). This study indicated that oxygen consumption in *S. vigatus* was most significantly affected by temperature. The effect of food availability was insignificant, although numerous reports have demonstrated that oxygen consumption was reduced under low values of food quality (Babarro et al. 2000) as the result of a lowering of digestive activity and growth (Bayne & Widdows 1978, Bayne et al. 1989).

Such a discrepancy may be due to small fluctuations in food availability in this study when particulate organic matter was shown to vary from 1.13 to 3.36 mg l^{-1} (except in January). Significant correlation between reproductive activity and oxygen consumption have been reported by a number of authors. Bayne and Widdows (1978) obtained a significant correlation between oxygen consumption rate and gametogenic index and not with temperature for *Mytilus edulis*. Similar results were reported for the cockles *Cerastoderma edule* by Newell and Bayne (1980), whereas other studies have reported significant correlation between oxygen consumption and temperature and reproductive period (De Vooys 1976, Iglesias & Navarro 1991, Smaal et al. 1997). As the gametogenesis of *S. virgatus* covaried with temperature and growth was resumed in spring, it is difficult to distinguish the relative importance of temperature, growth and reproductive activity in determining the oxygen consumption rate in spring. Oxygen consumption rate, however, was lower in winter when the gonads were developing.

Unlike oxygen consumption, the correlation between excretion rate and temperature was weak. A number of workers have documented a close relationship between excretion rate and reproductive cycle (Bayne & Scullard 1977, Bayne & Widdows 1978, Smaal et al. 1997, Babarro et al. 2000). Such correlations were suggested to be the result of a heavy reliance on protein catabolism for energy when mussels are reproductively ripe and have low glycogen content (Bayne & Scullard 1977). Spawning started in August when excretion rate increased abruptly. As glycogen stores are low during that time, energy for maintenance was derived from substantial protein and ammonium production increases. This is further confirmed by the coupled oscillation between DGSI and O:N ratio from June to December (Fig. 4, see later). The problem of post-reproductive stress is aggravated by high rock temperatures at midday coinciding with low spring tides (Morton 1995). Such stresses also resulted in high mortality of limpets (Williams & Morritt 1995), barnacles and *S. virgatus* (Liu & Morton 1994). Temperature started to decrease in October and there was a suspension of spawning and a resumption of growth; excretion rate also started to decrease and O:N ratio increased.

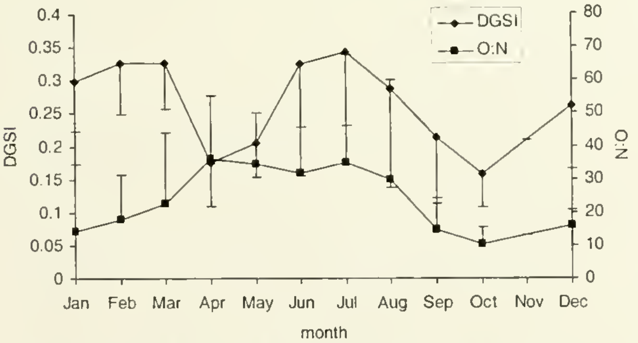

Figure 4. Relationships between temporal variations (±SD) in DGSI and O:N ratio of a standard 40 mm *Septifer virgatus* from January to December 1999.

A low O:N ratio (<20) has been used as an indicator of nutritional stress for marine bivalves (Bayne et al. 1985) as it shows an increased reliance on protein as a catabolic substrate rather than carbohydrates and lipids (Huang & Newell 2002). It may also be related to the greater demand for dietary carbon than nitrogen so as to preserve carbon based energy for utilization in seasons when food resources are low (Kreeger 1993, Huang & Newell 2002). High O:N ratios (>30) coupled with gametogenesis and body growth in spring (April to June), resource demands for gametogenesis, therefore, were mostly derived from temporal nutrition acquisition instead of body reserves. As stress became intense in summer, growth was suspended and spawning was initiated and there was a heavy reliance on protein catabolism for energy resulting in a low O:N ratio (Fig. 4). When growth and gametogenesis resumed in autumn as temperatures decreased, the O:N ratio increased gradually and peaked in spring.

A number of studies have demonstrated the significance of reproductive activity to oxygen consumption, ammonia excretion and O:N ratio for species with a well-defined reproductive cycle such as *Mytilus edulis* (Bayne & Widdows 1978, Widdows et al. 1984, Smaal et al. 1997) and *Mytilus galloprovincialis* (Navarro et al. 1991, Babarro et al. 2000). Being a subtropical species with a diphasic spawning pattern, seasonal variations in energy metabolism and utilization by *S. virgatus* are satisfactorily reflected in O:N ratio and are closely related to reproductive cycle, in addition to environmental influences such as temperature and food availability. Although oxygen consumption is most significantly affected by temperature, excretion rate is mainly influenced by growth and nutritional stress associated with intense heat and reproductive activity.

ACKNOWLEDGMENTS

The work described in this study was substantially supported by a grant from the Research Grants Council of the Hong Kong Special Administrative Region, China (CityU Project No. 9040279). The authors thank Professor Brian Morton for improving an earlier draft of this manuscript and the staff and graduate students of the Swire Institute of Marine Science, The University of Hong Kong for their assistance in facilitating the experiments conducted in their laboratory.

MICROALGAL FOOD OF THE RIBBED MUSSEL *AULACOMYA ATRA* (MOLINA, 1782) IN GOLFO NUEVO (PATAGONIA, ARGENTINA)

NÉSTOR FERNANDO CIOCCO* AND ANA MARÍA GAYOSO
Centro Nacional Patagónico, CONICET, Boulevard G. Brown s/n, 9120 Puerto Madryn, Chubut, Argentina

ABSTRACT Stomach contents of the ribbed mussel *Aulacomya atra* and phytoplankton samples from the west coast of Golfo Nuevo (Chubut Province, Argentina) were analyzed monthly between August 1997 and December 1998. Twenty-five taxa of microalgae ranging from 9 to 231 μm in size were found in stomach contents along with other miscellaneous items. A marked seasonal variation of microalgal food was not observed in *Aulacomya atra*. Diatoms such as *Paralia sulcata* and *Thalassiosira* sp. were observed year round. Variation in the benthic to total species ratio revealed that during most of the year benthic and pelagic microalgae contributed equally to the diet of the ribbed mussel. In contrast, during dinoflagellate blooms, as occurred during late spring and summer, dinoflagellate cells dominated the ribbed mussel stomach contents. This finding is of special importance in relation to the recurrent blooms of the PSP causative agent, *Alexandrium tamarense*, in the Golfo Nuevo.

KEY WORDS: ribbed mussel, *Aulacomya atra*, food resources, phytoplankton, Southwest Atlantic, Patagonia

INTRODUCTION

Mussels are suspension feeders. Quality and abundance of food affects growth rate, gonad development and survival of bivalve mollusks (Bayne & Widdows 1978, Newell et al. 1982, Berg & Newell 1986). It is generally assumed that suspension-feeding species rely on phytoplankton as their main source of energy. Yet it has been demonstrated that benthic species can also play an important role in the feeding ecology of various bivalves (Mikulich & Tsikhon–Lukanina 1981, Tsikohn–Lukanina 1982). In fact, it is possible to find benthic and pelagic food species equally represented in the guts of bivalves from shallow waters (Shumway et al, 1987). However, several authors have pointed out that food selection occurs within in bivalves (Shumway et al. 1985, Sidari et al. 1998).

The ribbed mussel, *Aulacomya atra* (often incorrectly cited as *Aulacomya ater* according to Cazzaniga, 1994) (Molina, 1782), locally named cholga, supports shellfisheries in the northern Patagonian gulfs of Southwest Atlantic (Ciocco et al. 1998). It is one of the most common bivalve species around the coasts of southern South America (Fig. 1), ranging northwards to San Matías Gulf (41°S) on the Atlantic and to Perú along the Pacific (15°S).

The quantity and quality of food available is a major limiting resource for suspension feeding organisms (MacDonald & Thompson 1985, MacDonald & Thompson 1986, Chauvaud et al. 1998). Until now information on the specific food items used by *Aulacomya atra* was only available for the Chilean coasts (Guzmán & Campodónico 1975, Osorio et al. 1982). This is the first report on feeding in *Aulacomya atra* along the Argentina coast.

Golfo Nuevo, situated at 43°S on the Patagonian coast of Argentina (Fig. 1), is a rough elliptical, semi-enclosed body of water in contact with the Southwestern Atlantic Ocean through a 17-km wide strait. Phytoplankton is dominated by diatoms and dinoflagellates (Gayoso 2001). Recurrent blooms of the toxic dinoflagellate, *Alexandrium tamarense* (Lebour) Balech, have been documented, resulting in human health hazard (Esteves et al. 1992, Ciocco 1995, Gayoso 2001). Other harmful dinoflagellate species including *Prorocentrum lima* (Ehrenberg) Dodge (Gayoso & Ciocco 2001) and *Dinophysis acuminata* Claparède & Lachmann have also been found in the area adding potential risks for human health and marine resources. In this study we describe the stomach contents of ribbed mussels in order to: (1) characterize the nature of the food items; (2) assess seasonal variation of food items; and (3) provide preliminary information about the relationships between microalgal species in water samples and algal cells in the stomachs of the ribbed mussel.

MATERIALS AND METHODS

Samples of phytoplankton and ribbed mussels (*Aulacomya atra*) were collected monthly from August 1997 to December 1998 at a station located in the west coast of the Golfo Nuevo (42°46'S; 65°02'W). On each sampling date, several adult ribbed mussels (length range: 55.2–116.4 μm) were collected by divers from the bottom (approximately 18 m depth). The mussels were transported to the laboratory and the digestive gland of six randomly chosen individuals were dissected. For microscopic analysis, stomach contents were diluted with filtered seawater and observed in a Sedgwick–Rafter chamber using a compound light microscope. Microalgae present in the stomach contents were identified and counted. Water samples (200 mL) were collected with a Van Dorn bottle at 0 and 15 m depth and immediately fixed in Lugol's iodine solution. For quantitative phytoplankton analyses, 50 mL sub samples, using mixed 0 m and 15 m depths, were settled in a chamber and counted using an inverted microscope.

RESULTS

Twenty-three taxa of microalgae, ranging in size from 9–231 μm, were found in the stomach contents of ribbed mussels (Table 1). The diatoms *Paralia sulcata* (Ehrenberg) Cleve and a *Thalassiosira* species characterized by linear areolae arrays and a diameter ranging from 26.4 to 32 μm, were the most frequent species (77% of all samples). A group of unidentified benthic pennate diatoms that included more than one species also showed high frequency. The dinoflagellate *Prorocentrum micans* Ehrenberg was the most abundant organism found in the ribbed mussel stomachs. During the summer (January to February, 1998), mean densities up to 225 cells per individual mussel were observed. On November 17 and December 2, 1998, cells of the toxic dinoflagellate, *Alexandrium tamarense*, were found in great number (mean values up to 105 cells per individual mussel). Both dinoflagellate species were observed mostly as intact cells. Additional items were observed including macroalgal fragments, foraminifera and empty tintinnid loricae (mainly *Stenosemella avellana* Meunier, *Helicostomella subulata* Ehrenberg and *Tintinopsis gracilis* Kofoid & Campbell). Broken cells of the diatom *Ditylum brightwellii*, (T. West) Grunow ex Van Heurck, and fragments of pennate diatoms were also frequently found.

Phytoplankton seasonal variation was characterized by two diatom peaks, spring and autumn blooms (Fig. 2A), dominated by *Chaetoceros socialis* Lauder, *C.curvisetus Cleve*, *C.diadema* (Ehrenberg)Gran and *C. didymus* Ehrenberg, *Skeletonema costatum* (Greville) Cleve, *Pseudonitzchia pungens* (Grunow ex Cleve) Hasle and *Guinardia delicatula* (Cleve) Hasle. Dinoflagellates tended to be abundant during spring and summer (Fig. 2B), when *Prorocentrum micans* was the most abundant species. Other dinoflagellates included *Pyrophacus horologium* Stein and *Dinophysis acuminata*. *Ceratium horridum* (Cleve) Gran, *C. fusus* (Ehrenberg) Dujardin and *C. tripos* (O. F. Müller) Nitzsch were also present during the autumn. The toxic dinoflagellate *A. tamarense*, responsible for PSP toxicity in the area, was found in phytoplankton samples taken in November to December, 1998 (up to 1.5×10^3 cells L^{-1}). Phytoplankton was dominated during late spring (late October to December 1997) by small forms of phytoflagellates, less than 10 μm in diameter, including *Phaeocystis* spp., coccolithophorids and small-unidentified monads.

All the microalgal taxa identified from the guts of ribbed mussels were also found in water samples. Many of them, however, were true benthic species and only occasional component of the phytoplankton community. The average ratio of benthic species to total species numbers from 6 stomachs per sampling date (Fig. 2C) widely varied throughout the year; it varied from less than 0.1 in summer (February 1997) and late spring (November to December 1998), during *Prorocentrum micans* and *Alexandrium tamarense* blooms, to a ratio of almost 1 in May 1998. Percentages between 0.4 to 0.5 were commonly registered (Fig. 2C). Moreover, some of the more representative phytoplankton taxa and algal groups, such as *Chaetoceros* spp., *Skeletonema costatum* and phytoflagellates, were never found in the stomach contents.

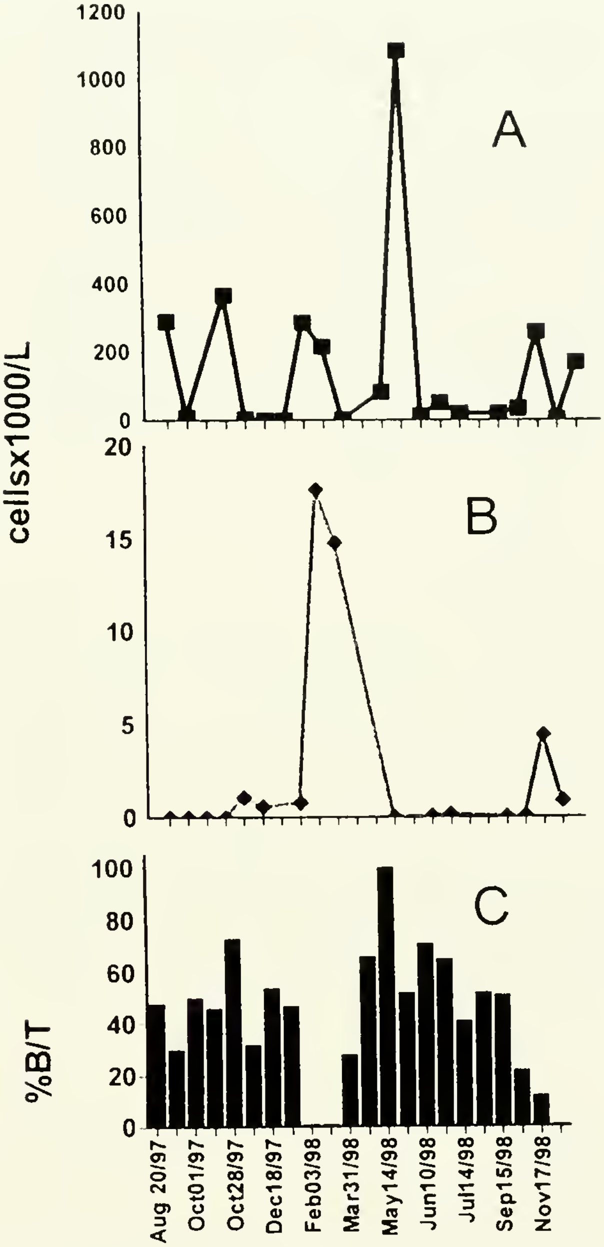

Figure 2. Cell number variation of diatoms (A) and dinoflagellates (B) in the water samples of Golfo Nuevo and ratio of benthic species over total species of *Aulocomya altra* guts in each sampling date (C).

DISCUSSION

The size range of the food items detected in the stomach contents in this study (9–231 μm) is similar to that reported for *A. atra* from Arica, Chile (21–270 μm, exceptionally up to 725 μm; Osorio et al. 1982) and other species such as *Mytilus edulis* Linnaeus (10–250 μm; Newell & Shumway 1993) and inshore *Placopecten magellanicus* (Gmelin)(8–240 μm; Shumway et al. 1987) from the Gulf of Maine. A wider size range of food items were reported in offshore *Placopecten magellanicus* (10–350 μm; Shumway et al. 1987) and *Patinopecten yessoensis* (Jay)(9–950 μm; Mikulich & Tsikhon–Lukanina 1981). Silicoflagellates, foraminifera, and specially tintinnids were other items observed in ribbed mussel stomachs in this study. The three groups are also miscellaneous items reported in *A. atra* from Arica, Chile (together with abundant detritus and other items; Osorio et al. 1982) and gut contents of other bivalves such as *Chlamys varia* (Linnaeus) (foraminifera, Hunt 1925), *Placopecten magellanicus* (silicoflagellates, Shumway et al. 1987), *Aequipecten tehuelchus* (d'Orbigny)(silicoflagellates, Vernet de Hall 1977), *Mytilus edulis* (silicoflagellates, Newell et al. 1989) and *Mytilus galloprovincialis* Lamarck (silicoflagellates, Sidari et al. 1998).

Two diatom peaks are observed as a recurrent feature of the annual phytoplankton cycle in Golfo Nuevo (Gayoso 2001). This common characteristic was not reflected in the annual variation of microalgal food of the ribbed mussel. Among the most representative species of the diatom bloom, *Skeletonema costatum*, *Chaetoceros socialis*, *C.curvisetus*, *C.diadema*, *C. didymus* and *Pseudo-nitzchia pungens*, only the latest, was observed in the ribbed mussel gut (Table 1). Absence of dominant planktonic microalgae has been reported for other bivalve species such as the absence of *Chaetoceros spp.* in *Placopecten magellanicus* (Shumway et al. 1987) and *S. costatum* in *Aequipecten tehuelchus* from Golfo San José, Argentina (Vernet de Hall 1977). These cases suggest a probable selective feeding capacity as indicated for others bivalves (Field 1922, Vernet de Hall 1977, Shumway et al. 1985, Shumway et al. 1987, Sidari et al. 1998). The absence of phytoflagellates in *A. atra* stomach contents may be explained by quick digestion of some small (mainly <10 μm in diameter) algal species (Shumway et al. 1987), reduced retention efficiency of particles less than 7 μm (Mühlenberg & Riisgard 1978) and/or difficulties in identification of micro-flagellates in bivalve stomach contents due to the fragility of these small cells (Vernet de Hall 1977).

A marked seasonal variation was not observed in the microalgal food of *Aulacomya atra*. Diatoms such as *Paralia sulcata* and *Thalassiosira* sp. were observed year round. Variation in the ratio of benthic over total species demonstrated that during most of the year benthic and pelagic microalgae contributed equally to the diet of the ribbed mussel in the Golfo Nuevo. In contrast, during dinoflagellate blooms, as occurred during late spring and summer, the percentage of benthic species dropped to less than 10% (Fig. 2C). The fact that *P. micans* and *A. tamarense* were found mostly as intact cells in the stomachs suggests, however, that they are not assimilated by the ribbed mussels. The capacity of concentrate large amounts of dinoflagellates was also observed in *Mytilus galloprovincialis* during a bloom of *Dinophysis* (Sidari et al. 1998). In *A. atra* from Magellanic Region (Southern Chile) Guzmán and Campodónico (1975) identified *Alexandrium catenella* (Whedon & Kofoid) Balech (formerly *Gonyaulax catenella*) in *A. atra* from Punta Arenas, Chile. Lembeye (1981) reported the toxic dinoflagellates *Alexandrium catenella* and *Dinophysis acuta* Ehrenberg (DSP causative agent) in stomach contents of *A. atra* from Chilean Magellan waters. Great densities of *Alexandrium tamarense* can explain the high toxicity of the ribbed mussels when the species is blooming in the Golfo Nuevo (Esteves et al. 1992, Andrinolo et al. 1999). Toxicity values up to 1,750 μg STXeq/100 g were reported in *A. atra* from Golfo Nuevo by Andrinolo et al. (1999).

TRIPLOID INDUCTION OF *MYTILUS EDULIS* USING 6-DIMETHYLAMINOPURINE

JOHN BRAKE,[1] JEFFREY DAVIDSON,[2]* AND JONATHAN DAVIS[3]

[1]*Coastal Oregon Marine Exp. Station, Hatfield Marine Science Center, 2030 S. Marine Science Dr., Newport, Oregon 97365;* [2]*Department of Health Management, Atlantic Veterinary College, University of Prince Edward Island, 550 University Avenue, Charlottetown, PEI, Canada, C1A 4P3;* [3]*Baywater Inc., 15425 Smoland Lane, Bainbridge Island, Washington 98110*

ABSTRACT The induction of triploidy in *Mytilus edulis*, using 6-dimethylaminopurine (6-DMAP), was investigated as a potential method of providing high quality sterile product in Prince Edward Island (PEI), Canada. Initial results indicated induction by blocking the second polar body would require a treatment starting time of 21 min post-fertilization at 20°C. Poor yields in subsequent spawns caused a re-examination of these factors by investigating the meiotic events post-fertilization. The resulting description was used to develop a series of suitable treatment time windows for testing inducing techniques. Triploids were successfully produced with the use of 6-DMAP at various concentrations and at various times post-fertilization. The optimal investigated procedure for induction of triploidy in *Mytilus edulis* was the treatment of eggs at 20°C with 400 μmol/L of 6-DMAP starting at 24 min post-fertilization for a treatment time of 10 min. This treatment yielded 83.1% triploids in induced samples with a survivorship of 1.39% to the D- veliger stage. The investigated methods for producing triploid *Mytilus edulis* are not yet optimized to commercial levels. This work forms a basis for further work in the optimization of this technique.

KEY WORDS: 6-dimethylaminopurine, meiosis, mussel, *Mytilus edulis*, triploid

INTRODUCTION

The Prince Edward Island (PEI) mussel aquaculture industry is a large contributor to Canada's aquaculture sector, accounting for greater than 80% of all Canadian mussels over the past two decades. One area of concern to the PEI mussel aquaculture industry is the harvesting and marketing of mussels during, and just after the spawning season. Ripe mussels (near spawning) can spawn due to the stress of shipping. Also, mussels that have recently spawned have significantly reduced meat yield making them less appealing to the consuming public. In PEI, the marketing of non-spawning triploid mussels during this period would alleviate these problems and allow the industry to market a high quality product year round.

Triploids are organisms with three sets of chromosomes, differing from most other sexually reproducing organisms that have two sets (diploids). Triploids also do not normally undergo meiosis, as the three sets of chromosomes cannot properly synapse. Therefore triploids have poorly developed gonads and produce far fewer gametes than diploids (Allen 1988). Triploidy is an aberrant genetic state in molluscs, and most organisms, and therefore must be produced artificially. The main objective of this study is to develop and optimize a triploid induction strategy. The important considerations for developing a triploid-inducing technique for commercial use are effectiveness and safety. 6-dimethylaminopurine (6-DMAP) is far less dangerous than cytochalasin B (CB) and equally effective in most cases (Dèsrosiers et al. 1993), therefore it was selected as the chemical induction agent for testing in this study.

In molluscs, triploid induction occurs through the use of an external treatment on a fertilized egg. The goal of commercial triploid induction of shellfish is to produce a high percentage triploid cohort with high survivorship throughout the hatchery stage (Allen et al. 1986). Imperative to the induction of both a high percentage of triploids and a high survival rate in a cohort of triploid mussels is the determination of the proper time at which to begin triploidy induction, and the treatment duration. In the past, the stage of development when 50% of the eggs showed polar body formation has been used as a common cue to start triploid induction treatment in oysters (Allen et al. 1989). Although the duration of the treatment varies between hatcheries, this treatment has a finite duration, the optimal time of which is determined by the timing of meiotic events. The time, from which a triploid induction treatment may be initiated until it is no longer effective, may be referred to as the induction window. One of the objectives of this study is to determine the optimal time for triploid induction initiation in *Mytilus edulis* embryos. Another objective of this study is to define the induction window for *Mytilus edulis* using an effective concentration of 6-DMAP and a standardized set of parameters. This work serves as the foundation for the future optimization of the triploid-inducing technique (using 6-DMAP) in *Mytilus edulis*.

MATERIALS AND METHODS

All experiments were conducted at the Ellerslie Shellfish Hatchery (ESH), in Ellerslie, PEI. Flow cytometry, to define ploidy level in samples, was performed at the University of Washington in Seattle, Washington, and at the Whiskey Creek Shellfish Hatchery in Tillamook, Oregon. Broodstock were obtained from a mussel lease located in Lennox channel, near Lennox Island, PEI. These animals were conditioned for 6 weeks, during which time they were batch fed a mix of cultured microalgae at water changes every 2 days. Spawning was induced by a +10°C thermal shock. Fertilization occurred within 2 h of gamete collection so as not to compromise gamete quality.

Description of Polar Body Extrusion Timing

Temperatures of 15°C and 20°C were investigated. 20°C was selected as it is an easy achievable temperature in most shellfish hatcheries, and 15°C was selected, as it is closer to the temperature during the natural local spawning in this species, and also common in many shellfish hatcheries. Approximately 3 million eggs were pooled from 3 females for use in each temperature treatment. Sperm was also pooled from 4 individuals for egg fertilization.

Figure 1 illustrates the sampling procedure used for this experiment. Eggs were placed on a 20 μm sieve within a 20 L bucket of 1 μm filtered sea water (FSW). This bucket was placed in a water bath to keep the eggs and surrounding sea water at 20°C. Eggs were sampled by raising the screen out of the water and aspirating eggs from the screen (without an excess of sea water) and immediately returning the screen to the bucket (Fig. 1). The aspirated eggs were immediately placed into a pre-loaded 2-ml microcentrifuge tube containing 2% buffered formalin fixative. The sample was mixed well so as to fix the eggs rapidly. The eggs were sampled prior to fertilization, at fertilization, and at subsequent 3-min intervals up to 2 h post-fertilization. Simultaneous to this sampling, the same procedure was being followed using the same egg and sperm pools in a water bath of 15°C. Under light microscopy, polar bodies in the fixed egg samples were visible using a 0.5% aceto-orcein stain (Guo 1991). For each sampled time, the number of eggs (out of the first 50 visualized on the slide) showing visible polar bodies was recorded. When this number reached 25 (50% of eggs), the target had been reached.

Effect of 6-DMAP Concentration on Percent Triploid Induction

The sperm from 6 males was pooled for this experiment. The sperm was used to fertilize the pooled eggs from 4 females. The pooled eggs were counted and loaded into 1L plastic beakers at a density of 100,000 eggs per beaker (100 eggs per ml of FSW). Treatments were replicated three times in this experiment and consisted of eight concentrations of 6-DMAP, at each of the two investigated temperatures. The tested 6-DMAP concentrations were similar to those used by Dèsrosiers et al. (1993) who ranged concentrations from 0 to 600 μmol/L. The same range was selected for experimentation in this case as the resolution in their results gave clear indications of the effect of chemical concentration on percent triploid induction. For each treatment the appropriate amount of 6-DMAP was weighed and placed in a labeled aluminum foil packet. When a treatment was initiated the chemical was emptied into the beaker and rapidly mixed into the water until it was dissolved. Egg suspensions were mixed every few minutes throughout the treatment duration to ensure adequate chemical contact with all eggs. Water baths of 15°C and 20°C were used to keep egg suspensions at the proper temperature. Eggs were allowed to acclimate to the proper temperature for 30 min just prior to fertilization for optimal induction (Allen et al. 1989). All eggs were treated at 21 min post-fertilization for 20 min duration. At the conclusion of the treatment duration the eggs were thoroughly rinsed, placed onto a 20-μm sieve, and resuspended into their respective treatment beakers with new FSW. The egg suspensions were allowed to incubate for 24 h, then samples were taken. Embryos that had grown to the D-veliger stage were collected by rinsing them onto a 64-μm sieve. Sampled embryos were transferred into a 15 ml centrifuge tube filled with FSW. These samples were used for ploidy determination.

Eggs developing on a 20μm sieve in FSW.

B
Sieve is removed, and eggs are aspirated without FSW.

C
Eggs are placed in a pre-loaded microcentrifuge tube and mixed well for rapid fixation.

D
Sieve is placed back in FSW to allow for more egg development prior to next sampling.

Figure 1. Schematic of the experimental sampling procedure used in the description of polar body extrusion timing and the description of meiotic events.

Description of Meiotic Events

Eggs from 4 females were pooled for use, and sperm from 7 males was pooled for fertilization. This experiment was only performed on one sample of pooled fertilized eggs held at 20°C. A water temperature of 20°C was used as this was shown in the results of the description of polar body extrusion timing (the first experiment) to have more synchronous meiosis, (therefore it should be more effective than 15°C for triploid induction). Samples of eggs were taken every minute from fertilization until one hour post-fertilization. Each of the first 50 eggs observed for every sample were categorized as being in a particular stage of meiosis. The first 50 readily scored comprised the sample for each time investigated.

Evaluation of Several Treatment Windows

Sperm from 5 males was pooled to fertilize the eggs pooled from 12 females. All treatments were standardized using a temperature of 20°C and a 6-DMAP concentration of 400 μmol/L and 100 eggs/ml of FSW. The treatments investigated included different treatment starting times based on the observed meiotic events in the previous experiment. Four treatment durations of 5, 10, 15, and 20 min were investigated along with four treatment starting times of 24, 27, 30, and 33 min post-fertilization. Survivorship was assessed by taking 15 ml samples of each culture at day 3 and fixing them with Lugol's iodine. A survivor was later scored as a fixed D-veliger that showed food in the gut, under light microscopy. Samples were taken for both ploidy and survivorship.

RESULTS

Description of Polar Body Extrusion Timing

Table 1 summarizes the results. In the 20°C group polar bodies appeared as early as 15 min post-fertilization and showed the mean

TABLE 1.

Percent of polar body 1 extension in the 15°C and 20°C groups.

Time (Min)	15°C	20°C
0	—	—
3	—	—
6	—	—
9	—	—
12	—	—
15	—	2.67 ± 1.15
18	2 ± 2.0	23.33 ± 3.05
21	30 ± 10.58	50.67 ± 4.16
24	38.67 ± 14.05	—
27	63 ± 15.56	—

desired score of 50% polar body display at 21 min (50.67% ± 4.16) post-fertilization. Samples taken from the 15°C group showed a slower development of polar bodies, with none appearing until 18 min post-fertilization. All samples from the 15°C group showed 50% polar body display by 27 min post-fertilization (63% ± 15.56). The 15°C group was also less synchronous, with replicates showing a standard deviation of as much as 15.56% (of eggs showing polar bodies) between them at 21 min post-fertilization. The largest standard deviation in the 20°C group at any given time interval was 4.16%.

Effect of 6-DMAP Concentration on Percent Triploid Induction

Figure 2 is a summary of the results. In all treatments the number of live D-larvae was too low to run each replicate separately for ploidy analysis. Therefore, all three replicates for each treatment were combined for ploidy determination by flow cytometry. There were no triploids in the controls, however with the addition of 6-DMAP, all of the tested concentrations except the 50 μmol/L treatment at 15°C produced triploids. In all cases except the 500-μmol/L concentration (that had an outlier percent triploid of 9.8% and was therefore excluded) the 15°C treatments gave a lower percent triploidy than did the 20°C treatments. For both temperatures, the rate of increase in the percent of triploids induced decreased at concentrations higher than 300 μmol/L. There is little increase in the percent triploids with an increase in 6-DMAP concentration beyond 500 μmol/L.

Description of Meiotic Events

Figure 3 is a summary of the results. Telophase 1 (the stage when polar body 1 is extruded) was visible as early as 12 min post-fertilization. Anaphase 2 (the stage that is a precursor to polar body 2 being extruded) began at 22 min post-fertilization. Telophase 2 (during which polar body 2 is extruded) began at a time of 27 min post-fertilization. Egg cleavage (the first mitotic embryonic cleavage) began at 44 min post-fertilization. Approximately 50% of the scored eggs were going through Anaphase 2, and 50% through Telophase 2 at 32 min post-fertilization.

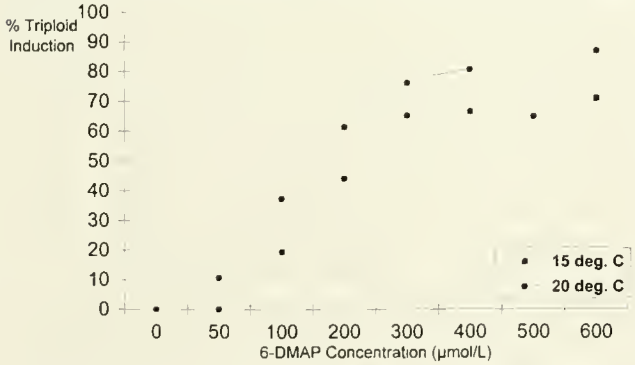

Figure 2. Percent triploid induction of *Mytilus edulis* using 6-DMAP.

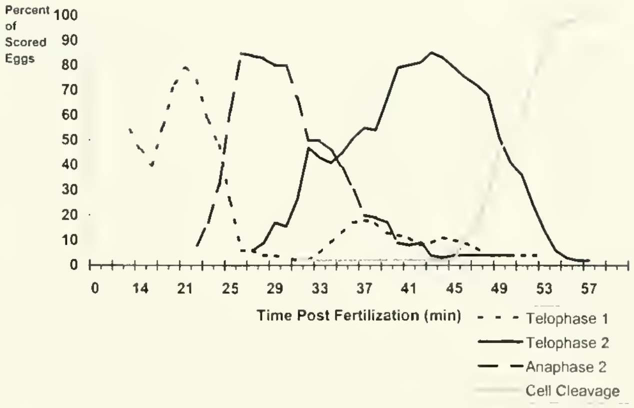

Figure 3. Summarized time-related meiotic events in *Mytilus edulis* at 20°C.

Evaluation of Several Treatment Windows

The investigated treatment windows varied greatly in both the percentage of survivors to the D-stage (survivorship) and also in the percent triploid induced. Table 2 is a summary of the obtained results. The control samples tested showed a 37.6% survivorship to the D-stage, with no triploids present. The highest mean treatment survivorship (9.33%) was found in the treatment begun 24 min post-fertilization for a duration of 5 min. The lowest mean survivorship (0%) was found in the treatment begun at 27 min post-fertilization for duration of 20 min. The highest mean percent triploid induction (83.1%) was found in the treatment begun 24 min post-fertilization for duration of 10 min. The lowest mean percent triploid induction (0%) was found in the treatment begun at 33 min post-fertilization for duration of 15 min. Tetraploid peaks were evident in a number of these treatments from the resulting printout of the flow cytometry (Table 2).

DISCUSSION

Evaluating the Induction Window Using Meiotic Events

The determination of the proper induction window is crucial to triploid induction for a number of reasons. First, the induction treatment is potentially lethal to fertilized eggs when exposure times are too long. Dèsrosiers et al. (1993) found that longer exposures to 6-DMAP interfered with first cleavage and resulted in developmental abnormalities, especially in *Mytilus edulis*. In cases where the induction comes early, although a cohort with a high percentage of triploids might be produced, the survivorship would be low, making the cohort less useful from a commercial perspective. Secondly, poor timing might not only lower survivorship, but also affect the percentage of triploids that would be produced in a given cohort. If the induction window (although the proper length of time) is initiated too late, meiosis II will not be blocked and the production of mostly diploids will result. This would result in a cohort with a high percentage of diploids, and thus a lower per-

M_s = mean % survivorship to the D-veliger stage (3 replicates/treatment).
M_t = mean % triploidy of the sampled D-veligers.
* tetraploids were found in the ploidy sample.

centage of triploids. It is important to note that not all eggs are in the same meiotic stage at any time. If the induction window begins too early, the result would be a blocking of meiosis 1 for most of the eggs, resulting in pentaploids (5N) being produced. Pentaploids do not survive to the D-veliger stage. This was shown to occur in *Mytilus galloprovincialis* by Scarpa et al. (1993). The authors exposed eggs to 1mg/L of cytochalasin B from 7 to 35 min after fertilization, blocking meiosis 1. The resulting developing pentaploid eggs showed a subsequent inhibition of first cleavage and died. Therefore the resulting cohort would have a large percentage of triploids at the D-veliger stage, as whatever wasn't a pentaploid would likely be a triploid (having meiosis I completed and being in meiosis II during treatment). This cohort would likely have a lower survivorship however, as the pentaploids would all die.

The first experiment (the description of polar body extrusion timing) was the first attempt to find a starting time for triploidy induction with reference to the time of fertilization. It was assumed at that time that it was more critical to find the initiation time of induction, as the exact duration of the treatment could be refined in further experiments. It was also decided that both temperatures of 15°C and 20°C would be investigated as they are both common, and easily achievable working temperatures in shellfish hatcheries, and they would give some insight as to a temperature effect in the induction window. The main objective of this experiment was to determine the time at which 50% of fertilized eggs developed polar bodies. Fifty percent polar body formation has been used as a common cue to start triploid induction treatment for shellfish, with treatments ending after various periods depending on the species (Baker 1996, Allen et al. 1989). It is important that most of the eggs are highly synchronous in terms of meiotic events. If most eggs are in the same stage during induction, and it is the effective stage, the result would be a higher percent triploidy. Lu (1986) found that meiotic events of the eggs are more synchronous at higher temperatures (not exceeding the physiologic limits). Given this finding, a higher temperature within the physiologic limit would be expected to produce more synchronous meiotic events. This was supported by the finding that more eggs were in the same meiotic stage on average at a given sampling time in the 20°C sample compared with the 15 °C sample in the first experiment.

One observation in related work was that during the production of both triploid and diploid animals for a simultaneous growth trial there was an unexpected high mortality level during repeated spawns. This initiated a reevaluation of the treatment window, particularly the induction initiation timing as determined to be between 21 and 24 min post-fertilization in the description of polar body extrusion timing. One possible explanation for repeated low survivorship (less than 0.01% to the D-veliger stage) may have been that initiation of treatment to induce triploidy might have been too early. If this were the case, polar body 1 extrusion would be blocked in most eggs, forming pentaploids. Pentaploids do not survive to the D-veliger stage. However, any eggs that were past this stage would likely have polar body 2 extrusion blocked and thus become a triploid. The observed trend in the related growth trial spawns was in concordance with this phenomenon as the survivors of these spawns,although few were mostly triploids (all over 80% triploidy, with many over 90%).

Therefore, the description of meiotic events involved a more in-depth study of the meiotic events in *Mytilus edulis* at 20°C. As opposed to attempting to treat at the time just after polar body 1 was extruded, a time-related description of the meiotic events was used. This strategy was shown to be successful in Geoduck clam triploid induction (Vadapolas 1999). Dèsrosiers et al. (1993) found that triploid induction treatment using 6-DMAP was effective at the metaphase I stage. In Geoduck clam induction however, Vadapolas (1999) found that extrusion blocking with 6-DMAP just at the point where 50% of the eggs were in Anaphase 2 and 50% of the eggs were in Telophase 2 produced optimum results.

The description of polar body extrusion timing and the description of meiotic events showed similar results in terms of polar body 1 extrusion times. The description of polar body extrusion timing illustrated that most eggs had extruded, or were in the process of extruding polar body 1 by 21–24 min post-fertilization. The description of meiotic events similarly showed that most eggs were undergoing polar body 1 extrusion, scored as Telophase 1, at a time of 24 min post-fertilization. The fact that both experiments showed a similar time of polar body 1 extrusion infers that if the induction initialization used in the growth trial spawns was in fact early, causing mortality, it was not because the target of first polar body extrusion was improperly identified.

Triploid Induction

The effect of 6-DMAP concentration on percent triploid induction demonstrated that 6-DMAP could be used at a number of different concentrations to induce triploidy in *Mytilus edulis*. Although 15°C was shown to be less synchronous (and thus less optimum for triploid induction) in the determination of polar body extrusion times, these results were not yet obtained at the time of the first induction experiment. In all cases the 20°C samples had a higher percentage of triploids than did the 15°C sample (Fig. 2). This is likely due to the fact that eggs at 20°C are more synchronous in terms of their meiotic stage, resulting in a higher percentage of eggs in the effective treatment stage, and a higher percent of triploids. This is in concordance with the results from the description of polar body extrusion timing that showed a higher degree of meiotic synchrony in eggs at 20°C compared with 15°C. This is also supported in the literature as Lu (1986) found that meiotic events of eggs are more synchronous, and thus should give a higher percent triploid induction, at higher temperatures (not exceeding the physiologic limits). In past studies, treatments with a higher degree of meiotic synchrony allowed for more effective induction treatments as more eggs were in the target stage during treatment, resulting in a higher percent triploid and a higher survivorship (Downing & Allen 1987, Allen et al., 1989, Gérard et al. 1994). In light of these past studies, and given that the 20°C gave both a higher percent triploid induction and a higher degree of meiotic synchrony, the 20°C treatment is considered more optimal than the 15°C treatment.

The evaluation of several treatment windows tested various induction windows (initiation and duration times), which could be compared with the meiotic events described previously. Survivorship was low in all cases. This was likely because a relatively high concentration of 6-DMAP (400 μmol/L) was used. A decrease in the number of normally developed D-larvae (presumed to not be capable of survival) with an increase in 6-DMAP concentration was reported by Gérard et al. (1994). In the case of the current experiment, the relatively high 6-DMAP concentration was required to ensure that a suitably high percentage of triploids was produced, and was based on the results from the effect of 6-DMAP concentration on percent triploid induction (Fig. 2). Treatments initiated at 24 min post-fertilization produced both the highest percent triploid (83.1 at a duration of 10 min) and the highest survivorship (9.33 at a duration of 5 min). Taylor Resources Inc., a hatchery that commercially produces triploid *Mytilus galloprovincialis*, typically obtains 95–100% triploidy with 10–15% survivorship. It is difficult to compare these refined procedures with the results from these preliminary experiments, as much more optimization is required to reach commercial relevance. As these were preliminary experiments, a triploid percentage of greater than 50% with as high a survivorship as possible was the objective. This was based on the caveat that further optimization would improve both the percent triploid induction and survivorship.

Past attempts at inducing triploidy in *Mytilus edulis* have given a wide range of optimal treatments, resulting in a wide range of percent triploid induction and survivorship. Beaumont and Kelly (1989) produced, at best, 25% triploid-producing eggs using heat shock alone (from 15°C to 25°C at 10 min post-fertilization for 10 min). The authors measured the percentage of eggs that were developing, and the percentage of those that were developing normally. They found that, at best, approximately 10% of treated eggs developed. Of those that developed, approximately 60% developed normally and would likely go on to develop as triploid embryos. One treatment had less than 5% development and less than 7% of those showed normal development. However, in the same study, it was found that CB treatments could produce up to 60% triploid larvae in the optimal treatment group (using 1mg/L of CB at 5 min post-fertilization for 15 min). Again there was a significant reduction in the percentage that developed, and of those, which developed normally. Approximately 8% of treated eggs developed, and approximately 63% of those developed normally. The current results (Table 2) illustrate some treatments that showed better induction performance when compared with the aforementioned study, with up to 83.1% triploid induction (the 24-10 treatment) and up to 9.33% survivorship (the 24-5 treatment) to the D-veliger stage. Yamamoto and Sugawara (1988) were able to produce up to 97.4% triploidy by the use of heat shock alone (from 20°C to 32°C at 20 min post-fertilization for 10 min), and found apparently no negative effect upon survival rates. However, these results are considerably higher than those produced by Beaumont and Kelly (1989). As well, Yamamoto and Sugawara (1988) report yields much higher than those found in these experiments that showed results slightly higher than those of Beaumont and Kelly (1989). Yamamoto and Sugawara (1988) gave high yields with heat shock alone despite the fact that 6-DMAP is generally accepted as being a more effective triploid inducer than temperature alone (Dèsrosiers et al. 1993). Yamamoto and Sugawara (1988) also found 2–22% triploids in their controls that they attribute to handling stress. No other known triploid shellfish work has shown triploids in their controls. In the Chilean blue mussel, *Mytilus chilensis*, Toro and Sastre (1995) found an optimum induction treatment using heat alone (from 18°C to 32°C at 10 min post-fertilization for 10 min) to induce 51% triploid with 29% survival to an age of 15 days. The optimum percent triploid induction in their study was lower than in these experiments, the survival rate was much higher however. Scarpa et al. (1994) compared six methods to induce triploidy directly (not including 6-DMAP) and found that cytochalasin B (CB) was the most effective at inducing triploidy in *Mytilus galloprovincialis*, obtaining 86% triploidy to the D-veliger stage. These authors also found that, averaged between their two trials, 71.6% survived the CB treatment. These reported results are higher than the results of this study, however, as mentioned previously, we excluded CB from our trials due its carcinogenic effects.

Although percent triploid induction in this study is comparably high (over 50%) in some treatments when compared with many shellfish studied (Beaumont & Fairbrother, 1991), survivorship is lower than expected. Future optimization of the triploid induction method should focus on increasing survivorship while not compromising percent triploid induction. Improved hatchery techniques and husbandry may also increase survivorship, but cannot help to increase the percent triploidy. When considering a commercial technique, a high percentage of triploids in a cohort are not the only consideration in an induction technique. It has to be balanced with finding a method that produces a high survivorship of the triploids to remain economically feasible.

One further noteworthy result is the incidental production of tetraploid mussel larvae during some of the treatments in the evaluation of several treatment windows (Table 2). Six different treatment combinations produced some measurable number of tetraploids. There may be commercial significance in these findings. Triploids can be produced at a rate of 100% with a high survivorship, and without using chemicals by mating a tetraploid to a diploid (Guo et al. 1996). Therefore, if tetraploids could successfully be produced and reared, they might become commercially important animals in the production of triploid mussels. Scarpa et al. (1993) found that tetraploidy could be induced in *Mytilus galloprovincialis* by suppression of both polar body 1 and 2. This may have been the mechanism for the production of the tetraploids found in these results. However, when these tetraploid-inducing treatments are compared with Figure 3, a pattern that suggests another mechanism is evident. All tetraploid producing treatments but the 24–15 treatment overlap cell cleavage. Theoretically, if an inhibition treatment overlaps cell cleavage, the chromosomes could divide into two sets but the cell would not cleave. The result will be one cell with double the diploid number of chromosomes, and subsequent mitotic divisions will result in tetraploid larvae (Beaumont & Fairbrother 1991). This has been shown as a viable method of tetraploid induction. Guo et al. (1994) attempted to produce tetraploids by inhibiting mitotic cell cleavage with heat shocks, producing up to 45% in one case, however no tetraploids in their study survived past the D-stage of development. Future work on triploid production of *Mytilus edulis* should focus on the production of tetraploid broodstock used to produce 100% triploid larvae without the use of chemicals. Many commercial triploid Pacific oysters are now produced using this method (Chew 2000).

It has been demonstrated that using the puromycin analogue 6-DMAP at various concentrations can produce triploid mussels. At the conclusion of this research the optimum investigated procedure for induction of triploidy in *Mytilus edulis* was to treat eggs at 20°C with 400 μmol/L of 6-DMAP starting at 24 min post-fertilization for a treatment time of 10 min. This treatment yielded 83.1% triploids in induced samples with a survivorship of 1.39% to the D-veliger stage. The current investigated methods for producing triploid *Mytilus edulis* are not yet optimized to commercial levels. These findings are a basis for further work in the optimization of this technique.

ACKNOWLEDGMENTS

The authors thank Garth Arsenault for technical support throughout this study. We also wish to thank Benoit Eudeline for assistance with flow cytometry throughout the project. Funding for this project was provided by a grant from the National Research Council (NRC) through its Industrial Research Assistance Program (IRAP), the PEI Aquaculture and Fisheries Research Initiative, the Prince Edward Island Aquaculture Alliance (PEIAA), and the PEI Department of Fisheries, Aquaculture and Environment.

MUSSEL CULTURE AND COCKLE FISHERIES IN THE NETHERLANDS: FINDING A BALANCE BETWEEN ECONOMY AND ECOLOGY

PAULINE KAMERMANS* AND AAD C. SMAAL,
Netherlands Institute for Fisheries Research, Centre for Shellfish Research, P.O. Box 77, 4400 AB Yerseke, The Netherlands

ABSTRACT In the Netherlands, wild stocks of mussel seed are fished and mussels are cultured on bottom plots. In addition, wild stocks of the edible cockle are dredged for harvest. Two of the areas where these activities are carried out are nature reserves. In 1993, the government implemented a policy in these reserves to ensure the conservation, protection and development of natural values and processes in which human activities should fit in. Fishing for shellfish is considered a traditional activity in these waters. Therefore, it is allowed, but under the restriction that no negative effects are caused. As a result of this policy, fishing for mussel seed and cockles is not allowed in areas with a high potential for the development of mussel beds and seagrass fields. A number of bird species are dependent on shellfish for their food requirements. Therefore, the policy makes use of a reservation system. This means that, in years when mussel and cockle stocks are low, an amount is reserved for the birds and cannot be fished. The government and shellfish industry agreed on co-management, (i.e., the fishermen are responsible for implementing the measures). This task is carried out by Producers' Organizations. An overview of the viewpoints of the interest groups and the role of policy makers and scientists is given.

KEY WORDS: *Mytilus edulis, Cerastoderma edule*, co-management, culture, fisheries, government regulations

INTRODUCTION

Shellfish are an important component of the ecosystem as they filter the water and are a food source for organisms such as birds and humans (Dame 1996). The protection and restoration of shellfish beds can contribute both to preservation of estuarine and near coastal ecosystems and to sustainable economic development of the coastal zone. In the Netherlands, six shellfish species are commercially exploited (Smaal & Lucas 2000). Different species are harvested in different areas (Fig. 1). In the coastal zone fishing is directed at wild stocks of the trough clam *Spisula subtruncata*, and the American razor clam *Ensis directus*. In the Oosterschelde estuary and the saline lake Grevelingen the European oyster *Ostrea edulis* and the Pacific oyster *Crassostrea gigas* are cultured. Fishing for seed of the blue mussel *Mytilus edulis* takes place in the Wadden Sea and on rare occasions in the Oosterschelde estuary. The mussels are cultured on bottom plots located in the Wadden Sea in the North and the Oosterschelde in the South. Fishing on wild stocks of the edible cockle *Cerastoderma edule* takes place in the Voordelta, Western Scheldt, Oosterschelde and Wadden Sea.

This article describes an attempt to combine the exploitation of shellfish stocks and the protection of estuarine habitats in the Netherlands. To reach such a goal agreement among stakeholders is essential. A description of the mussel culture and fishing for mussel seed and cockles is presented. Regulations concerning the management of shellfish stocks and other habitats are summed up. Furthermore, an overview of the viewpoints of the interest groups and the role of policy makers and scientists is given.

METHODS

Mussel Culture in the Netherlands

In the Netherlands, the culture of the blue mussel *Mytilus edulis* depends on seed that is fished twice a year in the most western part of the Wadden Sea (see Fig. 1). Seed mussels are approximately 10–30 mm in length. These mussels are transported to the bottom culture plots, which are leased from the government. The plots are located in the Wadden Sea and the Oosterschelde (see Fig. 1). The mussels are left to grow to market size (>45 mm). Depending on the environmental conditions this size is reached in 1–3 y (Dijkema 1997). The mussel seed catches show large annual fluctuations that reflect the variability in spat fall (Fig. 2a). Experience of the mussel growers shows that a catch of 65 × 10^6 kg seed mussels is needed to sustain a yearly production of 100 × 10^6 kg mussels (see Fig. 2b). This relatively low conversion is caused by heavy mortality as a result of predation by birds and starfish, and losses due to storms. The mussel seed target is not always reached. In fact, during the last ten years the target was reached only once. Thus, mussels are imported from other areas such as Germany (Dijkema 1997). The Netherlands is the fourth largest blue mussel producer in the world, after China, Spain, and Denmark (FAO 2000a, FAO 2000b). In 1999 the total landing value of mussels was Dfl 125 million = 55 million USD (Productschap Vis 2000). Almost 40% of the mussels are exported to Belgium.

Cockle Fisheries in the Netherlands

Dredging for cockles takes place in the Wadden Sea, the Voordelta, the Oosterschelde and Western Scheldt (see Fig. 1). Wild stocks are fished mechanically with suction dredges. In addition, a small group of fishermen makes use of rakes with nets that are deployed by hand. The majority of the cockles is not sold in their shell, but cooked and canned for transportation to Spain. Therefore, landings are expressed in meat instead of fresh weight (Fig. 3). The catches show considerable variability again caused by fluctuations in spat fall. The main harvest area is the Wadden Sea. In 1998 a large cockle stock was available, and the total value of the catch was Dfl 60 million = 27 million USD (Steins 1999). The Netherlands is the number one cockle producer in the world (FAO 2000a).

Producers' Organizations

All groups involved in the mussel and cockle industry (i.e., fishermen, vessel owners and shellfish sellers) are organized in the Mussel Producers' Organization (PO Mussels) and the Cockle Producers' Organization (PO Cockles). The POs depend on voluntary

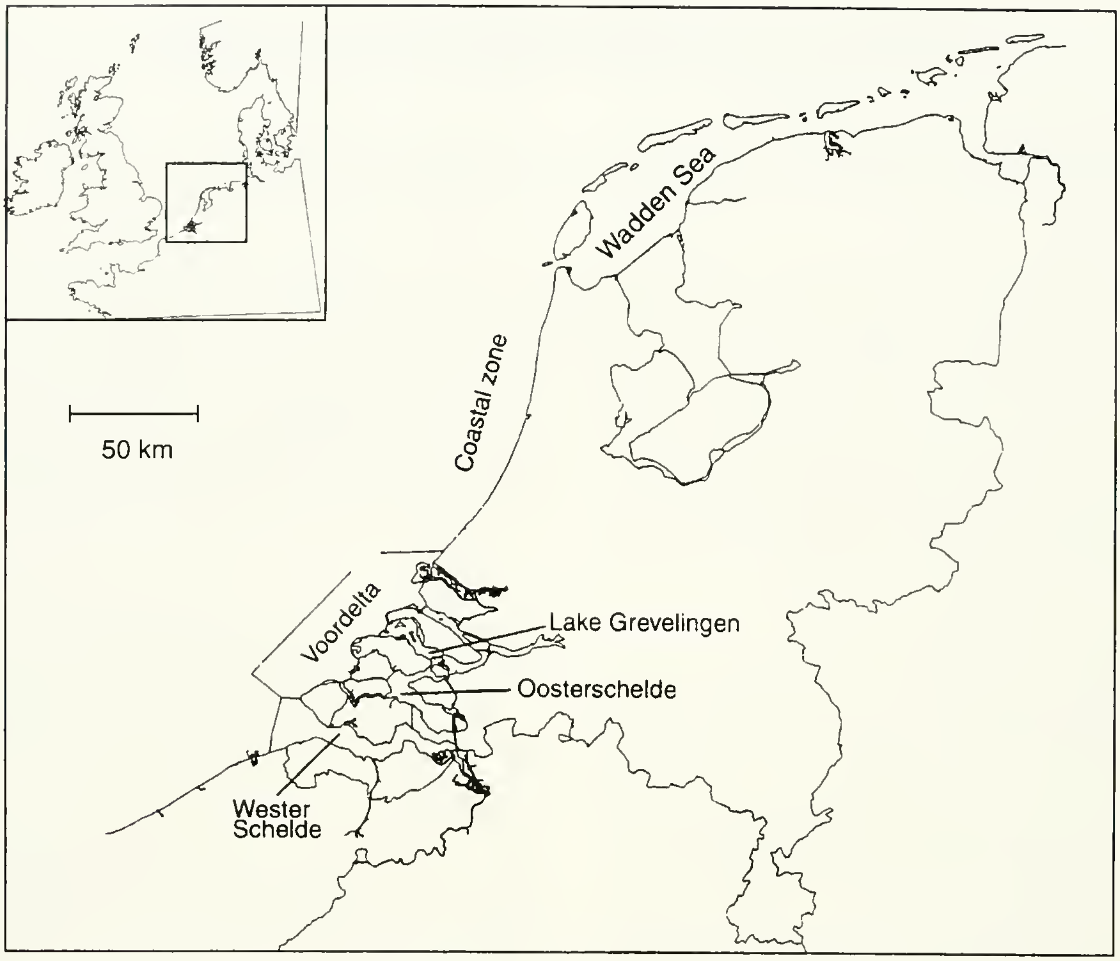

Figure 1. Shellfish fishing and culture areas in The Netherlands.

membership. POs offer attractive facilities to its members and they have legal powers to enforce binding agreements. The POs formulate Shellfish Fisheries Management Plans (e.g., Productschap Vis 2000). These include yearly fish plans, which are based on results of yearly surveys that determine the amount and distribution of mussel seed and cockles. In some cases (e.g., when mussel seed is present on a sheltered location), seed is not fished in fall, but left for next spring.

The Role of the Netherlands Institute for Fisheries Research

Every March, since 1992, the Netherlands Institute for Fisheries Research (RIVO) carries out a subtidal mussel seed survey in the western part of the Wadden Sea. This survey is conducted by order of the PO Mussels. The sampling set-up is stratified (i.e., the sampling grid is intensified at locations where subtidal mussel beds are present). These locations are known from the previous year and qualitative assessments carried out in early spring by fishery inspectors of the Ministry of Agriculture, Nature Management and Fisheries. At every sampling point a 20-cm-wide cockle dredge is used for 150 m. The mesh size is 5 mm. For profitable seed fishery a biomass of 0.1 kg mussels per m^2 is necessary (Fig. 4). The RIVO also monitors the distribution of seedbeds and the development of mature mussel beds in the intertidal with aerial photography surveys in combination with ground truthing.

Each May, since 1990, RIVO carries out a basin-wide cockle survey in the Wadden Sea, the Oosterschelde and the Western Scheldt. The survey is under contract by the Ministry of Agriculture, Nature Management and Fisheries and the PO Cockles. The sampling grid is stratified with a denser grid at cockle beds (Fig. 5). The location of these beds is derived from a qualitative survey that the fishermen carry out just prior to the annual RIVO survey. From the survey data the total cockle stock is determined.

Dutch Regulations

The Wadden Sea and the Oosterschelde do not only function as areas where shellfish fishing and culture takes place, but also as nature reserves. The birds, wetlands and other habitats in these areas are protected under several national and international laws such as the Ramsar Convention, the European Directive on the Conservation of Wild Birds, and the UNESCO Man and Biosphere Program. The areas used to have extensive seagrass meadows and intertidal mussel beds. Renewed development of these habitats is desirable. For migrating birds, the Wadden Sea and the Oosterschelde are important wintering areas or stopover sites for refueling on the flyway between the North Pole and Africa. In addition, a number of resident species, such as oystercatchers and eider ducks, are present (Rosner et al. 1993).

In these protected areas human activities are possible only when they do not cause negative effects. In the early 1990s, low stocks of both cockles and mussels were present in the intertidal

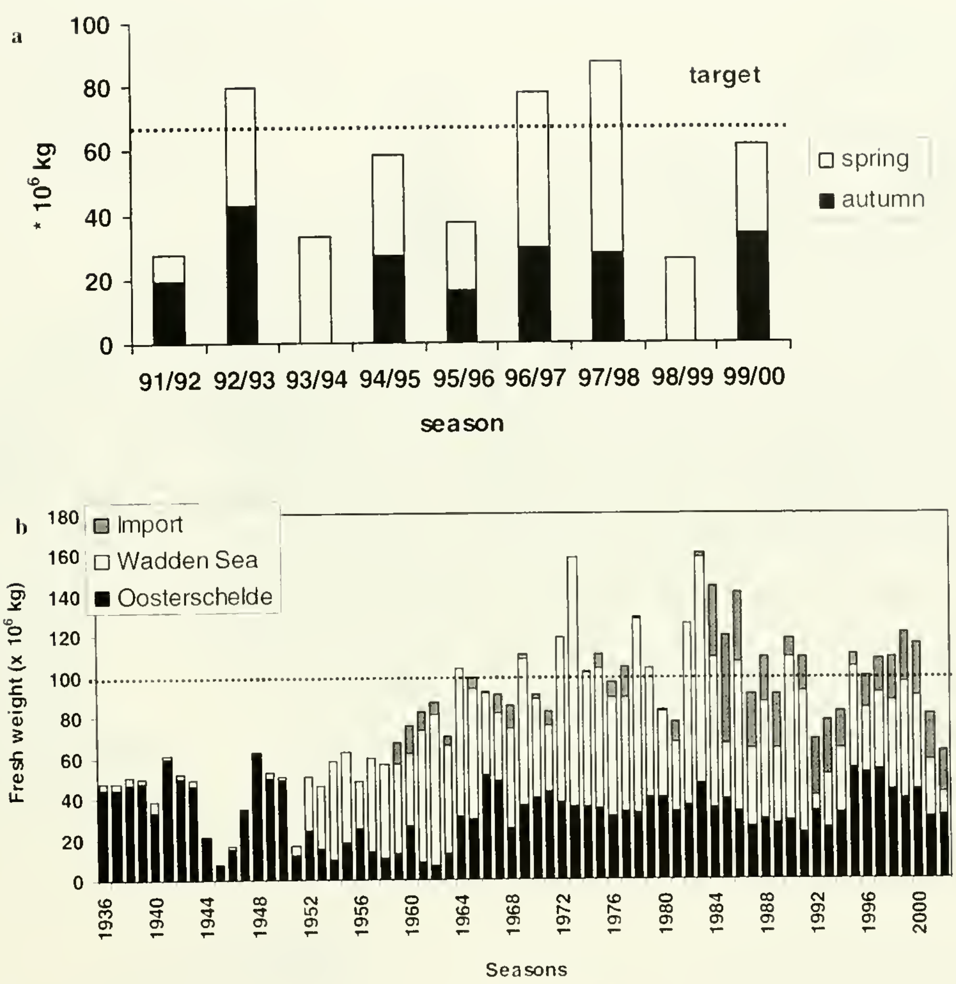

Figure 2. Mussel seed catches and mussel landings in the Netherlands in million kg fresh weight. Targets are indicated with dotted lines.

Wadden Sea (Beukema 1993). This was a result of a number of factors including reduced natural spat fall, storms and unrestricted fishing activities (Dankers 1993). At the same time, high mortality of a shellfish eating bird species was observed (Smit et al. 1998). Thus, the possibility of a link between bird mortality and shellfish fisheries appeared. The public awareness and social commotion caused by these events triggered the formulation of regulations to better protect the area.

In 1993, the government implemented a policy for the period 1993 to 2003 to ensure the conservation, protection and development of natural values and processes in the Wadden Sea and Oosterschelde estuary (LNV, 1993). Human activities must fit into this policy. Targets are restoring bird populations at levels of the 1980s, and promoting development of seagrass beds and 2,000–4,000 ha of stable intertidal musselbeds (LNV 1999). Fishing for shellfish is considered a traditional activity in these waters. Therefore, it is allowed, but under the restriction that no negative effects are caused. The government makes use of co-management (i.e., the fishermen are responsible for implementing the measures). The PO Cockles and the PO Mussels carry out this task. Consumption-sized cockles and mussels are also the preferred prey of oystercatchers and eider ducks (Zwarts et al. 1996, Nehls & Ruth 1994). Therefore, the policy makes use of a reservation system in the shellfish fisheries. In years when mussel and cockle stocks are low, the aim of the policy is to ensure that 60% of the food requirement of birds is reserved. However, the calculations underlying the policy have been questioned by (Ens 2000). Figure 6 shows large annual fluctuations in cockle stock as a result of variability in spat fall. Since the implementation of the food reservation policy in 1993, fishing for cockles was not allowed in the Wadden Sea in 1996 and restricted to the subtidal areas in 1997. In the Oosterschelde fishing was not allowed in 1997, 1998, 1999, and 2000. Another regulation is that fishing for mussel seed and cockles is not allowed in areas with a high potential for the development of mussel beds and seagrass fields. In 1993, 14% of the intertidal flats in the Oosterschelde and 26% of the intertidal Wadden Sea were permanently closed to shellfishing. In 1999, an additional 5% of intertidal flats in the Wadden Sea were closed (Fig. 7). The location of these areas is based on habitat maps for seagrass meadows and mussel beds. The maps are produced with GIS models that include parameters such as exposure time, wave action, sediment characteristics (Brinkman et al. 2002, de Jonge & de Jong 1999). To monitor that shellfish fishing does not take place in the closed areas all vessels are equipped with a black box. This system registers the ship's position at 1-min intervals when the ships are fishing. The data are retrieved from the boxes by an independent agency and the POs give penalties to offenders. In addition to the government measures, the Shellfish Fisheries Management Plan of

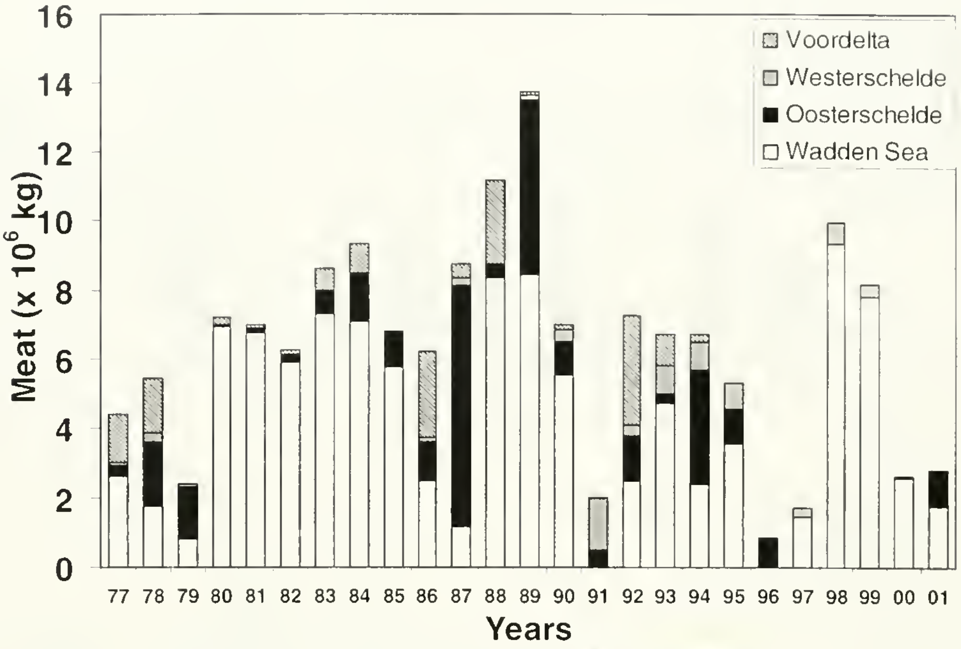

Figure 3. Cockle landings in the Netherlands in million kg meat.

the POs for the period 1993 to 2003 includes a reduction in the number of cockle vessels, a more spread out distribution of the cockle fleet, restricted fishing periods for both cockles and mussel seed, and yearly fishing plans on amounts fished and fish locations based on survey data (Productschap Vis, 2000).

Evaluation Projects

In 1998, the effectiveness of the governmental measures was evaluated for the period 1993 to 1998 in the so-called EVA I project (LNV 1998, Smit et al. 1998). Due to a series of cold

winters with high shellfish mortality in this period, clear conclusions on effects of shellfisheries could not be drawn from the available dataset. The rate at which intertidal mussel beds developed was lower than expected. Intertidal mussel spat fall occurred in 1994 only (van Stralen & Kesteloo–Hendrikse 1998), and the intertidal mussel area in the Wadden Sea is approximately 1000 ha in 2000 (Kater & den Os 2001) Therefore, an additional 5% of the intertidal flats was closed based on the newly developed mussel habitat map (Brinkman et al. 2002). In 2000, the second phase of the evaluation started. In this EVA II project (Ens et al. 2000) the effects of shellfish harvests on nature in the Wadden Sea and Oosterschelde is evaluated for the entire 10-year period from 1993 to 2003 (LNV & VW 1999). The project is based on the following policy questions (Ens et al. 2000).

- What are allowable effects of shellfish harvests on mussel beds, seagrass meadows and shellfish consuming birds?
- Have the measures taken so far had the expected effect?
- Do we comply with the international regulations on bird protection?
- When effects are negative, what can we do to reduce these effects?

These policy questions were translated into a number of research sub-projects. Effects of mussel fishery and culture on bird populations are studied. The effects of cockle dredging on cockle stocks; stable intertidal mussel beds, other zoobenthos, seagrass meadows, and sediment composition are studied by comparing their development in open (fished) and closed (unfished) areas. In addition, availability of black box data gives the opportunity to further specify the fishing intensity within the open areas. Linking survey information with black box data and catch data gives information on the relationship between density of shellfish, fishing intensity and yields. Another subproject checks the assumptions on which the calculation of the amount of food reserved for birds is based. What is the profitable shellfish density for birds? Does it matter where the food is located (both in the tidal zone and in the horizontal plane)? Which fraction of the total stock is usable by birds? And finally, the slow recovery of both seagrass meadows and mussel beds warrants refinement of the habitat maps. In this way a better selection of closed areas is possible. The results of the evaluation project will play a role in the final decision on the continuation of shellfish harvesting, which the government will take in 2003.

Finding a Balance Between Economy and Ecology

Cockle fishermen and mussel farmers make a living with their activities and represent the commercial economy, while nature conservationists protect birds and habitats, such as seagrass beds and mussel beds, and are concerned with ecology. Both groups agree that the Wadden Sea and Oosterschelde should not be completely closed for human activities (e.g., recreation and fishing) provided that these activities do not have negative impacts. The discussions center on these impacts. Despite the policy to reserve food for shellfish eating birds, a further decline in oystercatcher population is taking place (Fig. 8). In addition, the development of intertidal mussel beds and seagrass meadows is slow. These observations cause tension between the different stakeholders. The different forms of shellfish fishing and farming show different degrees of opposition between the stakeholders. Traditional fishing for cockles by hand does not cause much tension. Fishing for mussel seed in the subtidal area is starting to become an issue, as these stocks also provide food for eider ducks. The main disagreements are on fishing for intertidal mussel seed and mechanical cockle fishing (Piersma et al. 2001, Smaal et al. 2001, Camphuysen et al. 2002).

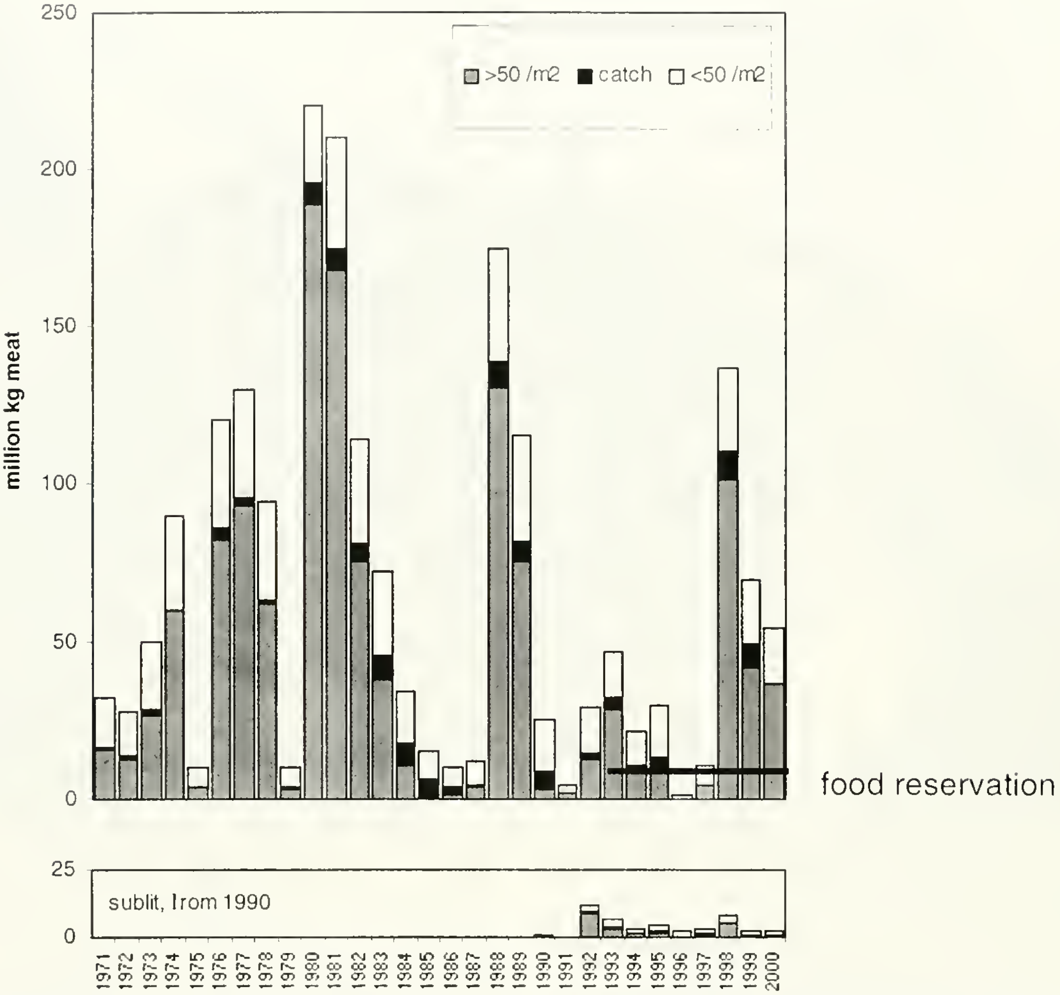

Figure 6. Cockle stock in the Dutch Wadden Sea as determined by extrapolation from various sampling campaigns in the Wadden Sea and the basin wide RIVO surveys from 1990 onwards. It is assumed that both birds and fishermen need a cockle density of more than 50 per m^2 for profitable use of the stock (grey part of the bars). Part of the grey bar is black, which indicates the catch. From 1993 onwards 12.6 million kg meat is reserved as food for birds. This is indicated with a horizontal line.

The cockle and mussel seed fishermen see an increase in restrictions, without the expected restoration of the ecosystem. As they have already put considerable effort in a changed management (e.g., the use of fishing plans and black box systems), they are reluctant to agree to more. Shellfishermen point out that, although bird populations are smaller than in the eighties, they have increased since the seventies. Nature conservation groups see the continued decline of bird populations as a sign to stress the precautionary principle. The definition of the precautionary principle is under debate. The conservation groups define it as: when uncertainty on the effects of a human activity exists, do not allow it. The European Commission have extended this with a balancing of interests: measures taken on the basis of the precautionary principle need to be in relation to the chosen protection level and need to be based on research on possible costs and benefits of carrying out that measure (COM 2000). Both fishermen and environmentalists question the calculated amounts of food needed by the birds. Fishermen ague that the lower level of bird populations in the seventies did not coincide with lower shellfish stocks. Nature groups and ornithologists (Ens 2000, Camphuysen 1996, Camphuysen et al. 2002) point out that not the total shellfish stock, but the stock that is available for birds is of importance. This may lead to higher food reservation values. Furthermore, there is debate about the closure of intertidal areas to promote development of mussel beds. Fishermen have the impression that moderate fishing improves the sediment and enhances survival of mussel seedbeds, while environmentalists are of the opinion that natural processes should not be interfered with. The images that both groups have of each other strongly influence the discussions that are part of the decision-making process (Steins 1999). Thus, securing ongoing communication between interests groups is of great importance. Identification of common interests should play a key role.

In addition to the tension between fishermen and conservationists, there is tension between science and politics. The government wants to keep the shellfish industry and protect nature at the same time. To do this properly they want to make decisions on objective scientific grounds. The scientists are unable to reach consensus on scientific grounds for the presence or absence of a link between shellfishery activities and the recent ecosystem developments (decline in bird populations, and slow recovery of intertidal mussel beds and seagrass meadows). Scientists generally work on a micro scale and can be fairly certain about their conclusions, while politicians need answers on a macro scale. The advice of the scientists needs to be objective and exact. However, when findings from

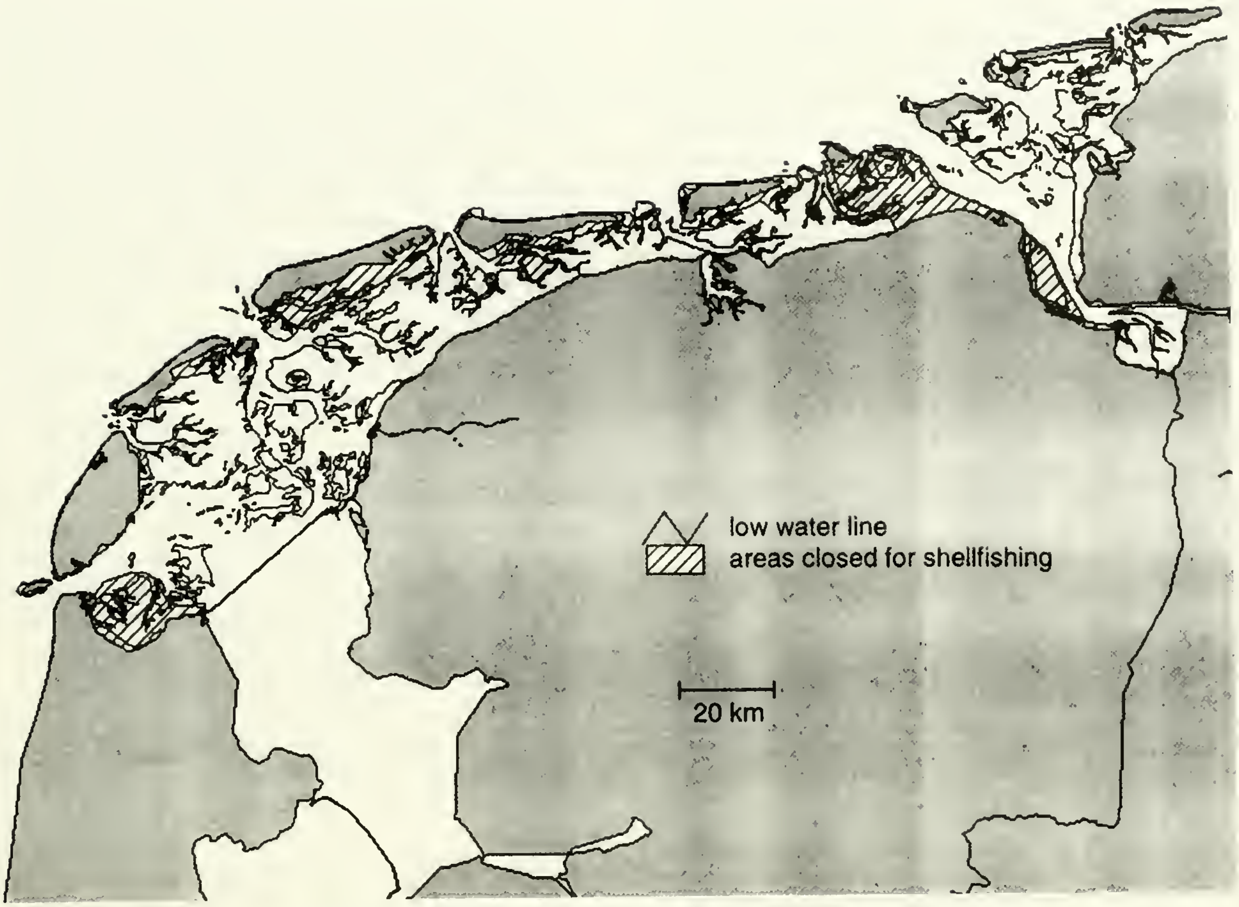

Figure 7. Location of areas that are closed for shellfish fisheries in the Dutch Wadden Sea.

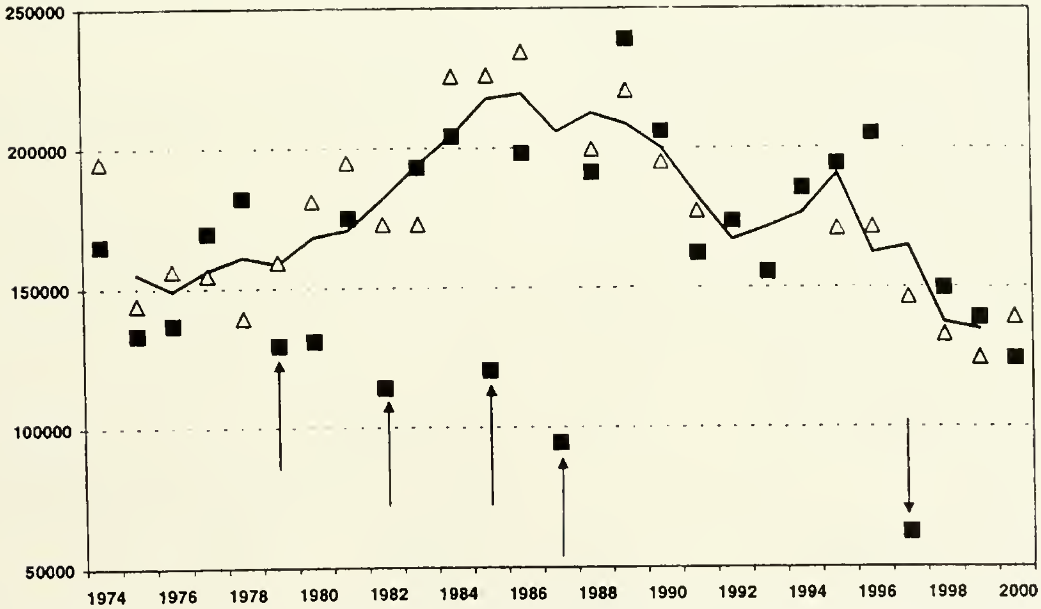

Figure 8. Development of total oyster catcher population in the Dutch Wadden Sea from 1975 to 1999. Counted numbers in fall (open squares) and following winter (closed squares) are indicated. Running mean (black line) is calculated from these counts. Counts in severe winters (closed squares with arrows) are not included in mean (Ens 2002).

small scales are upgraded to larger scales the results will always have a certain degree of uncertainty. To avoid scientific conflicts, and remain credible to society, it would be better to present results in the form of ranges instead of single values (Hauge 2000). However, this causes problems for the managers, as they need single values when drawing up permits. Thus, alternative ways to deal with scientific uncertainties concerning natural resources are needed.

CONCLUSIONS

The balance between economy and ecology is very delicate. In fact, balancing between economy and ecology is a more appropriate way to describe the current situation. Co-management has not brought the solutions the government hoped for. At present, two options dominate the discussion on the future of shellfisheries in the Wadden Sea and Oosterschelde. These are:

- A continuation of the fisheries as before, which seems unacceptable to the nature conservation groups.
- A buy out of the mechanical cockle fishery, which seems unacceptable to the fishermen.

The shellfish-fishermen, -farmers, and -sellers have set up a foundation called ODUS (Development Sustainable Shellfisheries). This foundation proposes the following methods for cockle fishing and mussel farming that aim for effects that are within the restoration capacity of the system and could be more sustainable (ODUS 2001).

- Selecting optimal areas for harvest may enlarge the efficiency of cockle dredges. Newly developed fishing gear may reduce the effects of the dredges on the bottom.
- Management of closed areas can be dynamic instead of static. The location of closed areas could be based on annual variations according to the location of the cockle stock
- Relaying of cockles may reduce mortality and enhance growth. This can be the beginning of a development from fishery to culture.
- Fishing of unstable mussel seed beds will use seed before it is lost in storms.
- Methods should be developed to avoid large seed losses on culture plots. This will enhance the yield and thus reduce the amount of mussel seed needed.
- Optimization of the mussel stock on culture plots to the exploitation capacity of the system will enhance the yield.

In our opinion, these promising options should receive more scientific attention. Conservation of the natural system is a common interest of all stakeholders. Degradation of the system will lead to reduced biodiversity and lower resilience. Both birds and fishermen need a well functioning ecosystem that guarantees the continued presence of shellfish stocks.

SETTLEMENT OF *POMATOCEROS TRIQUETER* (L.) IN TWO SCOTTISH LOCHS, AND FACTORS DETERMINING ITS ABUNDANCE ON MUSSELS GROWN IN SUSPENDED CULTURE

DIRK A. CAMPBELL AND MAEVE S. KELLY*
Scottish Association for Marine Science, Oban, Argyll, PA37 1QA, Scotland, United Kingdom

ABSTRACT In Scotland, some 2,000 tons of mussels (*Mytilus edulis*) are produced each year from suspended rope cultures. Mussels can act as a settlement substrate for tubeworm, *Pomatoceros* spp. and badly fouled mussels are devalued and may be discarded. The estimated cost to the Scottish rope-grown mussel industry is between £300,000 and £500,000 per annum. Established growers believe the problem is worsening. Collector plates were deployed at two sites in two lochs on the West Coast of Scotland to monitor *Pomatoceros* spp. settlement. In conjunction, *in situ* trials at a mussel farm site assessed tubeworm settlement on rope-grown mussels. The tubeworm *P. triqueter* was found to be the prevalent species settling on the collector plates and on the mussels. The timing of peak tubeworm settlement differed between lochs but was synchronous between sites and different depths within the same loch. Peak settlement in both lochs occurred after the highest seawater temperatures were recorded. Settlement intensity differed between lochs, sites, and depths, indicating the scale of variation in settlement within lochs. Mussel shell size was distinguished as a significant factor influencing *Pomatoceros* spp. settlement as higher numbers of tubeworm settled on larger mussels. In large mussels (mean shell length 60.8 mm ± 0.70 SE) tubeworm settlement was greatest in treatments where conspecific adults were already present and higher levels of settlement were found in mussels stocked at lower densities. In small mussels (mean shell length 33.5 mm ± 1.03 SE) the initial stocking density and tubing system had no effect on tubeworm settlement. Differences in the fouling intensity between mussel stocks were attributed to variation in the abundance of tubeworm larvae in the water column and the size of the mussels at the time of retubing. A 100% mortality could be expected in adult *P. triqueter* after 24.1 h and 35.4 h when exposed to air at 7°C and 13°C, respectively. In areas where tubeworm is a persistent problem consistent annual monitoring of the *Pomatoceros* spp. settlement is recommended as part of a management strategy to avoid heavy fouling on mussel stock. Grow-out strategies to alleviate tubeworm fouling on rope-grown mussels are discussed.

KEY WORDS: *Pomatoceros, Mytilus edulis*, settlement, tubeworm fouling, mussel cultivation

INTRODUCTION

Calcareous tube-dwelling polychaetes from the genus *Pomatoceros* have long been considered to be primary fouling organisms (Crisp 1965, OECD 1967). In Scottish waters, mussels are likely to be colonized by two species, *Pomatoceros lamarcki* (Quatrefages) and *P. triqueter* (L.). *P. lamarcki* is an intertidal to shallow subtidal species, whereas *P. triqueter* is generally considered subtidal, particularly adjoining deep water (Hayward & Ryland 1995). Mature adults are capable of breeding all year round; however, reproductive studies from other countries suggest episodes of peak settlement over relatively short periods (1–3 wk) (Klockner 1976, Castric-Fey 1983). The larval phase is temperature dependent and lasts for approximately three weeks (Seagrove 1941); however, monitoring larval populations from plankton tows has proved unsatisfactory in the past because the soft-bodied larvae do not preserve well (Senz-Braconnot 1968). Newly settled worms can reach full tube length (20–60 mm) and sexual maturity in four months (Castric-Fey 1983) and are therefore capable of rapid colonization. However, the species distribution and settlement of *P. lamarcki* and *P. triqueter* in Scottish lochs has not been described.

The cultivation of *Mytilus edulis* L. in suspended culture in Scotland increased to approximately 2,000 tons in 2000. The Scottish rope-grown mussel industry maintains its competitive edge over the Irish rope-grown mussel and UK dredge industries by trading in premium-quality mussels only. Farmed mussels constitute an excellent substrate for the settlement of many other organisms, which from the perspective of the mussel farmer are collectively termed fouling. Suspended long line cultures are particularly vulnerable to fouling because they are continually submerged and considerable effort is required to clean crop for marketing (Hickman 1992). Both barnacles and tubeworms frequently settle on mussel shells. Barnacles are not as problematic and are usually removed by the brushes used to strip mussels from culture lines, however, tubeworm (*Pomatoceros* spp.) longer than 5 mm are resistant to brushing and result in badly fouled mussels being devalued or discarded. Mussels with more than 7% of the shell fouled are not considered Grade A quality. Tubeworm-fouled mussels are not suitable for sale as "live-in-shell" product to retailers as the fouled shells are considered visually unattractive, the tubeworm can die before the mussel causing an offensive smell and the tubeworm can be released from the tube on cooking and appear unappetizing. In Scotland, it is considered uneconomical to produce Grade B rope-grown mussels because of the higher economic investment involved compared with dredged mussel operations, and the competition for the export market from the larger Irish cultivation industry which produces primarily Grade B stock. The estimated cost of tubeworm fouling to this industry is between £300,000 and £500,000 per annum (P. Marshall SSMG) and established growers believe the problem is worsening.

Previous work has focused on the competition for food resources between fouling suspension feeders and rope grown mussels (Lesser et al. 1992). However, few data exist with regard to reducing the impact of fouling organisms in cultured mussel systems. A survey of Irish rope-grown mussel growers indicated the most important factors in managing tube-worm fouling on their farms were the timing of handling (delaying grading and thinning of stock until after the main tubeworm settlement), the density of mussels on the lines (outer mussels forming a barrier to settlement), the influence of weather and the depth of culture line (Purcell & Cross 1994). All of these factors have been identified by Scottish mussel growers as potentially being of major importance to fouling levels on their sites.

The objectives of this study were to first describe tubeworm species colonizing Scottish rope-grown mussels, monitor settlement, and determine the timing of peak settlement in two contrasting lochs and at different depths, thereby ascertaining inter and intra-loch variation in settlement abundance. Second, field trials were conducted to assess the effect of mussel density, depth, retubing material, and the presence of adult tubeworm conspecifics on tubeworm settlement intensity in two size classes of mussels. Third, to evaluate the use of aerial immersion as a method to control tubeworm growth on mussels. The data collected provide basic information for the development of husbandry practices to alleviate tubeworm fouling.

MATERIALS AND METHODS

Sample Sites

Two lochs, Loch Striven (N55°59′,W5°07′) and Loch Beag (N56°53′,W5°44′) with established mussel farms, were selected as the rope-grown stock here was known to be prone to annual settlements of tubeworm species (Fig. 1). Loch Striven is a narrow Fjordic loch, almost 13 km in length with the third longest flushing time (12 days) of any sea loch (Edwards & Sharples 1986). In contrast, Loch Beag is not a true fjordic loch but an elongated embayment with greater mixing and fresh water run-off (Howson et al. 1994).

Timing of Settlement

The collector strings consisted of settlement plates (a roofing slate, 40 × 25 mm) attached by cable ties to a length of 6 mm polypropylene rope, at depths of 2, 5, and 8 m. Before deployment, the plates were conditioned for two weeks in aquaria of sand-filtered seawater and kept in darkness to promote a predominately bacterial biofilm (Hammer et al. 2001) because lack of an established biofilm on slates has been shown to limit settlement (Chan & Walker 1998). Fortnightly, from mid-April to mid-December 2001, at each of two sites within Loch Striven and Loch Beag (Fig. 2), four replicate collector strings were deployed and two replicate collector strings, which had been in place for a fortnight, were recovered for tubeworm enumeration. Thus, on every sampling visit, two replicate collector strings were added to those in the water, and they remained there until completion of the monitoring program. A Tinytalk™ II temperature logger was deployed at a depth of 5 m in each loch to record sea temperatures throughout the sampling period. All tubeworm observed on both sides of the 12 slates recovered from each loch, every fortnight, were enumerated with the aid of transparent counting grid.

Pomatoceros *Species Identification*

Tubeworms were identified from slates retrieved at the end of the experiment, which had been placed in the water during the peak settlement period. Individuals (>20 mm tube length) were randomly selected from replicate slates at each depth, site, and loch; removed from their tubes; and identified under a dissection microscope on the basis of opercular structure (Zibrowius 1968), which has been confirmed by previous genetic studies as suitable to distinguish the two species (Ekaratne et al. 1982).

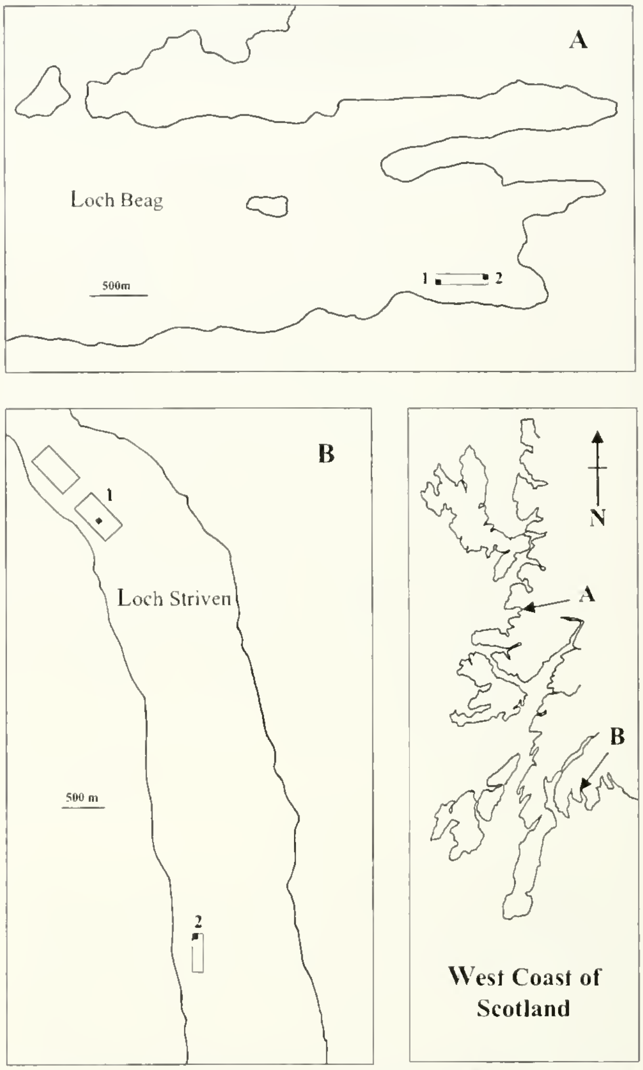

Figure 1. Map of the West Coast of Scotland and sampling locations at Lochs Beag and Striven. Rectangles represent areas of long line mussel cultivation. Small black squares show subsites at which collector plates were deployed (mid-April to mid-December 2001).

Effect of Mussel Size, Density, Retubing System, and Conspecifics on Tubeworm Settlement

At Loch Striven in mid-August 2001, before peak tubeworm settlement, rope-grown mussels, with <2% of individuals fouled with tubeworm (termed "clean"), were graded to create two distinct size classes with 1) large clean mussels (mean shell length 59.9 mm ± 1.05 SE, $n = 50$) and 2) small clean mussels (mean shell length 33.5 mm ± 1.03 SE, $n = 50$). Mussel cultures are allowed to establish on 8-m lengths of polypropylene rope hanging vertically. Before attachment by the byssal threads, the mussels are supported by a mesh tube. Mussels may migrate through different tubing systems at different rates and/or establish different feeding structures on the culture line, which could influence tubeworm abundance on mussels. For this experiment the clean large and small mussels were retubed using two common tubing systems: cotton tubing and plastic "pergolari" mesh, at a high and a low stocking density forming eight different treatments (Tables 1 and 2). A further group 3), large mussels (mean shell length 61.7 mm

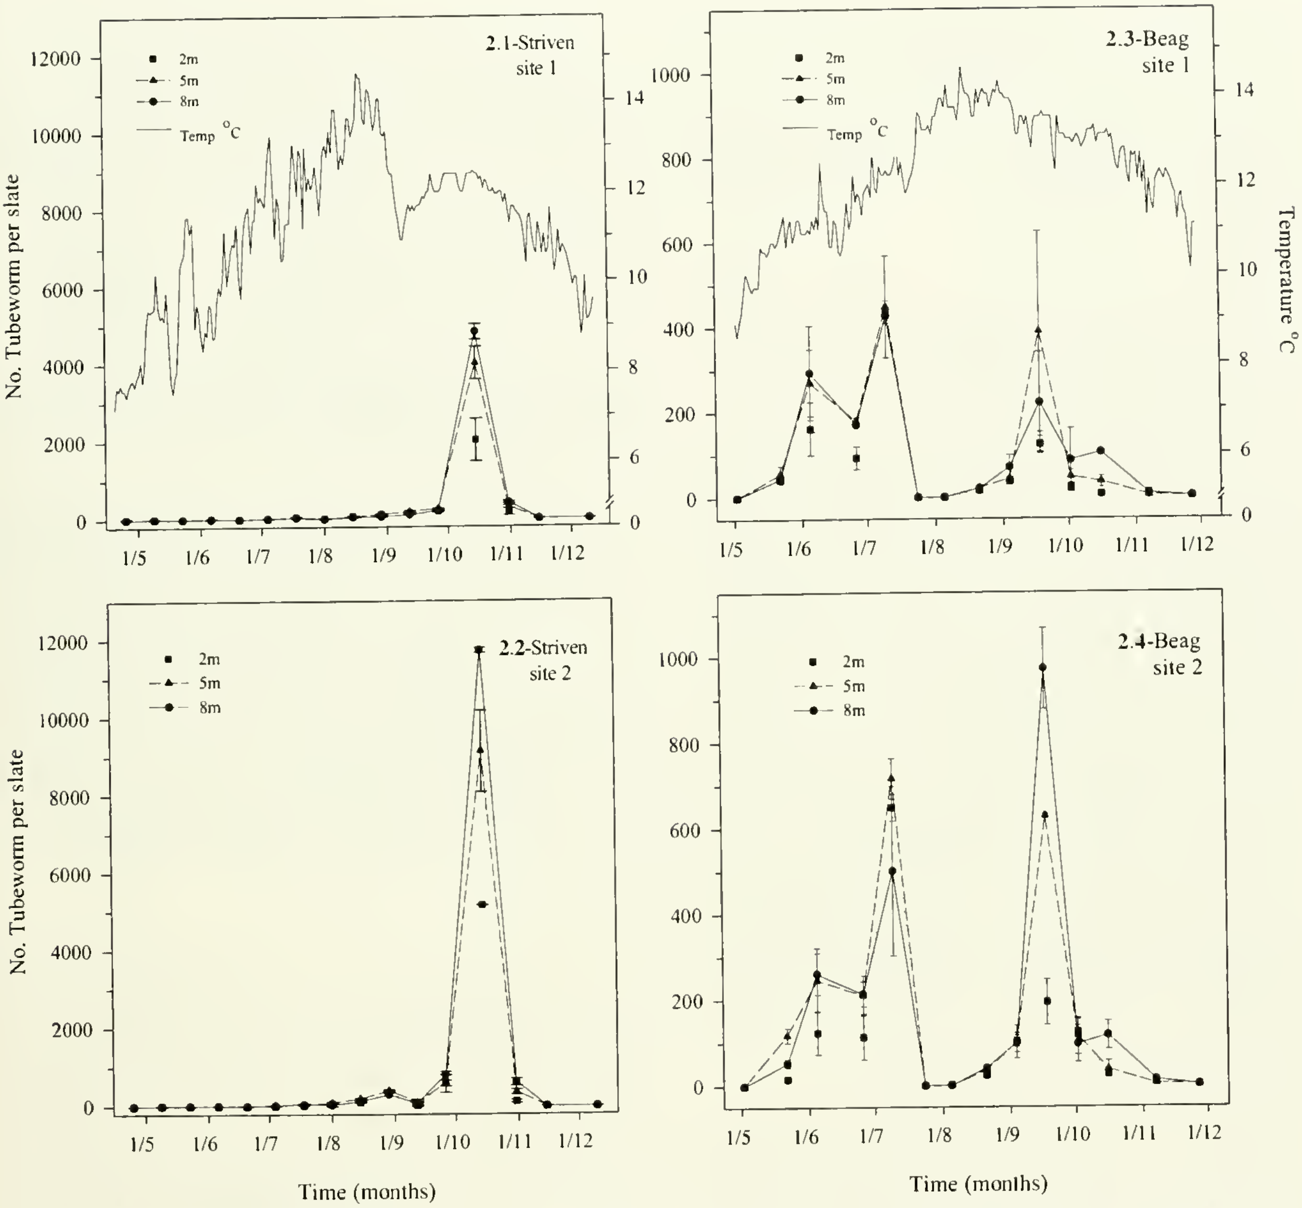

Figure 2. Mean and standard deviation for *Pomatoceros* spp. settlement counts per slate at 2, 5, and 8 m at two sites 4 km apart within Loch Striven (Apr to Dec 2001), 500 m apart in Loch Beag (note difference in scale on the Y-axis), and seawater temperature (°C) at 5 m.

± 0.915 SE, n = 50) with >98% of individuals fouled with tubeworm, were graded and retubed using plastic "pergolari" mesh only at a high and a low stocking density, forming a further two treatments (Tables 1 and 2). The mean shell length was significantly smaller in the small clean mussel treatment than in the two large mussel treatments, which were not significantly different in terms of shell length, thus allowing the inclusion of mussel shell length as a treatment effect (F = 250.2, $P < 0.001$, df = 2, Tukeys $P < 0.05$; Table 2).

Each of the 10 treatments had 5 replicates that were suspended vertically and at random, approximately 40 cm apart, along the horizontal main line. The treatments were removed from the water after 16 wk (mid-December) during which peak tubeworm settlement had occurred and then declined to a base level. The number of *Pomatoceros* spp. that had settled on individual mussel shells sampled from a depth of 4–5 m from each replicate was counted.

TABLE 1.

Treatment characteristics.

Treatments	Replicates	Tubing	Density
(A) Large clean mussels			
1	5	Cotton	High
2	5	Cotton	Low
3	5	Pergolari	High
4	5	Pergolari	Low
(B) Small clean mussels			
5	5	Cotton	High
6	5	Cotton	Low
7	5	Pegolari	High
8	5	Pergolari	Low
(C) Large fouled mussels			
9	5	Pergolari	High
10	5	Pergolari	Low

TABLE 2.

Shell length (mm) and standard error (SE) and stocking densities of the mussel treatments.

Treatment	Length (mm) (n = 50) (±S.E.)	Stocking Density kg/m) High	Low
Large clean	59.9^{a} (±1.05)	5	2
Large fouled	61.7^{a} (±0.92)	5	2
Small clean	33.5^{b} (±1.03)	1.75	0.875

Means with different superscripts in the same column are significantly different ($P > 0.05$, ANOVA and Tukeys).

Mussel Stock Fouling Comparisons

In early August 2001, the fouling intensity of tubeworm on rope-grown mussel stocks with varying treatment histories in Loch Striven was assessed. In Loch Striven the mussel spat generally settles from the plankton in spring (late-April to early-May), by the following spring the mussels are termed 1-y-olds. At intervals over the growing cycle the mussel stocks may be stripped from the culture rope, graded according to size, and resuspended at a lower density. The different groups and depths examined were determined by the stocks (settled in spring 1999 or 2000), which were available at the site. Tubeworm fouling intensity was compared on 1-y-old ungraded mussels (1-y ungraded), 1-y-old mussels that had been thinned in November 2000 (1 y Nov), and in small 2-y-old mussels that had been graded in July 2001 (2 y July). Mussels from 2, 4, 6, and 8 m depth on culture line from each stock were compared. A 1-m length of mussel culture line was removed from five replicate culture ropes at the four different depths and individuals separated and washed. As a measure of mussel density the total weight of individuals per m was recorded to the nearest 0.1 kg. Finally, the percentage of mussels with tubeworm and the number of tubeworm per mussel for a kg sample per replicate were ascertained.

Aerial Immersion Time and Tubeworm Survivorship

In December 2001, rope-grown mussels heavily fouled with tubeworm were collected from Loch Striven and transported in cool boxes to the laboratory aquaria. In each of two temperature-controlled rooms at 13°C and 7°C (both at 95% humidity), groups of five mussels with three or more adult tubeworm per mussel shell were divided among raised trays randomly placed within a continuous flow seawater tank. The mussels with tubeworm were left for five days to allow recovery and acclimatization to laboratory conditions before the start of the experiment. All tubeworms were identified as *P. triqueter*. At time 0, all trays were removed from the seawater, excluding six replicate control trays, which remained immersed for the duration of the experiment. Six replicate trays of mussels were returned to their respective tanks after 6, 12, 18, 24, 30, and 36 h of aerial exposure at either 13°C and 7°C. Forty-eight hours after each tray was returned to the seawater, the percentage of tubeworms alive on each mussel was recorded. Individuals were assumed to be dead when they did not retreat into their tubes when touched by a pin.

TABLE 3.

Mean and SD *Pomatoceros* spp. counts at peak settlement for each depth at sites in Loch Striven and Loch Beag.

Site	Depth (m)	n	Mean No. *Pomatoceros* spp. per slate (±SD) Loch Striven	Loch Beag
1	2	2	2029^{a} (±552)	124^{a} (±18.4)
	5	2	4019^{b} (±423)	389^{ab} (±236)
	8	2	4825^{b} (±202)	222^{ab} (±120)
2	2	2	5159^{b} (±127)	194^{a} (±53.0)
	5	2	9124^{c} (±1039)	628^{bc} (±5.0)
	8	2	11711^{d} (±65.0)	971^{c} (±94.0)

Means with different superscripts in the same column are significantly different ($P > 0.05$, ANOVA and Tukeys).

Statistical Analysis

ANOVA was used to test for significant differences among treatments and depths, the data having met the assumptions of the test. Test of association (χ^2) was used to compare tubeworm frequency distributions among the treatments. The linear correlation between variables was assessed using Pearson's correlation coefficient (r). Regression analysis was performed to determine the functional relationship between tubeworm survivorship (%) and immersion time (h). ANCOVA and Tukeys pairwise comparison was used to compare regression lines between the different treatments. The statistics package Minitab® version 13.1 was used for all analyses.

RESULTS

Throughout the experimental period, juvenile *Pomatoceros* spp. were the most abundant species observed on collector slates in both lochs. The distribution of settled juvenile tubeworm on the slates tended to be uneven, composed of aggregated groups with a greater proportion of individuals on the lower half of the slate. After two weeks of immersion at each site, the tube length of individuals on the slates was <3 mm.

Pomatoceros *spp. Species Identification*

All individual tubeworms examined on slates from the peak settlement period at Loch Striven and Loch Beag were identified as *P. triqueter*. Therefore, *P. triqueter* was assumed to be the most abundant of the *Pomatoceros* species present and, furthermore, responsible for colonization and fouling of rope-grown mussels in the lochs.

Pomatoceros *spp. Settlement*

The timing of peak settlement differed between lochs but was found to be synchronous between sites and over depth within the same loch. Significant differences in settlement intensity were observed between lochs, sites, and depths. At the Loch Beag sites two periods of peak settlement were observed (26.6.01–10.7.01 and 4.9.01–18.9.01) with the highest mean number of *P. triqueter* per slate (971 ± 94 SD, site 2) recorded in the later peak (Table 3 and Fig. 2). It is not known whether settlement at Loch Beag was in fact two discrete periods or one potentially more intense period disrupted by environmental conditions. A single period of peak settlement was recorded at Loch Striven (26.9.01–15.10.01); with the highest mean number of individual *P. triqueter* per slate (11711 ± 65 SD, site 2), an order of magnitude higher than in Loch Beag (Table 3 and Fig. 2). The Loch Striven and Loch Beag later peak events occurred as summer seawater temperatures declined. In both Loch Striven and Loch Beag at peak settlement, site 2 had significantly greater settlement than site 1 (Loch Striven, $F = 280.0$, $P < 0.001$, $df = 1$; Loch Beag, $F = 27.2$, $P < 0.02$, $df = 1$; Tukeys, $P < 0.05$), indicting the scale on which *P. triqueter* settlement intensity can vary within lochs at sites 500 m to 4 km apart (Loch Beag and Loch Striven, respectively).

In Loch Beag, no effect of depth on settlement intensity was observed at site 1, whereas at site 2, significantly greater settlement occurred at 5 m and 8 m than at 2 m. The effect of depth on *P. triqueter* settlement was more pronounced at Loch Striven. Site 1 had significantly greater settlement at 5 m and 8 m than at 2 m and at site 2 settlement increased significantly with increasing depth.

Effect of Mussel Size, Density, Retubing System, and Conspecifics on Tubeworm Settlement

The number of *Pomatoceros* spp. settling on small mussels was found to be significantly lower than that on the large mussel treatments. Among the small size class treatments, the percentage of mussels with ≥1 tubeworm on the shell ranged between 21.5% and 28.4%, whereas in the large size class treatments, the percentage of mussels with ≥1 tubeworm on the shell ranged between 91% and 100% (Tables 4 and 5, Fig. 3 and 4). Thus, analyses on small mussel treatments were performed separately to the large mussel treatments.

Small Mussel Treatments

The small mussels migrated successfully from the two tubing systems. *Pomatoceros* spp. were observed to have settled predominately along growth checks on the mussel shell exterior with a smaller proportion having settled on the umbo and shell ligament regions.

No significant difference in the mean percentage of individuals fouled was found (ANOVA, $F = 1.24$, $P = 0.329$, $df = 3$) and no significant differences were observed among frequency distribution of *Pomatoceros* spp. fouling between the small mussel treatments (four classes, 0, 1, 2, 3+, $\chi^2 = 10.29$, $P = 0.328$, $df = 9$; Table 4, Fig. 3).

Large Mussel Treatments

Significant differences in number of tubeworm per individual were identified between the large mussel treatments (ANOVA, $F = 17.1$, $P < 0.001$, $df = 5$; Table 5). However, in all large mussel pergolari treatments, the mussels did not establish outside the tube because the mesh size proved too small to allow mussels to migrate through the apertures. Thus, the mussels were confined within the tube for the duration of the field trial, affecting the structure of the feeding colony and preventing comparison between pergolari and cotton tubing systems with respect to tubeworm fouling.

Clean cotton-tubed mussels at low density had a significantly greater number of tubeworm per mussel than clean cotton-tubed mussels stocked at high density. No significant differences were observed between clean cotton-tubed mussels at low density and clean pergolari-tubed mussels at high and low densities. No significant differences were observed between clean cotton-tubed mussels at low density and fouled pergolari mussels at high and low densities. Tubeworm numbers per individual were significantly greater in fouled pergolari-tubed mussels at high and low densities compared with clean pergolari mussels at high and low densities (Table 5).

From the test of association analysis (χ^2), four significantly different distributions among frequency classes of tubeworm on large mussels were identified: 1) clean cotton-tubed and clean pergolari-tubed at high density had the greatest proportion of mussels with low frequencies of tubeworm and the proportion of mussels decreased steeply in higher tubeworm fouling classes (Fig. 4, 4.1 and 4.3); 2) clean pergolari tubed at low density had a large proportion of mussels with low frequencies of tubeworm fouling, which did not decrease as steeply over higher tubeworm fouling classes compared with distribution 1 (Fig. 4, 4.4); 3) clean cotton tubed at low density comprised of an approximately even frequency distribution of mussels throughout the tubeworm fouling categories (Fig. 4, 4.2); 4) fouled pergolari-tubed mussels at high and low density also consisted of an approximately even frequency distribution of tubeworm frequency classes among mussels yet had the lowest proportion of mussels in low tubeworm fouling categories (Fig. 4, 4.5 and 4.6).

TABLE 4.

Mean (%) of mussels with *Pomatoceros* spp. and SE in the small mussel treatments.

Treatment	Tubing	Density	Replicates	Mean % Mussels With *Pomatoeeros* spp (±SE)	CV %
1	Cotton	High	5	22.3^a (±2.65)	26.7
2	Cotton	Low	5	28.4^a (±4.82)	38.0
3	Pergolari	High	5	21.3^a (±2.02)	21.2
4	Pergolari	Low	5	21.5^a (±1.81)	18.8

Coefficient of variation is given (CV%). Means with different superscripts in the same column are significantly different ($P > 0.05$, ANOVA and Tukeys).

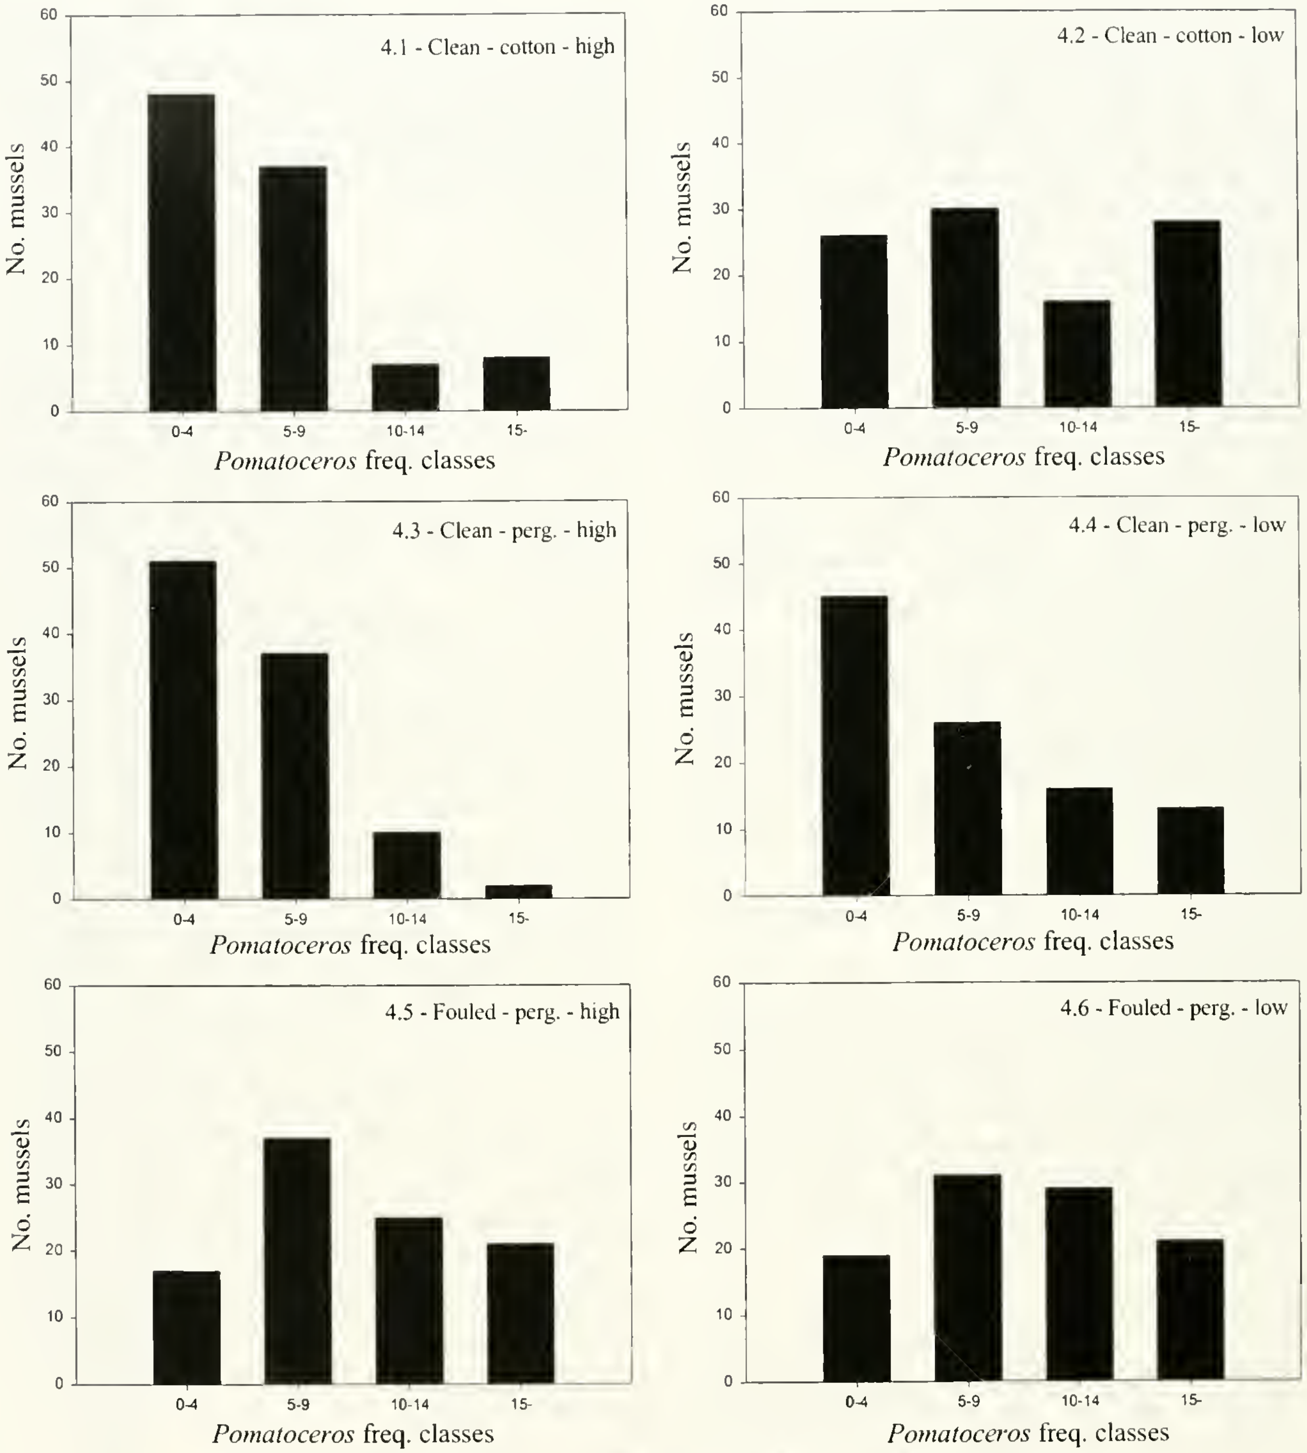

Figure 4. ***Pomatoceros*** **spp. frequency classes on large mussels (100 mussels per treatment).**

Mussel Stock Fouling Intensity Comparisons

The results demonstrate the wide variation in the percentage of mussels fouled that exists among different mussel stocks within the farm site, with the mean percentage mussels fouled among the different mussel stocks ranging between 0.7% (1-y ungraded stock) and 5.9% (1-y Nov-graded stock; Table 6). The stocks—1-y Nov, 1-y ungraded, and 2-y July mussels were all significantly different with respect to levels of tubeworm fouling, with a greater percentage of mussels fouled in the 1-y Nov stock and least in the 1-y ungraded stock ($F = 55.6$, $P < 0.001$, $df = 2$; Tukeys $P < 0.05$).

Variation in fouling intensity was observed to increase as depth increased. However, no correlation between the percentage of fouled mussels and the variables depth (m) and density (mussels kg/m) among individual stocks or stocks combined was found. A negative correlation was found between depth (m) and mussels density when all treatments were combined ($r = -0.532$, $P < 0.001$, $n = 60$), indicating that as depth increases mussel density along the culture line decreases.

TABLE 5.

Mean number of *Pomatoceros* spp. per mussel and SE in the large mussel treatments.

Treatment	Fouling	Tubing	Density	n	Mean No. *Pomatoceros* spp. Per Mussel (±S.E.)	CV%
1	Clean	Cotton	High	100	5.81^{a} (±0.50)	87.1
2	Clean	Cotton	Low	100	10.55^{b} (±0.84)	79.6
3	Clean	Pergolari	High	100	5.07^{a} (±0.38)	75.1
4	Clean	Pergolari	Low	100	7.24^{a} (±0.58)	80.7
5	Fouled	Pergolari	High	100	10.10^{b} (±0.65)	64.4
6	Fouled	Pergolari	Low	100	10.45^{b} (±0.66)	63.3

Coefficient of variation is given (CV%). Means with different superscripts in the same column are significantly different ($P < 0.05$, ANOVA and Tukeys).

Aerial Immersion Time and Tubeworm Survivorship

Although increasing *P. triqueter* mortality was clearly evident, as aerial immersion time (h) increased, no mortalities amongst the mussels occurred during the trials. No *P. triqueter* mortalities were observed in the control treatment, which was never immersed during the experiment (Fig. 5)

The interaction term (time × treatment) was significant (ANCOVA, $F = 5.90$, $P = 0.02$), indicating that the slopes, (*P. triqueter* % survival rates over time) were significantly different at 7°C and 13°C, at the 95% confidence level. Adult *P. triqueter* were predicted to achieve a mean 100% mortality after 24.1 h and 35.4 h at an air temperature of 7°C and 13°C, respectively (Table 7).

DISCUSSION

P. triqueter was the most abundant of any species settling on collector plates and the only species of tubeworm found on the mussels. This is in concordance with the observation that *P. lamarcki* occurs more frequently in intertidal and shallow turbid subtidal waters (Hayward & Ryland 1995) and that *P. triqueter* can out-compete *P. lamarcki* for settlement space at depths of 13 m, although the dominance of one species over the other is thought to be dependent on climatic conditions (Castric-fey 1983).

The pattern of settlement in the two Scottish lochs was consistent with that in other temperate populations of *P. triqueter* (Klockner 1976, Castric-fey 1983), with peak settlement occurring later in the year, possibly the result of the more northerly latitude (Klockner 1976). The timing of peak settlement differed between lochs, presumably as a result of specific biologic and physical differences (Crisp 1974, Dirnberger 1990) but was synchronous within each loch and over depth. Levels of settlement differed between lochs, sites, and over depth within the same loch, giving indication of the scale on which intra-loch variation in environmental factors influence settlement abundance. Such monitoring should be repeated to ascertain year-to-year variation in occurrence of peak settlement within Scottish lochs.

The higher settlement levels observed at Loch Striven may result from a long flushing time combined with comparatively little fresh water input and mixing (Tett et al. 1986); consequentially, the larvae are retained within the loch for longer periods of time and rarely experience lowered salinity, which is reported to reduce settlement (Castric-fey 1983). In addition Loch Striven has had an established mussel site (8 y), whereas the site in loch Beag was recently established (3 y) and is approaching its second harvest. The scales of the operations are also significantly different (standing mussel stock at Loch Striven is 200 tons and Loch Beag is 30 ton). A longer period of mussel production at Loch Striven may have increased the standing population of tubeworm through the accumulation of live mussels and shell material beneath the farm, reported to increase site availability for settlement of calcareous polychaetes (Tenore et al. 1982, Kaspar et al. 1985).

Increasing or peak seawater temperature may act as a direct or indirect cue for optimum gamete production or spawning or create optimal conditions for larval settlement and survival, resulting in discrete and intense periods of tubeworm settlement. At higher temperatures bacterial loading would also be maximal and may also generate a cue for settlement. A high bacterial density has been identified as a major cue for the settlement response of *P. lamarcki* (Hammer et al. 2001), and mussel farms have been shown to possess increased microbial assemblages resulting from elevated levels of organic enrichment (La Rosa et al. 2001).

Speculatively, the exaggerated metabolic output from mussels intensively farmed within a restricted loch environment may enhance or promote a tubeworm larval settlement response. Natural concentrations of ammonia (NH_3), a principle component of excretion in bivalves, released by adult oysters can be sufficient to induce settlement of oyster larvae, particularly at highest temperatures when peak values for total NH_3–NH_4^+ occur (Fitt & Coon 1992). Mussels may therefore be more susceptible to tubeworm

fouling immediately upon re-immersion after grading, for in addition to offering an unprotected surface for settlement, a pulse of excreted nitrogenous waste, accumulated during immersion and released on re-immersion, could further induce *P. triqueter* larvae to settle. Tubeworm settlement cues with respect to environmental conditions on a mussel farm warrant further research.

The field trial highlighted mussel size (shell length) as an important factor influencing *P. triqueter* abundance on farmed mussels because small mussels had consistently fewer tubeworms. This may be a result of the fast growth rates of smaller mussels, preventing successful tubeworm attachment. Tubeworms were not found on areas of fastest growth such as the posterior shell edge but predominately on shell growth checks and on the umbo indicating settlement to have occurred on regions of relatively slower growth and/or at periods of disturbance and slow growth. The density of smaller mussels established on culture lines is greater than large mussels, having smaller interstices between individuals and less of a surface area for settlement of fouling organisms. As mussels age, a change in the nature of the mussel shell texture or its biofilm may make them more attractive for tubeworm settlement. No effects of initial stocking density or tubing system on tubeworm settlement on small mussels were distinguished, indicating that size has a greater influence on settlement than either of these two factors. Further work should determine the relationship between mussel size and susceptibility to tubeworm settlement.

P. triqueter settlement was greatest in treatments with conspecific adults on the mussels. However, there was no difference in tubeworm settlement levels between high and low densities in the fouled mussel treatments. This suggests that the cue to settle provided by conspecifics was sufficient to outweigh the effects of stocking density. Settlement on or near conspecific adults has benefits; adults derive reproductive benefits from being within aggregations and larvae that settle near adults benefit from choosing a habitat likely to support post larval growth (Pawlik 1992). *P. lamarcki* has been shown to settle in response to chemical substances originating from the body of conspecific adults or juveniles (Chan & Walker 1998). As a result, whenever practical, individuals with fouling should be removed from mussels that are to be retubed for on growing.

Tubeworm numbers were more abundant on the clean large mussels stocked at low stocking densities; this may be attributed to greater shell surface areas exposed for settlement and or a decrease in overall feeding activity in mussels at lower densities on the culture line. In areas of high tubeworm settlement, mussel lines should be stocked at optimum densities for maximal rapid growth and distributed evenly throughout the tubing.

A wide variation in fouling intensity was observed among mussels stocks with different treatment histories at the farm site. Differences in the fouling intensity between the stocks are most likely to be attributed to the settlement intensity of tubeworm and the size of mussels at the time of retubing. The influence of depth on settlement was not as distinct along mussel culture lines when compared with the collector slates. Consequently, adjusting culture line depth to control fouling may prove ineffectual. No correlation could be found between mussel density and degree of fouling. However, counting the number of mussels on a meter of culture rope may have been too insensitive as a measurement of density as mussel density was not always homogenous within a meter of culture line and settlement site selection by tubeworm is influenced over small scales (Pawlik 1992). Further studies of increased precision would determine the true effect of these variables.

As a result of the discrete nature of *P. triqueter* settlement, mussel growers could routinely monitor tubeworm settlement and to avoid practices such as grading and returning mussels to the water in periods of intense tubeworm settlement. Monitoring settlement should be conducted specifically for each loch. Growers should monitor settlement in conjunction with physical variables such as seawater temperature and salinity specific to individual sites to reveal areas and conditions that consistently yield lower levels of tubeworm fouling, and criteria for establishing new mussel farm sites should include hydrographic conditions that minimize tubeworm fouling. Furthermore, mussel-management strategies should adhere to minimizing the time mussel stocks are in the water, particularly in the second growing season when individuals reach a critical size and become vulnerable to excessive tubeworm fouling. In contrast, an alternative approach to limiting tubeworm settlement might be to avoid grading in the second year, thereby

TABLE 7.

The regression coefficients α and β and respective SE, Pearson's correlation coefficient (*r*), probability and predicted aerial emersion times (t_{pred} [hr]) with upper and lower 95% confidence intervals (C.I.), to achieve 100% mortality for *P. triqueter* at 7°C and 13°C after a 48-h recovery period.

Temperature	*n*	Coefficient α (±SE)	Coefficient β (±SE)	*r*	t_{pred} (h)	Lower 95% C.I.	Upper 95% C.I.
7°C	24	116.8 (±6.52)	−4.86 (±0.402)	−0.919 ($P < 0.001$)	35.4	33.0	38.6
13°C	24	126.2 (±9.38)	−3.57 (±0.323)	−0.940 ($P < 0.001$)	24.1	22.3	26.5

leaving mussels undisturbed and allowing a mixed size-class feeding colony to develop.

Adult *P. triqueter* were comparatively resilient with respect to aerial immersion, with a predicted mean 100% mortality after 24.1 h and 35.4 h at an air temperature of 7°C and 13°C, respectively. However, as a result of the lengths of immersion time needed to achieve 100% *P. triqueter* mortality, it may not be practical for growers to use aerial exposure as a method to control tubeworm growth on mussels to be retubed and harvested at a later date. Although no mussels died within the experimental period, aerial immersion over such periods of time may cause undue stress in rope-grown mussels unaccustomed to exposure, resulting in higher mortalities after grading and retubing and delayed growth.

ACKNOWLEDGMENTS

The authors thank David Scott of Loch Striven Mussels and Ian MacKinnon of Loch Beag Mussels for their invaluable contribution towards the project. Sincerest thanks are also due to Simon Howard and Callum Cameron of Loch Striven Mussels for their support throughout. This study was funded by Highlands and Islands Enterprise, The Highland Council and The Crown Estate.

MUSSEL DREDGING: IMPACT ON EPIFAUNA IN LIMFJORDEN, DENMARK

PER DOLMER*

Danish Institute for Fisheries Research, Charlottenlund Castle, 2920 Charlottenlund, Denmark

ABSTRACT Species composition and population density of epibenthos are described in two areas in Limfjorden, Denmark. Both areas covered both a mussel fishing ground and an area that has been permanently closed for mussel dredging since 1988. Furthermore, mussels were dredged in a part of the mussel fishing grounds in both areas four months before the investigations. The rest of the fishing grounds had not been exploited for at least four years. This study describes the short-term impact (4 mo) and long-term impact (>4 y) of mussel dredging using the permanently closed areas as controls. The data were analyzed by multivariate statistics. In both short-term study areas significant effects of dredging were observed. A number of taxa (sponges, echinoderms, anthozoans, molluscs, crustaceans, and ascidians) had a reduced density or were not observed in fished areas four months after the fishing was ended. In one of the two long-term study areas, significant differences in species composition and density were observed between fished and closed areas, indicating that the fishery may have a long-term impact on the epibenthic community, whereas in the other long-term area no difference was observed between fished and control areas. Significant reductions in the amount of shell debris and gravel were observed in the dredged areas. The impact of the loss of these benthic structural components on ecosystem processes and functions is discussed.

KEY WORDS: long-term impact, short-term impact, fishery impact, benthic epifauna, mussel dredging, seabed structure

INTRODUCTION

The use of dredges, beam-, and otter-trawls in demersal fisheries and the development of heavier gear types with increased fishery effort have raised a growing concern on the impact at benthic ecosystems (see review by Jennings & Kaiser 1998, Hall 1999, Collie et al. 2000). Recent studies have investigated the direct impact of towed-bottom fishing gear on benthic organisms (Bergman & Hup 1992, Eleftheriou & Robertson 1992, Brylinsky & Gibson 1994, Thrush et al. 1995, Currie & Parry 1996, Collie et al. 1997, Tuck et al. 1998, Hall-Spencer et al. 1999, Hoffmann & Dolmer 2000, Dolmer et al. 2001), the impact on seabed topography and seabed composition (Hall et al. 1990, Pranovi & Giovanardi 1994, Kaiser & Spencer 1996, Schwinghamer et al. 1998), and the effect of suspension of bottom sediment and release of oxygen-consuming substances and nutrients (Riemann & Hoffmann 1991, Dyekjær et al. 1995, Pilskaln et al. 1998). Indirect effects of the fisheries include changes in the trophic structure (Babcock et al. 1999) as the reported increase in density of scavengers feeding on injured or discarded species (Gislason 1994, Jennings & Kaiser 1998) or as changes in species behavior and species interactions (Ramsay & Kaiser 1998).

Because the blue mussel is an economically and ecologically important species in many coastal areas, mussel dredging may significantly affect the form and the function of benthic ecosystems. Blue mussels form tridimensional matrices of byssus-thread interattached mussels. These stabilized structures are important for assemblages of associated organisms (Tsuchiya & Nishihira 1985, 1986, Svane & Setyobudiandi 1996, Ragnarsson & Raffaelli 1999). In soft-bottom habitats, solid components such as gravel and biogenic structures such as mussel beds and shell debris substantially increase substratum heterogeneity and complexity. These structures are reported to be important for invertebrates as spatial refuges from predators (Heck & Crowder 1991, Dumas & Witman 1993, Lee & Kneib 1994, Thiel & Dernedde 1994) or as a substratum for settling invertebrates and sessile organisms (Witman & Suchanek 1984, Baker 1997, Lapointe & Bourget 1999). Mussel dredging may destroy mussel bed structures and remove important seabed structuring components such as shell debris and gravel. The fishery thus exerts a potential direct impact on the ecosystem by changing benthic habitat structures and indirectly interfering with invertebrate settling processes and prey–predator interactions.

In Limfjorden, Denmark, an extensive fishery for blue mussels, *Mytilus edulis*, exists. In a previous study in Limfjorden, Dolmer et al. (2001) demonstrated that mussel dredging reduced the density of invertebrates living in the bottom. In particular, the polychaetes were significantly reduced in number. Another investigation in 1997 of the long-term impact of mussel dredging on the epifauna in an area that has been closed for mussel dredging since 1988, however, failed to show any effects of the mussel fishery (Hoffmann & Dolmer 2000). The aim of the present study was to compare the spatial composition of assemblages of epibenthic fauna on mussel fishing grounds four months after a fishery was finished, in areas that have not been fished for more than four years, and in areas that have been permanently closed since 1988 to test the short-term and long-term impacts of mussel dredging on the epifauna. The second objective of the study was to measure the impact of mussel dredging on the amount of shell debris and gravel on the seabed.

MATERIAL AND METHODS

The study was conducted in Limfjorden (Fig. 1). This area is a micro-tidal, eutrophic water system of interconnected enclosures in northern Denmark, supporting a high production of blue mussels. The mean mussel biomass in the part of the area open to mussel dredging (~750 km^2) is about 600,000 tons with large temporal variations (Dolmer et al. 1999). This biomass supports the largest fishery in Europe exploiting natural mussel populations. The annual mussel landing is approximately 100,000 tons or 15% of the mussel stock.

The short-term and long-term impact of mussel fishing on benthic epifauna was investigated in two different areas in Limfjorden: in Løgstør Broad, in the central part of the fjord, and in the Agerø area, in the western part of the fjord (Fig. 1). Part of both areas has been permanently closed to mussel fishing since 1988. In Løgstør Broad, the northern part of the area is closed and in the Agerø area, the central part is closed. During April–May 1999 (4 months before the investigation) mussels were commercially dredged in the area just southwest of the closed area in Løgstør

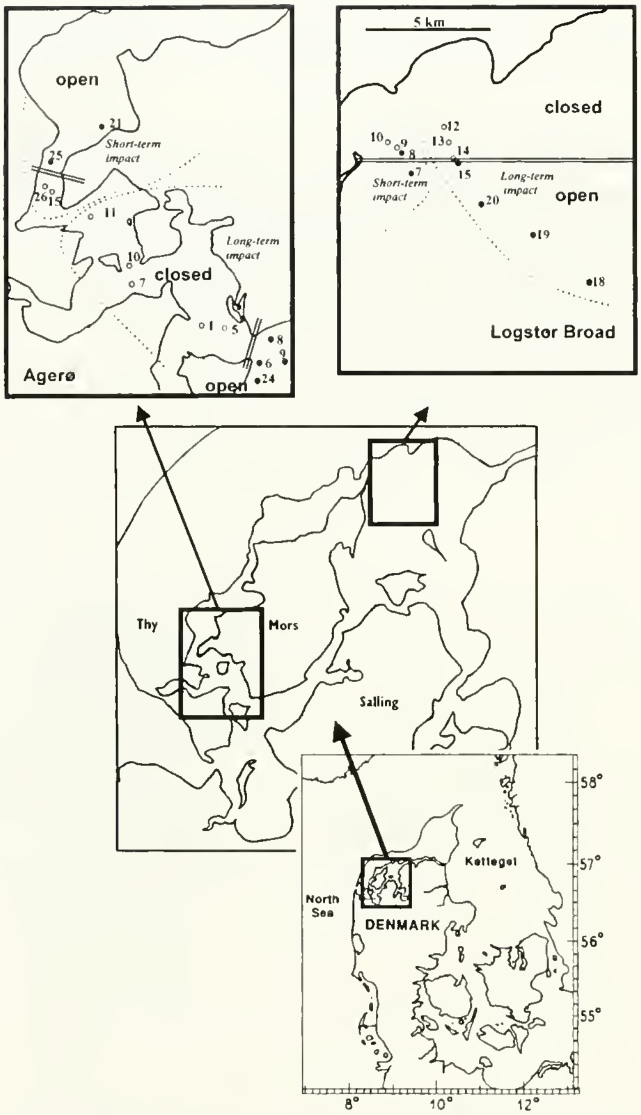

Figure 1. Map of the two study areas and their stations. The double lines indicate the separation between fished areas and areas that have been closed to mussel fishing since 1988. In Løgstør Broad (eastern area), the area north of the double line is closed and the area south of the line is fishing ground. In the Agerø area (western area), the area between the two double lines is closed to mussel fishing. The stations used in the analyses of long- and short-term impact are separated with dotted lines. (○) control stations and (●) stations with mussel dredging.

Broad and in the area just north of the closed area in the Agerø area. Furthermore, data from the mussel stock assessment program, where the mussel biomass at 250–350 stations in the Limfjorden is described annually (Dolmer et al. 1999), indicate that that the area southeast of the permanently closed area in Løgstør Broad and the area south of the permanently closed Agerø area has not been fished at least since 1996. Epifauna in the Løgstør Broad and the Agerø areas was described in September 1999 to test whether the species composition and density differed between permanently closed areas, areas that were fished four months before the study, and areas that had not been fished for more than four years. Replicated stations in the area closed to fishing were contrasted with replicated stations located in adjacent areas that were subject to harvesting practices.

Short-Term Impact (4 Mo)

Stations 7–8 in Løgstør Broad and stations 21 and 25 in the Agerø area were fished by mussel dredge during April–May 1999 and significant impact on the seabed was observed when diving in September. To test the impact of dredging on the epifauna species, composition on the two stations in each area was contrasted with two control stations in the nearby closed areas. Stations 7 and 8 were contrasted with stations 9 and 10 in Løgstør Broad and stations 21 and 25 were contrasted with stations 15 and 26 in the Agerø area (Fig. 1). No signs of dredging activity were observed on the seabed when diving at the control stations.

Long-Term Impact (>4 Y)

In the eastern part of Løgstør Broad, the stations in the closed area (12, 13, 14) were contrasted with the stations in the area open for mussel dredging (15, 18, 19, 20). In the Agerø area, the stations in the closed area (1, 5, 7, 10, 11) were contrasted with the stations in the area open for mussel dredging (6, 8, 9, 24).

At each station, the epifauna (>1) cm was identified and quantified. Colonial species such as hydrozoans and bryozoans were omitted from the study because of difficulties in quantifying these taxa. The sponges were included in the investigation, and here each distinct colony was classified as one individual. At each replicated station, the epifauna in 30 circles of 0.24 m^2 were quantified by use of SCUBA diving. The circles were marked with an iron ring randomly placed on the sea floor. The material in the last 10 circles was collected and the population density of blue mussels and the weights of shell debris and pebbles were measured in the laboratory.

The epifauna species composition and density data was tested with the PRIMER-5-package (Plymouth Routines in Multivariate Ecological Research). Before the analysis, the ring samples without epibenthic organisms were excluded from the datamatrix. Bray–Curtis similarity indices were calculated on 4^{th} root transformed species density data according to Clarke and Warwick (1994). The stations were plotted in a Multi-Dimensinal Scaling plot (MDS) to identify separate clusters of stations. Differences between contrasted stations were tested in two steps by ANOSIM analyses. It was tested if there were differences among replicated stations within each treatment area (fished contra closed) in each area and if differences ($P < 0.01$) were obtained then an ANOSIM analysis tested for differences in species composition between contrasted stations on average ranked data. If no differences were observed among replicated stations then an ANOSIM analysis tested for differences between contrasted stations on the set of data treating each ring observation observations as separate data. The SIMPER procedure identified which taxa contributed most to the dissimilarity among contrasted stations. The significances of the differences in density of these taxa were tested with t tests.

Observed differences between contrasted stations can be due to short-term and long-term impacts of mussel dredging or may be caused by environmental gradients in the study area. It was assumed that if an environmental gradient affected the similarity between stations there would be a positive relationship between spatial distance and similarity between stations. On a MDS plot, the stations would then form a unidirectional track with the spatial and similar close stations close to each other and most spatial distant and dissimilar station at the longest distance. To test whether the similarity among stations was related to their spatial relation, the MDS plots of the stations, including an indication of the stations spatial relationships, was analyzed.

Impact on Substratum

The data on weights of shell debris and gravel at each of the short-term impact study stations were tested separately for the Løgstør and the Agerø Area in nested two-way ANOVAs with fishery/closed status as the first factor and the stations as the second factor—nested to the fishery/closed factor. Before the tests, the data were *ln*-transformed and tested for homoscedasticity (F_{max}-test). To test the relationship between diversity and substratum composition, a Shannon–Wiener index was calculated for each sample from the short-term study stations. The relationships between this index and the amounts of shell debris and pebbles were analyzed by linear regression. To test the role of mussels forming a biogenic substratum important to the associated fauna, the relation between the Shannon–Wiener index and the density of mussels in each sample was analyzed by linear regressions at station 7 and 8 and 9 and 10 in Løgstør Broad.

RESULTS

During the investigation, a total of 11 and 20 different epifauna species were recorded in Løgstør Broad and the Agerø area, respectively. MDS ordinations of the stations in Løgstør Broad and the Agerø area showed that the stations in the short-term study areas were separated into two clusters, including stations from the fished and the closed part of the study areas, respectively (Fig. 2). The separation of the stations from the long-term study areas was not that clear-cut. Low oxygen concentrations (<2 mg O_2 l^{-1}) were recorded during two weeks in August 1999 in parts of Løgstør Broad. Some mortality of blue mussels was observed after this oxygen deficiency, but also other species may have been affected. Because the distribution of areas with oxygen deficiency did not overlap with the distribution of the fished areas, the low oxygen concentration did not interfere with the results of this study.

Short-Term Impact

In the two short-term study areas, no differences were observed among stations within each treatment area and the difference between dredged and closed stations was tested on complete sets of data. The ANOSIM analysis showed that there were significant differences between the two dredged stations and the two control stations in both Løgstør Broad ($P = 0.001$) and the Agerø area ($P = 0.001$). The SIMPER procedure and *t* tests indicated that a large number of species disappeared or had a reduced density in the two dredged areas, including poriferans, echinoderms, anthozoans, gastropods, crustaceans, and ascidians (Tables 1 and 2). Splitting the data into two functional groups, mobile and sessile species, indicated that the sessile species contributed to a larger part of the dissimilarity between the control and the dredged stations (51–61%) than the mobile species, although these species still contributed significantly to the dissimilarity (30–42%). ANOSIM analyses on data split into functional groups showed a significant dredging impact on sessile fauna both in Løgstør Broad and in the Agerø area (Table 3).

Long-Term Impact

In both Løgstør Broad and the Agerø area, significant differences among stations within each treatment area (fished contra closed) were observed (Table 3). Consequently, the analysis of the long-term fishery impact was conducted on average rankings and re-ranked data. The ANOSIM analyses testing the species composition at the stations in the fished area in the southern part of Løgstør Broad and in the closed northern part showed that there was no difference ($P = 0.771$) between stations indicating that no long-term effects could be observed. In the Agerø area, a significant difference ($P = 0.024$) between the species composition in the central closed area and the southern area where mussel dredging is legal may indicate a long-term impact. The SIMPER procedure and *t* tests on data from the Agerø area indicated that a number of species disappeared or had a reduced density in the area open to mussel dredging (Table 4).

The MDS of the similarity between stations and their spatial relationships (Fig. 3a and b) show no relationship between similarity and spatial distance in the two short-term study areas. This indicates that differences in species composition between stations are not due to an environmental gradient in the area. In the long-term study areas, some of the stations with the longest distance in-between showed a relationship between similarity and distance

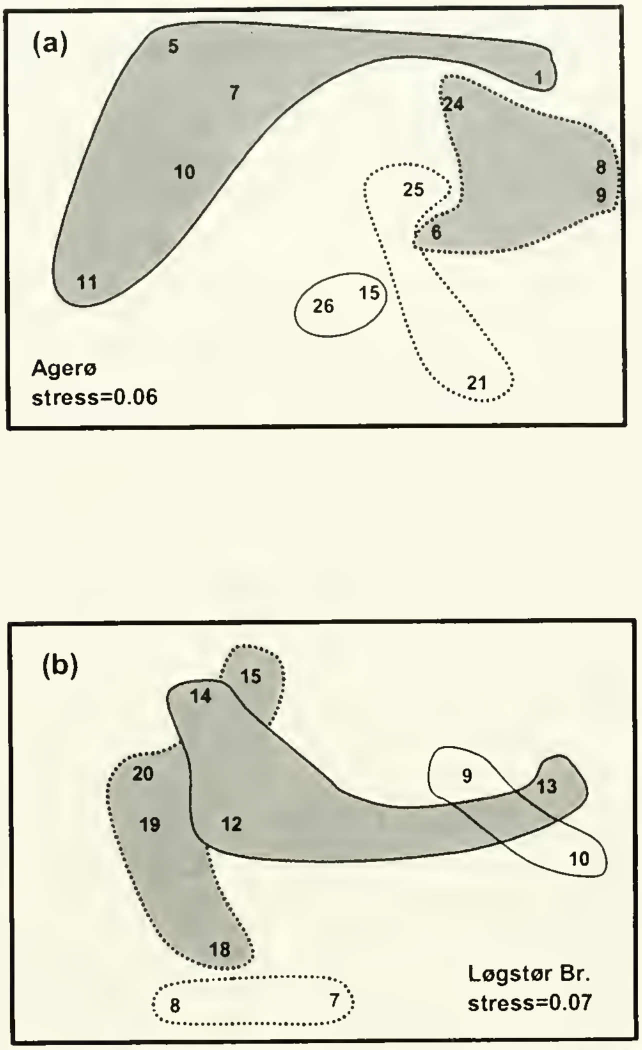

Figure 2. MDS plot of station means in the Agerø area (a) and Løgstør Broad (b). The control area stations are delineated with a solid line and stations from fished areas with a dashed line. The gray background indicates long-term study stations and the white background short-term stations.

(stations 11-10-7 in the Agero area and stations18-19-20-15 in Løgstor Broad). The spatial distribution of the dredged part of the long-term study area in Agerø, with a central station (station 6) and three stations in a semicircle, make an analysis of environmental gradients impossible because no relation between similarity and distance can be established because the distances from station 6 to all three stations in the semicircle are equivalent.

Impact on Substratum

Amounts of shell debris and gravel differed significantly between dredged and control stations in both areas (Fig. 4a and b). In Løgstør Broad, the weights of shell debris ranged from 0.5 kg m^{-2} at station 7 and 8 in the fished area to approximately 2 kg m^{-2} at station 9 and 10 in the control area. In the Agerø area, the weights of shell debris ranged from 0 kg m^{-2} at station 21 and 25 in the fished area to 1 kg m^{-2} at station 15 in the control station. Gravel was only found at the stations in Løgstør Broad ranging from 0 kg m^{-2} at station 7 in the fished area to 0.7 kg m^{-2} at station 9 in the closed area. The nested ANOVA analyses for both areas showed a significant effect of dredging on the weights of shell debris (P = 0.000) whereas no significant differences were observed among stations when nested to the fished/control areas (Løgstør B: P = 0.467, Agerø: P = 0.215). The weights of gravel were not only significantly affected by the dredging (P = 0.000), but also by the stations (P = 0.001). Plotting the Shannon–Wiener diversity (H′) index in the samples from Løgstør Broad as a function of the amount of shell debris a significant ($P < 0.01$) positively correlation was obtained for the data from the fished area. The similar relationship hold constant in the permanently closed area (Fig. 5). As the amount of shell debris in the Agerø and the weight of pebbles in Løgstør broad are low at the fished stations, similar relations cannot be plotted for these data. The relationship between H′ and the mussel density (Fig. 6) showed a similar pattern. A significant positively correlation ($P < 0.01$) was observed in the area open to mussel dredging whereas in the permanently closed area only a trend can be detected (P = 0.09)

DISCUSSION

To achieve a holistic sustainable management of fisheries, knowledge of the fishery impacts on the target populations and the ecosystem is required. In respect to fishery impact on ecosystems, such management has to consider both the short-term and long-term impact and the recovery time for the ecosystem to re-establish a habitat. This study describes significant differences in the species composition among stations in areas fished four months before sampling and control stations. A number of taxa (poriferans, echinoderms, anthozoans, molluscs, crustaceans, and ascidians) had a reduced density or were not observed in fished areas four months after the fishing was ended. These differences included reductions in both mobile and sessile species. Differences in the species composition were also observed between an area that had not been fished for more than four years and a closed control area. A significant reduction in shell debris and gravel was observed in dredged areas.

The observed differences between stations in fished and closed areas may be due to mussel dredging but could also be caused by environmental gradients in the study area (e.g., wind exposure, water current, sediment composition, primary production). A MDS plot relating similarity and spatial distance between stations, however, did not indicate any relation in the short-term areas, suggesting that the observed differences in species compositions are due to dredging activity and not due to environmental gradients. As the distance between the closest dredged and control stations in the short-term in Agero and Løgstør Broad is 750 and 200 m, respectively and that the demarcation line between fished and closed area was drawn without any reference to physical conditions in the area, it is reasonable to conclude that no environmental gradients were involved. The stations used in the long-term impact analysis had a more extensive distribution, with <10 km between the most distant stations. In Løgstør Broad, the dissimilarity was related to the distance between stations, indicating that a gradient probably influenced the area. This environmental gradient may increase the variability in species composition, making it more difficult to detect long-term impact of the fishery. In the Agerø area, the way the stations were distributed made the detection of an environmental gradient difficult. Consequently, it is difficult to judge whether the observed differences in species compositions were due to long-term impact of mussel dredging or to a gradient.

The design of fishery impact studies is a trade-off between a robust experimental design and the amount of effort that can be invested in the study. An often-used statistical design is a BACI

TABLE 1.

Short-term impact: species contributing to the dissimilarity (%) between fished stations 7–8 and control stations 9–10 in a closed area in Løgstør Broad.

			St 7–8 Dredged		St 9–10 Control

Sessile species Agerø	0.1–91	Complete set of data	0.039	4

The data in each area was analysed in two steps. First it was tested if there was difference among stations within each treatment area (fished contra closed), and if there were differences ($P < 1\%$) then the analysis of the fishery impact was conducted on average rankings. If no difference was observed, then the impact analysis was conducted on complete sets of data.

TABLE 4.

Long-term impact: species contributing to the dissimilarity (%) between fished stations (6, 8, 9, 24) and control stations (1, 5, 7, 10, 11) in a closed area in the Agero area.

		Dredged		Control

design (Before-After-Control-Impact) that also tests for temporal and spatial variability in a study area. It is important for the results of experimental impact studies of trawling and dredging that impacted areas are large (Thrush et al. 1995). A meta-analysis of the impact of demersal fishing gear on benthos (Collie et al. 2000) demonstrated that the recovery time is shorter in small impacted patches because of larger edge effects. The results of experimental studies may then be strongly dependent on the experimental design. This study investigated the impact of an unplanned mussel fishery, in which the scale of the study area is very large compared with the experimental studies. This ensures that the results are not affected by the experimental design. Contrary, the character of the study implies that a causal relation between the observed variations in species and substrate compositions and fishery impact not can be established, although the study represents strong indices of the impact of dredging.

Fishery impacts may significantly affect ecosystem function. Some of the species that were partly or fully eliminated from fished areas were sessile filter feeders (poriferans, anthozoans, molluscs, and ascidians). In shallow-water bodies such as Limfjorden, these filter feeders exert an important control mechanism over the pelagic primary producers (Cloern 1982, 1991, Petersen & Riisgård 1992, Dolmer 2000) and reduction of a benthic filtration capacity may weaken bentho-pelagic coupling. Apart from the filtration capacity, the coupling between the pelagia and benthos depends on the mixing rates of the water column and the transport rates of material and energy from the water column to the benthos. Seabed roughness is a determinant of near-bed mixing (Herman et al. 1999), so smoothing of the seabed by removing mussel beds and larger particles reduces the transport of particles to the seabed and reduces the population filtration rates. Consequently, the fishery interferes with benthic filtration both by removing filter feeders and by changing near-bed hydrodynamics.

The distribution of blue mussels was patchy, and in Løgstør Broad the density of mussels in the fished area was slightly higher than in the permanently closed area. This suggests that the density

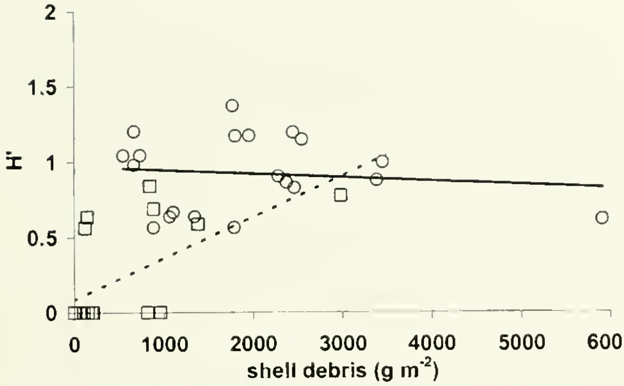

Figure 5. Relationship between the amount of shell debris and Shannon-Wiener indices for each sample at stations 7–10 in Løgstør Broad. (□) indicates samples from the area open to mussel dredging and (○) indicates closed areas. Data were analyzed with linear regression. The dotted line shows the regression on data from the fished area (R^2 = 0.385; $P < 0.01$), and the solid line that on data for the closed area (R^2 = 0.017; $P > 0.05$).

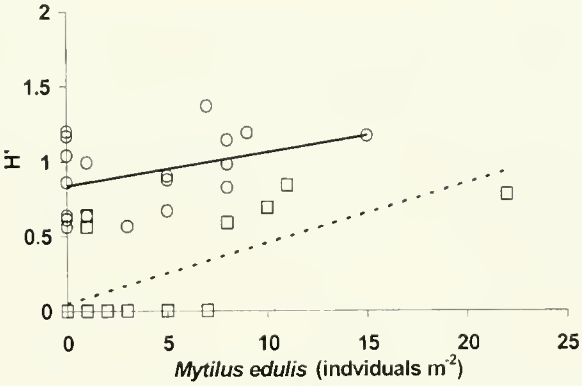

Figure 6. Relationship between density of blue mussels and Shannon–Wiener indices for each sample at stations 7–10 in Løgstør Broad. (□) indicates samples from the area open to mussel dredging and (○) indicates closed areas. Data were analyzed with linear regression. The dotted line shows the regression on data from the fished area (R^2 = 0.470; $P < 0.01$), and the solid line that on data for the closed area (R^2 = 0.152; P = 0.09).

of mussels was much higher in the fished area than in the closed area before the fishery was initiated. As the mussels form a biogenic substratum important for associated fauna, mussel density may influence the distribution of other species. A higher initial mussel density in the area open to mussel dredging, as in the short-term study area in Løgstør Broad, would result in an underestimate of the impact of mussel dredging, as a more diverse associated fauna probably characterized the fished area before the fishery was initiated.

In Løgstør Broad, no long-term impact of mussel dredging was apparent. A previous study also failed to show long-term effects (Hoffmann & Dolmer 2000). In the present study, the multivariate analyses of long-term impacts was conducted on average ranked data resulting from differences among stations within each treatment area. The power of this analysis is much lower than an analysis of the complete data set, which can be used when no difference is observed among stations. To detect an impact of mussel dredging fishery impact must be separated from the noise of other factors affecting the ecosystem (Jennings & Kaiser 1998). Limfjorden is almost bi-annually perturbed by extensive oxygen depletion lasting for several weeks resulting in mass mortality of mussels and other benthic invertebrates. In 1994 and 1997 oxygen depletion caused mortalities of 25–50% of the mussel populations. The scale of these events has to be considered when evaluating the impact of the mussel fishery.

Seabed heterogeneity and complexity is an important feature when discussing the character of benthic habitats. This study has shown that mussel dredging removes larger sessile animals, shell debris, and gravel from fished areas. Furthermore, dredging removes mussels forming an important biogenic substratum for associated fauna. The investigations measured the largest impact on sessile species, but the fishery also affected mobile species after 4 mo. Mussel and shell beds are reported to reduce predation by creation of spatial refuges (Thiel & Dernedde 1994, Lee & Kneib 1994) and Kraeuter and Castagna (1977) reported that *Mercenaria mercenaria* had a 75% better survival when reseeded on shell and gravel substrata than on sand. The impact on epibenthic species is 2-fold: a direct impact of mussel dredging by killing and injuring individuals by direct contact with the mussel dredge and an effect from the changed habitat heterogeneity and complexity. The recovery of the fished habitats is a function of immigration of mobile species and recruitment of sessile and mobile species. Recruitment may also be affected by the changed seabed structure. In many invertebrates larval settlement depends on solid substrata (Young 1983, 1985, Witman & Suchanek 1984, Baker 1997, Lapointe & Bourget 1999) but also changed near-bed hydrodynamic forces may modify larval distribution (Butman 1987, Jonson et al. 1991).

Changing the handling of benthic animals and materials in the fishery by-catch can accelerate the recovery process of ecosystems following mussel extraction. Today mussels below the legal minimum size (<4.5 cm shell length) and waste material (other animals and shell debris) are relayed in certain areas (Kristensen & Lassen 1997). Mussel shells from the cooking process must not be recycled to the seabed and are deposited or used on land. As a consequence of this procedure, important materials are transported away from the fishing grounds. These important materials should be brought back to fished areas. Habitat restoration by relaying small mussels and other invertebrates, shell, pebbles, and larger stones after mussel dredging would reduce the recovery-time both in respect of the form and the function of the ecosystem and would improve the sustainability of the mussel fishery.

The conclusion of this study is that the mussel dredging exerts a significant short-term impact on the benthic fauna. No unequivocal long-term impact could be demonstrated. The fishery changes the seabed structure by removing solid particles and biogenic particles. This impact may be long lasting or even irreversible and may significantly change the function of the ecosystem.

ACKNOWLEDGMENTS

The authors thank Prof. J Collie and Dr. S. A Ragnarsson and three anonymous referees for thoughtful comments and linguistic corrections on the manuscript, and to A. Hansen for practical help in the field. The study was part of the EU-project ESSENSE (Contract FAIR CT98-4201) and was also financially supported by the Limfjords Counties.

FOULING IN SCALLOP CULTIVATION: HELP OR HINDRANCE?

KATHERINE A. ROSS, JOHN P. THORPE, TREVOR A. NORTON, AND ANDREW R. BRAND*
Port Erin Marine Laboratory, University of Liverpool, Port Erin, Isle of Man, British Isles, IM9 6JA

ABSTRACT We examined the effects of fouling on physiochemical and food conditions inside nets used for suspended great scallop (*Pecten maximus*) cultivation. Conditions in clean nets and sites with no nets were similar for the parameters studied and differed from those in fouled nets. Fouling of nets reduced water movement and, contrary to common assumptions, was associated with high levels of plankton and detritus. Obvious negative effects of fouling (e.g., accumulation of inorganic matter or nitrate and ammonia) were absent. It was concluded that in some areas negative effects of fouling may be caused by foulers parasitising or mechanically interfering with scallops rather than creating an unfavorable environment. Our results have important consequences for scallop growers, researchers modelling cultivation in an ecosystem context, and those investigating relationships between the growth of cultivated scallops and environmental conditions.

KEY WORDS: scallop, aquaculture, biofouling, *Pecten maximus*, suspended culture, pearl nets, environmental conditions, particulate matter, Irish Sea

INTRODUCTION

Immersion in plankton-rich water generally enables scallops in suspended cultivation to grow faster than on the seabed, under natural conditions (MacDonald & Thompson 1985, Wallace & Reinsnes 1985, Hardy 1991). Unfortunately, the conditions that promote scallop growth also encourage fouling of cultivation nets and scallop shells. This is costly because it increases the weight and drag of cultivation equipment and is difficult to remove (Hardy 1991). Fouling can also affect scallop growth and appearance.

Fouling of scallop shells and cultivation nets has been shown to reduce the growth of immature scallops (Claereboudt et al. 1994a, Lodeiros & Himmelman 1996, 2000). It is assumed that fouling organisms reduce scallop growth by competing for food and space or by reducing water flow through nets, and hence the supply of food and oxygen and removal of waste products (Duggan 1973, Leighton 1979, Huguenin & Huguenin 1982, Côté et al. 1993, Enright 1993, Claereboudt et al. 1994b, Lodeiros & Himmelman 1996, Lu & Blake 1997). Fouling of scallop shells increases the weight of upper valves and can bind upper and lower valves together. This increases mortality or reduces growth, probably because scallop feeding and respiration is inhibited (Paul & Davies 1986, Minchin & Duggan 1989, Roman 1991, Lu & Blake 1997, Lodeiros & Himmelman 2000). Other potentially negative effects of fouling include irritation of the scallop mantle (Getchell 1991, Mortensen et al. 2000) and parasitism by species, including polychaete worms and amphipods (Leibovitz et al. 1984, Mortensen et al. 2000). However, the influence of fouling varies. Some researchers have concluded that fouling does not affect bivalve growth (Wallace & Reinsnes 1985, Widman & Rhodes 1991, Lesser et al. 1992, Lodeiros et al. 1993, Lodeiros et al. 1999), whereas other work suggests that fouling can have beneficial effects (Ross 2002). Potentially beneficial effects include a positive influence on plankton abundance (invertebrate assemblages release nutrients, promoting primary production, Dame & Dankers 1988, Asmus & Asmus 1991, Peterson & Heck 1999, Arzul et al. 2001, Mazouni et al. 2001) and, in areas of high flow, reduction of fast water currents that might otherwise inhibit scallop feeding (Côté et al. 1993, Devaraj & Parsons 1997).

The present study aimed to determine how fouling on pearl nets alters the environment for great scallops (*Pecten maximus* (L.)). Divers collected water samples from clean and fouled nets (both containing scallops) and from sites with no nets (i.e., the water column nearby), enabling us to isolate the influence of fouling on physiochemical and food conditions. This is the first investigation to examine environmental conditions inside bivalve cultivation nets and thus provides a unique description of how fouling could affect scallop growth. Fouling is typically countered by frequent net cleaning with high-pressure water hoses or regular net changes (Hardy 1991, Laing & Spencer 1997). Both methods are labor intensive, increase equipment requirements, and are thought to stress scallops, reducing their growth rates (Wildish & Kristmanson 1988, Parsons & Dadswell 1992, Enright 1993, McDonough 1998, Ross 2002). The results of this experiment should help growers to tackle fouling efficiently, thereby saving time and money. The study was conducted in an exposed Irish Sea location off the Isle of Man. However, the major foulers (hydroids and amphipods) are ubiquitous (see e.g., Hidu et al. 1981, Arakawa 1990, Enright 1993, Claereboudt et al. 1994a) and thus the results are likely to be relevant where scallop cultivation is performed in other areas with high water flow.

MATERIALS AND METHODS

Field Work

Two longline systems (subsequently referred to as the north and south systems) were positioned off the Southwest coast of the Isle of Man in approximately 23 m of water (Fig. 1). Longline head-ropes were approximately 10 m below the sea surface. The tidal range in this area is 6 m and peak flows are approximately 1 m/s. Experiments were performed in June 2000 during spring tides. Gross tidal flow runs parallel to the systems, but nearby rocky outcrops cause erratic local flow patterns that sometimes extended to the south system. Salinity is 34 ppt, and water temperatures reach a summer maximum of about 15°C and winter minimum of 6°C (T. Shammon, personal communication 2001). To the north east of the longlines untreated sewage from Port Erin (population ca. 2,800) is discharged in the lower intertidal (Fig. 1).

Pearl nets were hung in strings of three, with a 2-kg weight attached below the lowest net. The nets had a plastic covered square wire frame base with sides of 34 cm and black, monofilament mesh with 16 mm^2 spacing. The mesh is the same as that

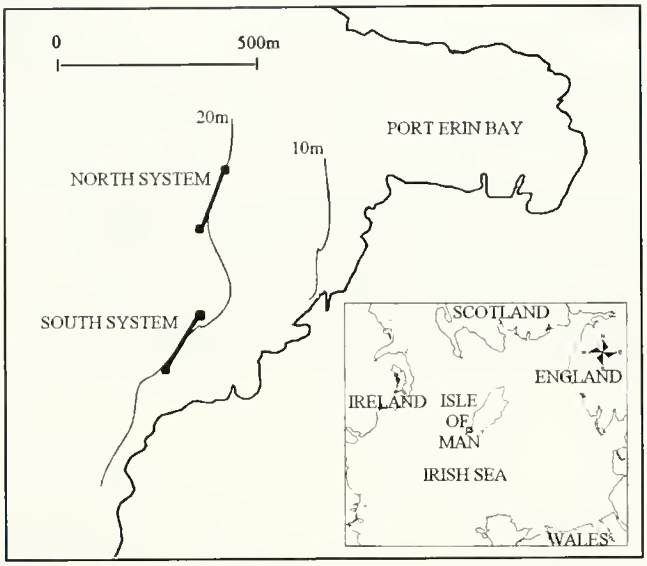

Figure 1. Location of longline systems off the Isle of Man, Irish Sea.

commonly used for lantern nets, and thus the results of these investigations are probably relevant for on-growth in both pearl and lantern nets. For logistical reasons only the top nets, hung about 0.15 m below the head-rope, were sampled. The nets used for nutrient samples contained ten 2–3 yr old *P. maximus* with a shell length of 65–85 mm. For water flow experiments, nets contained 10 flat pebbles whose combined weight equalled that of 10 scallops. Pebbles were used instead of scallops because scallop movement may have abraded the plaster balls, leading to inaccurate estimates of water motion. Scallop-sized pebbles were chosen so that water flow and net movements matched those of nets containing scallops. Nets for flow measurements had loops in the central, supporting rope, and a door so that plaster balls could be inserted and fixed centrally. Door fastenings and support were on net seams so that they did not alter water flow.

Ammonia, nitrate, particulate matter, plankton, and water motion were measured in clean nets, fouled nets, and open water sites. Fouled nets had been immersed for 16 weeks before the sampling whereas "clean" nets had been deployed for only 2 wk. Open-water sites were positions under the head-rope of the longline, at the same depth as experimental nets. Treatments were arranged randomly, at 1-min intervals, along the two systems. On each system, treatments were replicated five times for nutrient experiments and four times for water flow experiments. Nutrient and water motion experiments were performed side by side on the longlines. Water motion was measured for 48 h, during which time water samples were collected.

Diving was performed from the R.V. Sula. Syringes with 120-mm Teflon tubing tips (3-mm diameter) were used to collect samples in preference to permanent sampling tubes (which would have become fouled) or electronic probes, which are difficult to use accurately *in situ*. Divers collected a complete set of 15 or 20 nutrient samples (for example, all of the ammonia samples from one longline) using labeled syringes. To prevent disturbance, nets were not touched or moved either before or during sampling. To remove any trapped debris from the syringe tip, 5 mL of water was taken up outside the nets and expelled once the tip was in position. Water samples were then collected slowly to minimize disturbance and to avoid sampling water from outside the net. Dives lasted a maximum of 20 min, after which samples were returned to the boat. Samples were collected from nets by two pairs of divers deployed at 10-min intervals. Sampling was alternated between longlines so that no more than two samples, totalling 160 mL of water (1% of the net volume), were taken from a net in 4 h. Before sampling, all bottles and syringes were washed in dilute acid and rinsed in distilled water.

Physiochemical Conditions

Ammonia and nitrate were measured in 100-mL water samples, which were kept in the dark on ice during the short boat journey back to the laboratory. In the laboratory ammonia and nitrate samples were filtered, through GF/F papers, into bottles and frozen. An Alpkem autoanalyser (RFA 2) was later used to determine nutrient concentrations.

Plaster of Paris spheres can be used to accurately measure time integrated water motion (Thompson et al. 1994); in these experiments, they proved to be a reliable alternative to expensive micro-flow meters. The spheres were made by combining 100 g of Plaster of Paris ($CaSO_4$) with 90 mL of distilled water. The plaster was mixed to a smooth paste, tapped to remove air bubbles, and then poured into moulds. Moulds were plastic spheres (70-mm diameter) with a central wire. Filled moulds were vibrated for 10 min to remove trapped air. Plaster spheres were removed from their moulds after approximately 12 h and placed in a well-ventilated area to dry. After at least 4 wk, spheres were dried at 30°C to a constant mass (accelerated drying at high temperatures can affect the crystalline structure of $CaSO_4$ (Muus 1968).

Before immersion, plaster spheres were wrapped in soft cloths to prevent chipping and to minimize dissolution. Divers opened nets and fixed spheres centrally so that they were not abraded by contact with fouling organisms or nets. At open water sites, wire was used to suspend spheres below the head-rope, at the same level as spheres inside nets. Once in position, the cloths were removed and the nets were resealed. After 48 h, divers retrieved spheres and wrapped them in soft cloths before returning to the boat. In the laboratory, the spheres were dried to a constant mass and their final surface area was calculated from volume measurements obtained by fluid displacement.

Plaster dissolution rates (V_d) provide an indication of relative water motion:

$$V_d = \frac{(W_1 - W_2)}{AT}$$

Where W_1 and W_2 are the weight of the sphere at the beginning and end of the experiment respectively, A is the mean surface areas of the sphere, calculated from start and end values, and T is the time over which spheres were immersed (Thompson et al. 1994).

Food Conditions

Water samples (100 mL) for particulate matter analysis were kept in the dark on ice during the boat journey back to the laboratory. Particulate matter was filtered onto preashed papers immediately on return to the laboratory. The papers were rinsed with isotonic ammonium formate and then dried at 40°C to a constant weight and ashed overnight at 450°C. The GF/F filter paper used to collect particulate matter had a pore size of 0.7 μm. Particulate organic matter (POM), particulate inorganic matter (PIM), and total particulate matter (TPM) were calculated as follows:

$$\begin{aligned}\text{POM} = {} & \text{dry weight of filter paper and sample} \\ & - \text{ashed weight of filter paper and sample}\end{aligned}$$

TPM = dry weight of filter paper and sample
– filter paper ashed weight
PIM = ashed weight of filter paper and sample
– filter paper ashed weight

As soon as the water samples were taken up to the boat, 60-mL samples were transferred to bottles with 1.2 mL of neutral Lugol's iodine. The bottles were stored in the dark until plankton were counted, measured, and categorized using inverted microscopy and the computer programme SCION image analysis for Windows. Samples were settled in a counting chamber following the methods of Utermöhl (Hasle 1978). Dense samples were diluted with filtered seawater so that all of the plankton in the chamber could be counted. To ensure that the precision of plankton counts was greater than 20% of the total count, the volume of sample enumerated always contained more than 150 individuals of the most abundant organisms (Postel et al. 2000). Organisms were recorded according to type (small plankton, centric diatoms, pennate diatoms, diatom chains, solitary chain-forming diatoms, pelagic ciliates, benthic ciliates, dinoflagellates, flagellates, crustaceans, nematodes, invertebrate larvae, and eggs and spores) and maximum length (5–10, 11–20, 21–50, 51–100, and >100 μm). Small plankton were all organisms of 50–10 μm; generally these were flagellates and diatoms.

Statistical Analyses

The experimental design was balanced; location was a random factor with two levels, north and south systems, and treatment was a fixed factor with three levels, open-water sites, clean nets, and fouled nets (Underwood 1997). Physiochemical conditions were measured in five replicates per treatment for each system, but time constraints meant that plankton data were obtained only for three replicates per treatment-longline combination. Concentrations of plankton and nutrients and rates of plaster erosion for each treatment were examined using two-way analysis of variance (ANOVA). Heterogeneity of variance was tested for using Cochran's test (Winer 1971) and where necessary data were transformed. Some data were heterogeneous even after transformation, but ANOVA was still applied because the experimental design was balanced and large (Underwood 1997). However, such analyses increase the probability of a type I error, and therefore significant results should be interpreted with caution. When ANOVA showed that the probability of a treatment effect exceeded 0.05 and there was no interaction between location and treatment ($P > 0.25$), data for the two systems were pooled, thus increasing the power of ANOVA to detect treatment effects (Underwood 1997). When ANOVA indicated significant factors or interactions between factors, post-hoc Student–Newman–Keuls tests were performed to determine which means differed. All analyses were performed using GMAV5 (Underwood et al. 1998). Ammonia measurements were analyzed by ANOVA and concentrations below the limit of detection were included as 5 μg/L, the highest undetectable value. This conservative approach increased the probability of type II error.

As described above, plankton were classified as one of 45 groups according to their size and type. The data set was then analyzed using nonparametric, multivariate techniques included in the PRIMER (Plymouth Routines in Multivariate Research) software package (Clarke & Warwick 1994). Bray-Curtis similarity indices (Bray & Curtis 1957) were calculated between all pairs of samples to produce a data matrix (after a square-root transformation was used to slightly reduce the contributions to similarity of the most abundant species). The similarity matrices were ordinated and clustered using non-metric multi-dimensional scaling (MDS) and hierarchical agglomerative clustering (on group-average linkage), respectively (Clarke & Warwick 1994). The two-dimensional MDS plot had a low stress value and hence the dendrogram from CLUSTER analysis is not presented here. Instead, levels of similarity from cluster analysis are indicated on the MDS plot (Fig. 4). *A priori* tests of the differences between locations and treatments were performed using a two-way, crossed ANOSIM (analysis of similarity), and the plankton groups contributing most to any differences found between the groups were determined using

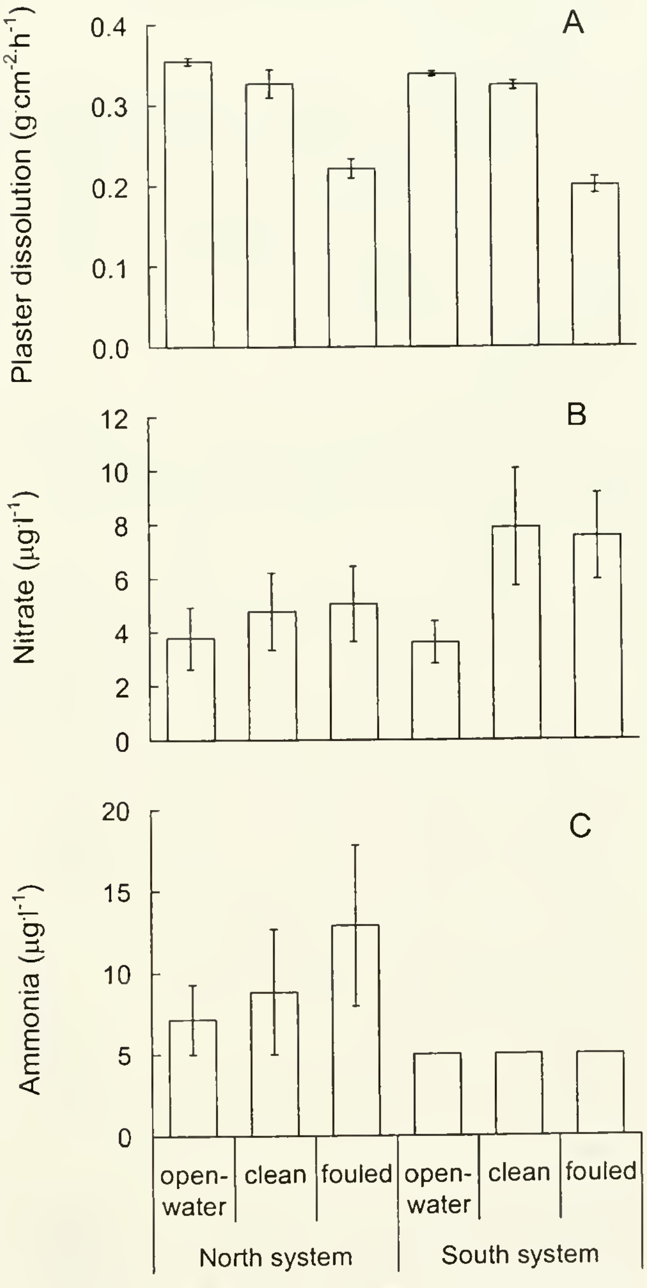

Figure 2. Physiochemical conditions. A, Water motion; B, nitrate concentrations; C, ammonia concentrations (mean ± SE) in clean and fouled pearl nets and open-water sites.

SIMPER (similarity percentages analysis, Clarke & Warwick 1994).

RESULTS

Macrofouling Communities

Fouled nets were almost entirely covered (>90%) in the hydroids *Tubularia indivisa* L. and *T. larynx* Ellis & Solander; the amphipod *Jassa falcata* (Montagu) and its silt tubes were common as were the nudibranchs *Dendronotus frondosus* (Ascanius), *Coryphella lineata* (Lovén), and *Facelina bostoniensis* (Couthouy). Small hydroids (e.g., *Obelia* sp. and *Clytia hemispherica* (L.)) were present but occupied little space compared with the large *Tubularia* spp. "Clean" nets were sparsely colonized (<5%) by small hydroids.

Physiochemical Conditions

The plaster spheres used to measure water motion remained spherical throughout their deployment. Water motion was similar on both longline systems (Fig. 2) and was only significantly reduced by fouled nets (Table 1). Nitrate and ammonia concentrations were not affected by treatment (Fig. 2). However, only four ammonia measurements exceeded the minimum detection level of the autoanalyser (5 μg/L); these were all on the north system, which therefore had significantly higher rates of dissolution than the south system (Table 1).

Food Conditions

Total particulate matter was most abundant on the south system and here there was significantly more in fouled nets compared with clean nets and open-water sites (Table 2). Although this trend was apparent on the north system (Fig. 3), differences were smaller and not significant. The ratio of PIM to POM was lowest in fouled nets, for both north and south systems (Fig. 3, Table 2). Microscopy revealed that particulate matter included detritus and invertebrate faeces, in addition to plankton.

Plankton larger than 21 μm were rare and thus numbers in the three largest size classes were pooled for univariate analysis. Total plankton and plankton in size classes 5–10 μm and 11–20 μm were most abundant in fouled nets (Table 2). Multivariate analysis also distinguished fouled nets from clean nets and open water sites (which clustered together on the MDS, Fig. 4). Interestingly fouled nets from the two systems were also distinct. ANOSIM revealed significant differences between both locations and treatments ($R = 0.42$, $P < 0.01$ and $R = 0.57$, $P < 0.01$, respectively). Pairwise comparisons found significant differences between fouled nets, open-water sites ($R = 0.78$, $P = 0.01$), and clean nets ($R = 0.89$, $P = 0.01$), but, as indicated by the MDS plot, open-water sites, and clean nets, contained similar communities ($R = 0.278$, $P = 0.08$). SIMPER analysis showed that high abundances of centric diatoms, flagellates, pennate diatoms (all 5–10 μm), and small plankton primarily distinguished fouled nets from clean nets and open water sites. High abundances of these organisms also distinguished samples from north and south systems. Although less common, eggs and spores, nematodes, pennate diatoms, and invertebrate larvae also appeared most frequently or uniquely in fouled nets. Consistently low plankton abundance explains the atypical position of one sample from fouled nets on the MDS plot (Fig. 4): despite its low content, this replicate contained most of the plankton that characterized other samples from fouled nets.

DISCUSSION

Fouling of cultivation nets created a unique environment for the scallops inside; physiochemical and food conditions differed from those both in clean nets with scallops and those in the water

nearby. Other work has indicated that sometimes scallops in fouled nets grow faster than scallops in clean nets (Ross 2002). High water flow can inhibit scallop feeding (Wildish & Saulnier 1993, Claereboudt et al. 1994b, Skjaeggestad 1997) and it could be that, in a high current area, heavy fouling aids scallop feeding by roughly halving water movement. Similarly, Skjaeggestad (1997) found that water-motion inside plastic cages was reduced by up to 68% by fouling. In addition, fouling might prevent seston depletion around scallops by creating turbulent flow and actively mixing the water (Fréchette et al. 1989, Larsen & Riisgård 1997).

Ammonia and nitrate concentrations were similar for all treatments, indicating that neither clean nor fouled nets caused a build

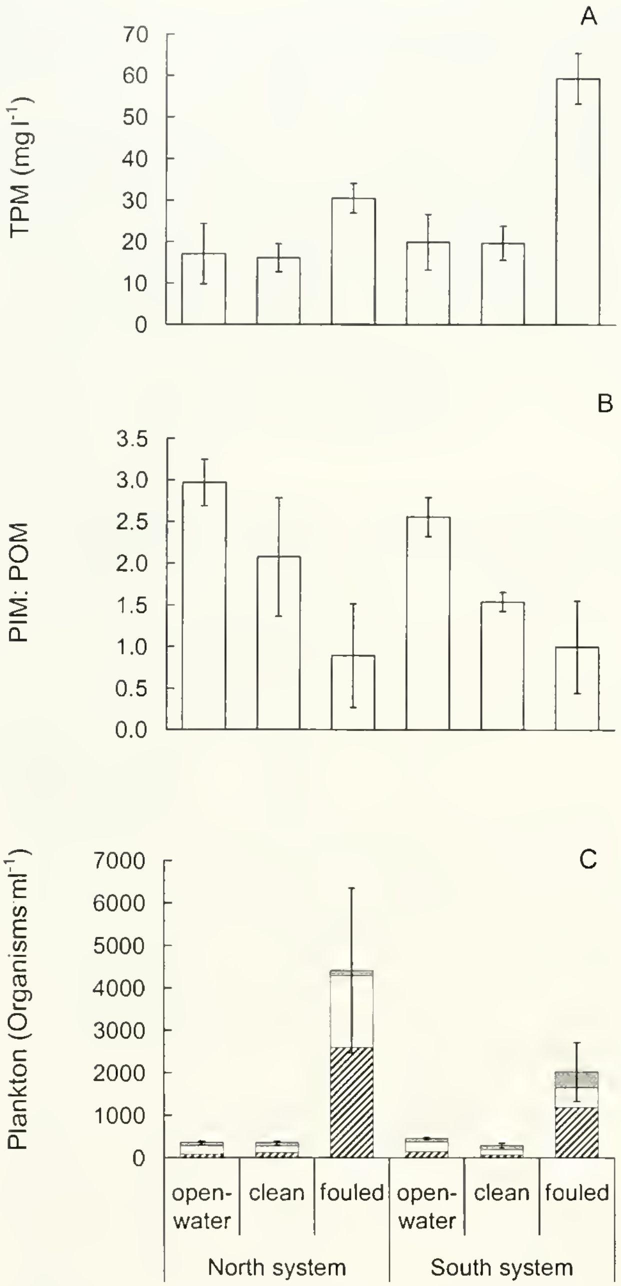

Figure 3. Food conditions. A, Concentrations of total particulate matter (TPM); B, ratios of inorganic to organic particles (PIM:POM); C, concentrations of 5–10 μm (hatched areas), 11–20 μm (white areas), and >21 μm (grey areas) plankton (mean ± SE), in clean and fouled pearl nets and open-water sites.

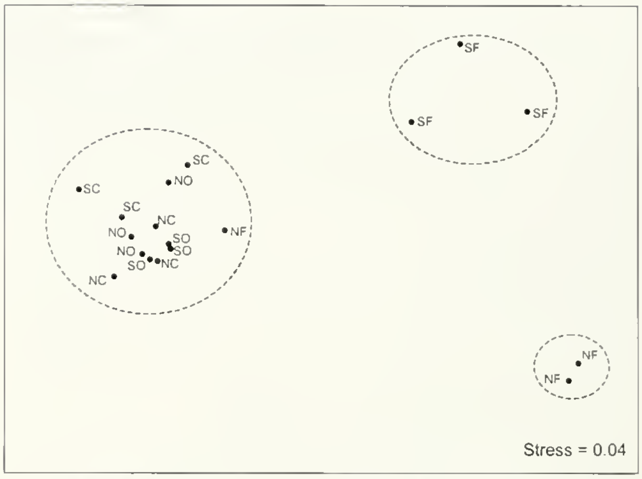

Figure 4. MDS ordination of Bray–Curtis similarity matrix for square-root transformed plankton-abundance-data. Samples are labelled with their location: north system (N), south system (S), and treatment: clean nets (C), fouled nets (F), and open-water sites (O). Samples are grouped at a 70% level of similarity from CLUSTER analysis.

up of decay or excretory products. A few apparently high ammonia measurements may have been caused by the capture of detritus in water samples (kelp detritus was abundant and the northern longline was close to a sewage outfall pipe). Inorganic nitrogen is absorbed by phytoplankton and it is possible that high numbers of phytoplankton reduced levels of nitrate and ammonia in fouled nets. In finfish cages, fouling can reduce water exchange, leading to oxygen depletion, fish mortality, or reduced growth (Cronin et al. 1999). Similarly, reduced oxygen levels have been invoked to explain reductions in scallop growth when fouling is heavy (Huguenin & Huguenin 1982, Enright 1993, Lu & Blake 1997). However, oxygen concentrations have been found to track the abundance of autotrophic plankton, peaking in fouled nets (Ross 2002). Thus, it seems unlikely that oxygen depletion is a consequence of fouling in scallop net culture in temperate locations with high water flow.

Contrary to previous suggestions (Duggan 1973, Leighton 1979, Huguenin and Huguenin 1982, Côté et al. 1993, Enright 1993, Claereboudt et al. 1994, Lodeiros and Himmelman 1996, Lu and Blake 1997), fouling did not reduce the quantity or quality of food particles available for scallops. Instead, net fouling was associated with abundant plankton and detritus and a favorable PIM/POM ratio. Trends in plankton abundance were strong enough to be identified, despite the low number of replicates and the notoriously patchy distribution of plankton (Hasle 1978).

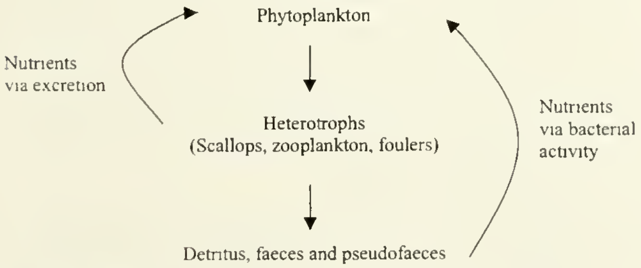
Proximity to the shore and to a sewage outfall may explain why the study area was characterized by high seston loadings (ca. 20 mg/L); similar loadings were found by Cranford et al. (1998) and Lodeiros et al. (1998) in the sea off Canada and Venezuela, respectively. High levels of organic matter in fouled nets suggest that fouling may trap, produce, and perhaps support the production of organic matter—a potential energy source for scallops. Even at high seston concentrations (15 mg/L) scallop scope for growth can be reduced by dilution of POM by PIM (MacDonald et al. 1998). When seston concentrations are not limiting a low PIM/POM ratio (critical values are between 3.5 and 6; the exact number varies between authors) is required by scallops to maintain a positive energy balance and maximum scope for growth (Vahl 1980, Wallace & Reinsnes 1985, Cranford 1995, MacDonald et al. 1998). In this study, open-water sites had PIM/POM ratios of around three, close to the critical value, and significantly higher than in fouled nets. Enhanced levels of POM in fouled nets could thus prevent high ambient PIM concentrations from depressing scallop growth rates.

Plankton communities were dominated by autotrophs of 5–20 μm, reflecting Graziano's conclusion that 65% of primary production in the northeast Irish Sea is from phytoplankton of 5–20 μm (Graziano 1988). Fouling may have encouraged primary production by releasing nutrients, by retaining plankton in a favorable light environment or by providing a substrate for benthic autotrophs. Increased primary production seems, in turn, to have supported heterotrophic and mixotrophic organisms such as dinoflagellates and ciliates. Although this finding contradicts common assumptions of those interested in shellfish cultivation, ecologists recognize that beds of suspension feeders have the potential to induce the growth of more phytoplankton than they consume (e.g., Asmus & Asmus 1991). This is because suspension feeders increase local inorganic and organic phosphate and nitrate concentrations directly through excretion and indirectly via bacterial decay of their faeces (e.g., Dame & Dankers 1988, Asmus & Asmus 1991, Peterson & Heck 1999, Arzul et al. 2001, Mazouni et al. 2001). A possible mechanism by which suspension-feeding foulers and scallops could produce and retain nutrients is described in Figure 5. This is important because in most marine systems, including the Irish Sea, phytoplankton are likely to be nitrate limited at certain times of year (Allen et al. 1998, Kennington et al. 1999). Mazouni et al. (2001), for example, suggest that during summer months nutrient recycling by oyster culture units may drive primary production in a French lagoon.

Benthic plankton are often suspended by coastal turbulence and generally survive well in the water column (Newell & Newell 1979); thus, the prevalence of benthic ciliates and pennate diatoms in our open-water samples. However, many benthic species were most common in fouled nets where they may have proliferated because of conditions described above or because of the presence of a solid surface onto which they could attach or settle. Benthic organisms might have been suspended by the passage of the sampling syringe, but movement of scallops and water currents are also likely to make them readily available as food for scallops. Increased plankton abundances in fouled nets could promote scallop growth because ambient levels (<600 cells/mL in this study) are unlikely ever to exceed maximum concentrations for scallop uptake or assimilation (ca. 15,000 cells/mL, Cahalan et al. 1989, Skjaeggestad 1997).

Proliferation of phytoplankton in fouled nets indicates that light levels were not reduced below their compensation point, even by thick *Tubularia* fouling. Perhaps strong sunlight in June penetrated the translucent stalks of this hydroid. Fouled nets may also have encouraged plankton growth and reproduction by preventing cells from sinking below the euphotic zone. Future studies might try to measure light attenuation by different fouling communities. Invertebrate larvae (including decapods and echinoderms) and nematodes were only found in fouled nets; although relatively rare, these potential predators and parasites could have deleterious effects on scallop growth and survival (O'Connor et al. 1999, Freites et al. 2000). Net fouling could also be problematic if it promoted the growth of plankton responsible for shellfish poisoning.

This is the first description of how fouling influences the environment inside nets used for shellfish cultivation. The data contradict the common assumption that fouling reduces food levels. Instead, fouling can be associated with increased food availability and does not necessarily encourage a build up of decay products or inorganic matter, even when scallop densities are high. These findings may help to explain why in high current areas scallops inside pearl nets grow faster than scallops outside (Claereboudt et al. 1994b). They also support anecdotal evidence that a degree of fouling promotes the growth of cultivated oysters (Arakawa 1990, Mazouni et al. 2001). It might be inferred that in some areas negative effects of fouling on scallop growth are caused by fouling organisms mechanically interfering with scallops (e.g., binding them in unfavorable positions, inhibiting shell opening or disrupting feeding behavior), or by harboring predators and parasites, rather than altering the environment. Growers of scallops in high current or oligotrophic offshore locations should perhaps strive to reduce the mechanical interference of foulers rather than trying to prevent fouling altogether. Strategies might include biological control, which can keep bivalves clean and free to move, but does not completely remove biofouling (Hidu et al. 1981, Enright et al. 1983, Cigarria et al. 1998, Ross 2002). This approach could benefit scallop growth by reducing mechanical interference whilst retaining the potential food enhancing properties of fouling.



Phytoplankton
Nutrients via excretion
Heterotrophs (Scallops, zooplankton, foulers)
Nutrients via bacterial activity
Detritus, faeces and pseudofaeces

Figure 5. Mechanism by which nutrients might be retained and recycled in fouled pearl nets.

That the environment inside scallop cultivation nets can differ significantly from the water-column also has important consequences for two areas of research. First, studies often relate patterns of scallop growth in suspended culture to environmental conditions (e.g., Wallace & Reinsnes 1985, Côté et al. 1993, Claereboudt et al. 1994a, Emerson et al. 1994, Lodeiros & Himmelman 1994, Thorarinsdóttir 1994, Vélez et al. 1995, Kleinman et al. 1996, Lodeiros et al. 1998, Lodeiros & Himmelman, 2000). This relationship may be better understood if future studies consider the influence of net fouling, or measure conditions inside nets. On a wider scale, water column data have recently been used by researchers assessing the affects of bivalve cultivation on nutrient and seston dynamics of bays, or to predict the capacities of areas for shellfish cultivation (e.g., Penney et al. 2001, Pilditch et al. 2001). Because of its potential to uncouple scallop processes from water-column seston conditions, the influence of net fouling should also be included in such models.

Here we have provided a snapshot examination of how fouling can alter environmental conditions. There is evidence that effects vary with season and the age or composition of the fouling community (Ross 2002). Though difficult, simultaneous assessment of fouling communities, the environment inside nets and scallop growth would enable the influence of fouling to be better understood. We used wide-mesh pearl nets containing intermediate sized scallops in a fast current area. Future work might examine the effects of fouling in low current areas or with the fine mesh nets used for growing spat. Studies to determine how common fouling assemblages (e.g., hydroid, tunicate and bivalve dominated communities) affect the net environment could help growers to choose cultivation sites, depths or methods of fouling control.

ACKNOWLEDGMENTS

We are very grateful to divers and boat crew for help with sampling in cold Manx seas. Thanks to T. Shammon, I. Allen, I. Laing and J. Berges for advice on nutrient and plankton sampling and J. Ludgate for help with maps. KAR was supported by a NERC research studentship GT4/97/148/MAS and the work by the Isle of Man Department of Agriculture, Fisheries and Forestry.

ABSTRACT This article deals with the diet of the Patagonian scallop, *Zygochlamys patagonica*, during a yearly period at Reclutas bed (39°S–55°W), Argentine Sea, and relates the results with the oceanographic conditions and the growth pattern known for this species. Scallops (n = 180) from six samples were dissected and the gut contents were identified and counted. Results showed a predominance of diatoms in the diet and maximum food ingestion in spring. Maximum somatic (muscle) growth for this species at the same study site was also found during spring. It is suggested that after the spring phytoplanktonic bloom, oceanographic conditions (thermocline in development) allow the sedimentation of food particles to the bottom; this input of energy could produce the somatic growth documented for this filter-feeding species.

KEY WORDS: diet, annual cycle, Patagonian scallop gut contents, *Zygochlamys patagonica*, Argentine Sea

INTRODUCTION

Scallops are suspension-feeding organisms, feeding on detritus and phytoplankton (Bricelj & Shumway 1991). Particles are mainly captured by cilia and mucus on the dorsal infrabranchial surface of the gill and the gill arch thus provides the major capture site (Beninger & Le Pennec 1991). Ciocco (1995) documented the importance of the labial palps in food particle transport to the mouth and also their contribution in preventing reflux and favoring agglutination and particle selection in *Aequipecten tehuelchus* (d'Orbigny). It is known that particle selection may occur at the labial palps and/or gills (Jørgensen 1990; Ward et al. 1997) and also that selection is not only based on particle size but on other important characteristics (Shumway 1985, Shumway et al. 1997). The effective lower limit of particle retention in studied pectinids ranges between 5 and 7 μm, and therefore bacterioplankton (typically between 0.3 and 1 μm; Bricelj & Shumway 1991) and picoplankton are not available as food. Some gut content studies in pectinids showed the importance of benthic and/or tychopelagic algae in the diet of scallops (Vernet de Hall 1977, Shumway et al. 1987, Bricelj & Shumway 1991).

Seasonal growth in bivalves, including scallops, is influenced by environmental changes, especially food supply (Bricelj & Shumway 1991). It is known that food availability is correlated with growth in scallops (Griffiths & Griffiths 1987, Barber & Blake 1991), and that it is possible to find abnormalities in growth during diatom blooms (Lorrain et al. 2000). In addition, Ciocco (1992) concluded that differences in growth between populations of *Aequipecten tehuelchus* were related with environmental factors, such as temperature, depth, and food availability, and not with genetic factors. Valero et al. (2000) studied growth in *Zygochlamys patagonica* (King and Broderip) using samples taken from the Reclutas bed of the Argentine Sea (Fig. 1). They found that maximum growth in shell, muscle and gonad occurred during different months of the year.

The Patagonian scallop, *Zygochlamys patagonica*, is distributed in the Magellanic Biogeographic Province, in the Atlantic Ocean, from 35°S to Tierra del Fuego, and in the Pacific Ocean, up to 42°S, between 40 and 200 m depth (Waloszek & Waloszek 1986, Ciocco et al. 1998). *Zygochlamys patagonica* and *Aequipecten tehuelchus* are the two commercial pectinid species in the Argentine Sea. There are nine Patagonian scallop beds in the Argentine Sea: Two are located in the intermediate shelf between 60 and 70 m depth and seven in the shelf break front area along the 100 m depth isobath (Lasta & Bremec 1995, 1998, 1999; Fig. 1), which is characterized by high productivity (Brandhorst & Castello 1971, Carreto et al. 1981, 1995, Podestá & Esaías 1988). The Reclutas bed is located in the northern zone of this area, where oceanographic seasonal changes occur. During summer, the water column is stratified, and the surface and the bottom layers are separated by a pronounced pycno and thermocline between 30 and 40 m depth. During autumn and winter, the water column is vertically mixed by convective circulation patterns, which result in breakdown of stratification (Guerrero & Piola 1997). Baldoni and Guerrero (2000) provided a more detailed study of the evolution of the temperature vertical structure of the water column in Reclutas bed area during the year.

The objectives of this work were to study the diet of the Patagonian scallop, *Zygochlamys patagonica*, from samples taken at Reclutas bed during an annual period, to detect possible seasonal changes in diet, and to relate these results with the oceanographic conditions in the study area and with the growth pattern of the species.

MATERIALS AND METHODS

Gut contents of 180 scallops (35–50 mm shell height) were analyzed from samples (n = 30) preserved in formaldehyde (10%), taken in June, August, October, and November 1996 and February and March 1997 in Reclutas bed (39°24′S–55°56′W, 100-m depth). The protocol used involved the dissection of gut + digestive gland complex in all sampled scallops. The gut was cut open and the contents were washed in 2 mL of fresh water. A 1-mL subsample of the gut content washed suspension was analyzed in a Sedgwick–Rafter counting chamber that was divided into 7 rows and 17 columns. All particles within six columns were counted and identified under the microscope (100–250×). This quantity repre-

sents approximately 1/6 of the total gut content. The number of samples and columns studied were statistically tested and the estimated error of the procedure was <16% (Schejter 2000).

Multivariate MANOVA (Morrison 1976), univariate ANOVA, and the Tukey test (Sokal & Rohlf 1979) were used to establish the significance in the observed differences in food groups or species found in gut contents during the study. The significance level was $P = 0.05$ in all cases, but a Bonferroni correction (Morrison 1976) was used when necessary. Data were normalized using the square root transformation; the variance was found to be heterogenous. However, as MANOVA and ANOVA are robust tests when there is a balanced design (Ito & Schull 1964, Ito 1988), it seemed correct to use them in this case in which sample sizes were the same in all months.

The IR index (an index of relative importance and abundance; Bucher & Herrera 1981) was calculated for the main groups and species in gut contents. This index [IR = (Ni/Nt) × (Mi/Mt) × 100] considers not only the total abundance of an item (or group) per month in all guts (Ni/Nt), but also whether the item (group) was present in all guts or just in a few (Mi/Mt).

RESULTS

Twelve species and resting stages of diatoms, five species of dinoflagellates and cysts, two species of silicoflagellates, prasinophytes, and a number of other organisms and remains grouped as miscellanea (tintinnids, foraminifers, nematodes, etc.) were found in gut contents of the Patagonian scallop (Table 1). Particle sizes varied between 19 and 170 μm (mainly 25 to 60 μm), although some crustacean remains (~250 μm) and some small diatoms (<19 μm) were found (Table 2). The majority of items found in gut contents had a planktonic origin. This is the case of dinoflagellates, silicoflagellates, prasinophytes and tintinnids, and most diatom species. Nevertheless, some of them, namely *Paralia sulcata*, are tychopelagic. Dinoflagellate cysts and resting diatom stages are typically benthic.

The total number of ingested particles varied between 300 and 8,000 per gut and their mean number differed significantly among months ($F_{[5,174]} = 55.859$; $P < 0.001$). Maximum food ingestion was registered in November, and minimum food ingestion periods were October and March (Fig. 2). Total abundance of diatoms, dinoflagellates, silicoflagellates, prasinophytes, foraminifera, and tintinnids differed significantly between months (MANOVA: $F_{[30,678]} = 46.86597$; $P < 0.001$; Fig. 3).

Diatoms were always the most abundant food item (IR = 45–90%, with mean values between 320 and 1450 diatoms per gut) and were present in all guts during the entire sampled period (Fig. 4). The most abundant species was *Paralia sulcata* (maximum values in November: IR = 66%; Fig. 5). This species was present throughout all months and in all guts and was the dominant spe-

TABLE 2.

Size ranges of main food items found in *Zygochlamys patagonica* gut contents from Reclutas bed.

Food Item	Size (μm)
Paralia sulcata	19–180[a]
Thalassiosira spp.	30–55
Nitzschia spp.	34–64
Pleurosigma normanii	100–121
Pennate 1	30–42
Dinophysis spp.	36–62
Dictyocha fibula	50–55
Dictyocha speculum	38–50
Pterosperma spp.	19–75
Dictyocysta elegans	64–70
Acanthostomella sp.	31–37
Foraminifera	30–170
Rotifers	59–66
Invertebrate eggs	146–162
Sponge spicules	39–190
Pollen	19–23

[a] Minimum individual frustule diameter and maximum chain length, respectively.

cies, except in February. In this month, the typical planktonic diatom genus *Thalassiosira* was almost the only food item found in gut contents (IR = 80%). In March, this species was still an important component of the diet (IR = 46%) but decreased in importance during the remaining months (IR = 7–16%; Fig. 6). *Nitzschia* spp. and *Pleurosigma normanii* made a minor contribution to total gut content (IR < 19% and IR < 4.5%, respectively; mean = up to 140 items per gut and up to 23 items per gut, respectively).

Dinoflagellates followed diatoms in importance (up to 1,000 items per gut, maximum IR = 25%, in November) in four of the six sampled months (Fig. 4). *Dinophysis rotundata* was present most of the time. *Dinophysis mawsonii* was present only in the spring, *Gonyaulax digitalis* cysts were found by the end of summer (February and March) and only a few in June. Unidentified dinoflagellates cysts were found in February, March, June, and August.

Silicoflagellates (two species of *Dictyocha*) were always observed, and they were the second most abundant item in August (IR = 0.02–12%; mean between 1 and 156 items per gut). Prasinophytes were relatively important in gut contents in June and March (IR = 9.6 and 5%, respectively, mean = 110 and 32 items per gut, respectively). Foraminifers were present in all months and in most guts (except in March) but with low IR and abundance values (IR = 0.7–6.2, mean between 8 and 79 items per gut). Tintinnids were frequent in spring (October and November) but even in these months had low IR and abundance values (IR < 1.7; mean <20 items per gut). Invertebrate eggs and copepod spermatophores were abundant in February and March.

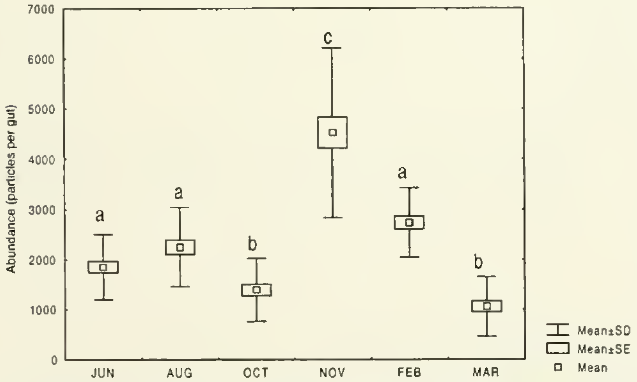

Figure 2. Mean abundance of particles per gut of *Zygochlamys patagonica* in the Reclutas bed during the study period. Different letters (a, b, c) indicate significant differences ($P < 0.05$).

DISCUSSION

The diet of *Zygochlamys patagonica* is mainly composed of diatoms. These results agree with similar studies on bivalve gut contents, which also showed a predominance of diatoms (Vernet de Hall 1977, Pollovero 1984, Newell et al. 1989, Leonardi et al. 1996). In addition, it is remarkable that most of the food items found had a planktonic origin. *Paralia sulcata*, one of the more important diatoms recorded in the diet of *Zygochlamys patagonica* and known as a tychopelagic species, is frequent in the shelf and the shelf break area during most of the year (Lange 1985). Reclutas bed, approximately 110 nautical miles offshore and 100-m deep, is undoubtedly located in the pelagic zone.

It must be pointed out that among the food items found in *Zygochalmys patagonica* gut contents, there were two potentially harmful dinoflagellate species present, *Dinophysis acuminata* and *Dinophysis rotundata*, which could produce diarrhetic shellfish toxins (Lee et al. 1989).

The maximum food contents were recorded in November (up to 8,000 food items per gut; mean = 2,800 items per gut), being *Paralia sulcata* the main food item. *Paralia sulcata* was also dominant in gut contents during the year, except in February when *Thalassiosira* spp. predominated and represented about 80% of total gut content. It should be mentioned that samples were preserved in formaldehyde, some food particles could have been destroyed because of the preservation, and also that highly digestible particles or naked cells were not recorded by this method.

The vertical movement of particles in the seawater column is very important for those animals that live far away from the photic zone (Valiela 1995). Algal cells settling during spring and fall blooms are one of the main inputs of particulate organic matter from the pelagic to the benthic system. Downward mixing of plankton during certain times of the year undoubtedly plays a large role in making food organisms available to deep-water scallops (Smetacek 1982, Shumway et al. 1987). The northern Argentine shelf shows an annual phytoplankton growth cycle with two peaks of which the most important one occurs in spring (Carreto et al. 1995, Akselman 1998). This peak was reported to occur by the end of September–October at the boundary of the coastal system/intermediate shelf (Akselman 1998), and maximum recorded chlorophyll *a* levels increase from the intermediate shelf to the shelf break (Carreto et al. 1981, 1995, Bertolotti et al. 1996). Thermocline formation begins in spring at the intermediate shelf and extends all along the shelf (Carreto et al. 1995). In October and November, the thermocline is already in development in the Reclutas bed area (Baldoni & Guerrero 2000), and oceanographic data for October and November 1996 were similar to mean estimated values for the study area by Baldoni and Guerrero (2000, Baldoni, personal communication).

Smetacek (1982) indicated that nutrients accumulated in a

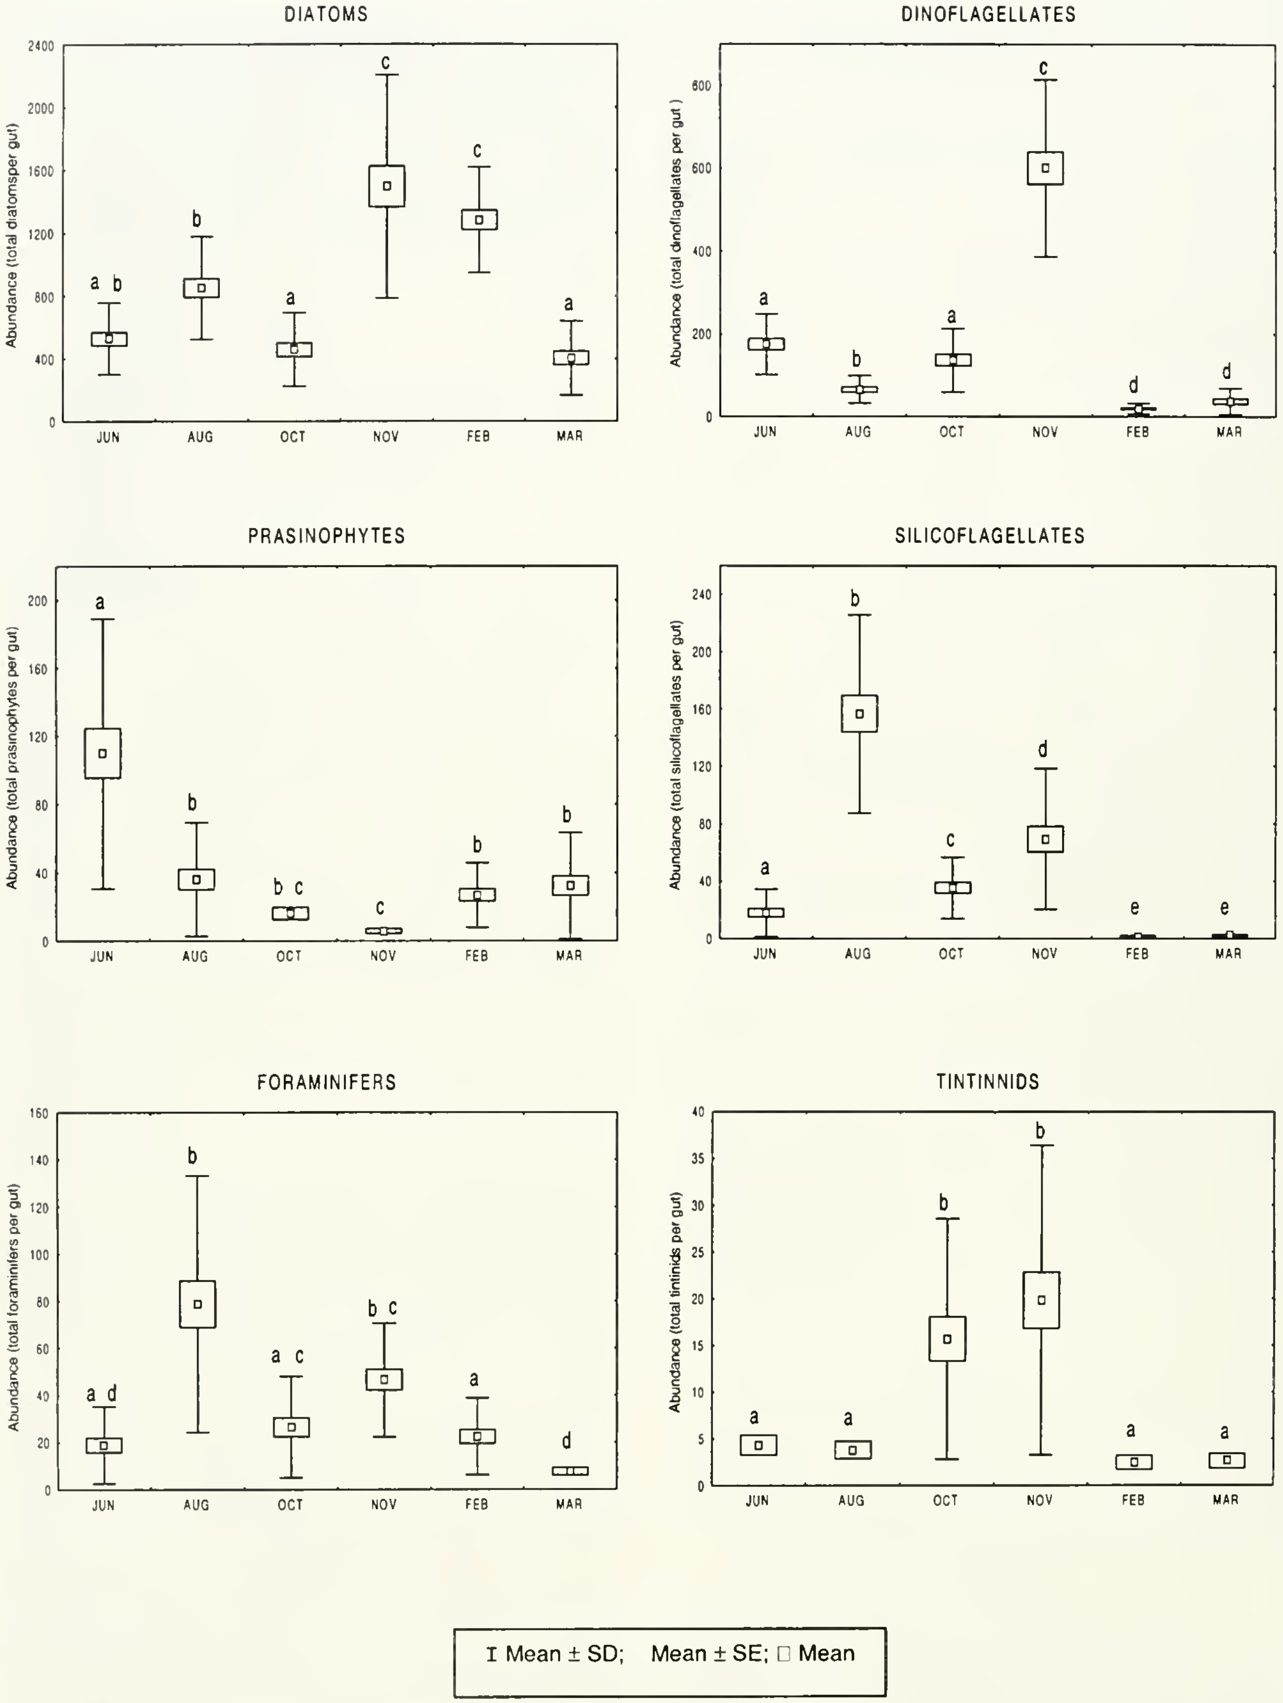

Figure 3. Mean abundance of principal food items per gut of *Zygochlamys patagonica* in the Reclutas bed during the study period. Different letters (a, b, c, d, e) indicate significant differences ($P < 0.05$).

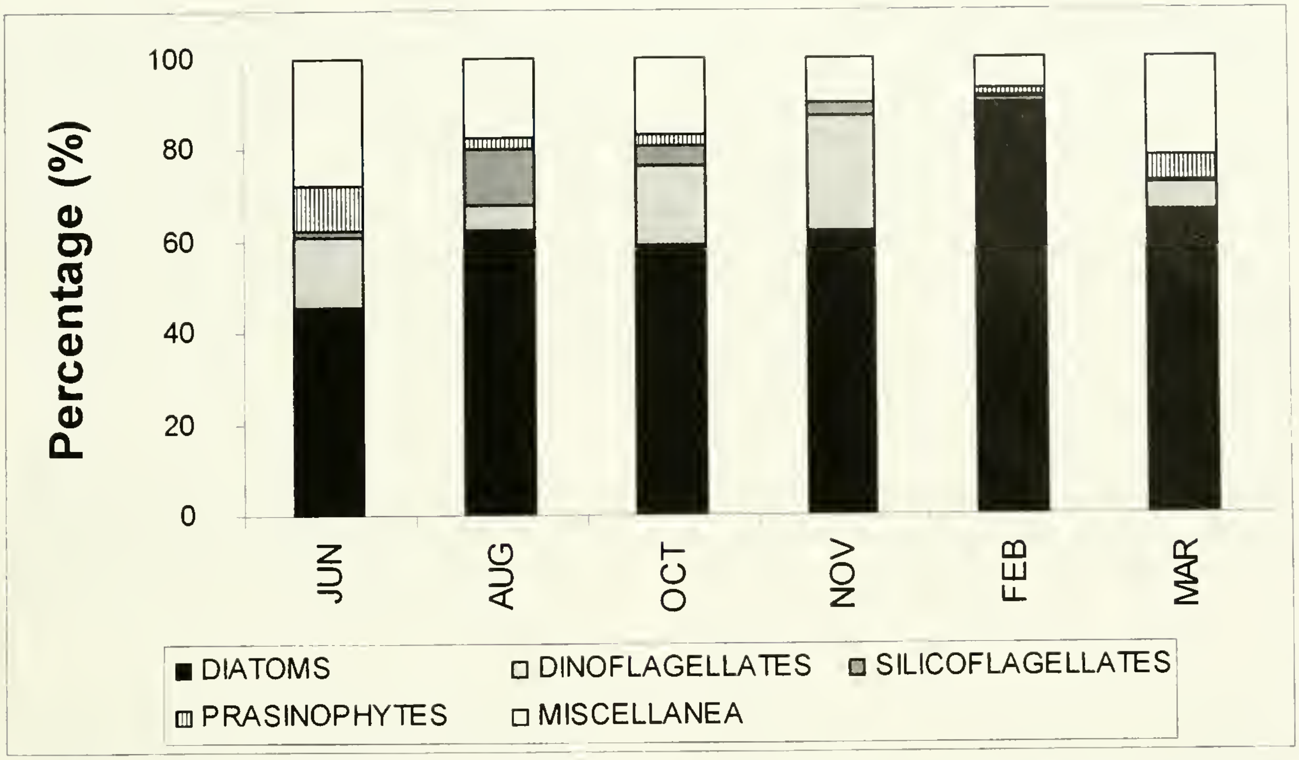

Figure 4. Percent composition of different food items groups in gut contents of *Zygochlamys patagonica* during the study period in the Reclutas bed. The group Miscellanea (see text) also includes tintinnids.

17-m water column at Kiel Bight over the winter were depleted within two weeks after phytoplankton bloom initiation. Sedimentation of phytoplankton took about one week and attained maximum values three or four days after bloom initiation. Sedimentation rates of diatoms and other phytoplankton components are related to their physiology, cell weight, and volume (Denman & Gargett 1983). As the organic matter sedimented was formed by a large number of living cells (and hence, was high in nutritional quality), benthic metabolic response to this input was rapid. For other deeper benthic systems a similar pattern is expected (Smetacek 1982).

It is thus possible that, given the oceanographic conditions described during spring at the Reclutas bed (thermocline in development), sedimentation processes or phytoplankton sinking downwards to the bottom have facilitated food availability to benthic organisms after the phytoplankton bloom started at the surface. This would explain the high abundance of cells observed in gut contents from scallops collected in November. It is probable that at the beginning of October (when samples were taken) increased primary production started in surface waters, as previously documented (Carreto et al. 1981), but availability of food at the bottom remained low because of the time requirement for sedimentation processes in a 100-m water column. During summer, the stratification of the water column is so pronounced that transport of phytoplankton cells to the bottom would probably be limited; under these circumstances we cannot explain the relatively higher abundance of *Thalassiosira* spp. during February. It is known that species of this genus are capable of producing blooms in other

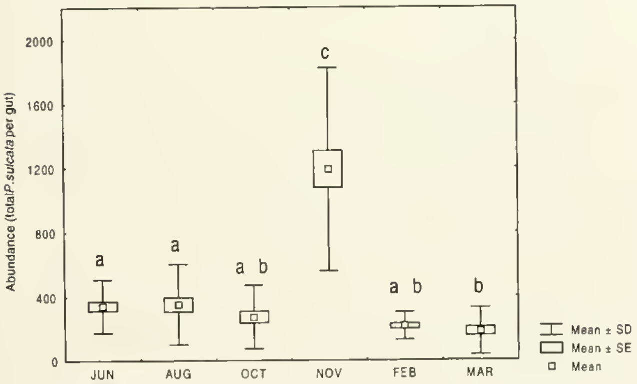

Figure 5. Mean abundance of *Paralia sulcata* per gut of *Zygochlamys patagonica* in the Reclutas bed during the study period. Different letters (a, b, c) indicate significant differences ($P < 0.05$).

areas of the Argentine Sea (Carreto et al. 1981), but oceanographic conditions at the Reclutas bed resulting in a strongly stratified water column would prevent cell sinking. However, occasional climatic events are able to disturb water column stratification, increasing sedimentation rates (Nielsen & Kiorbe 1991). On the other hand, Bode et al. (1998) conducted studies on the export of organic matter to the bottom, and found that most of it was pelagic in origin. Moreover, they determined that phytoplankton species found in sedimentation traps were not the same as those found at the surface, indicating that sedimentation traps were providing records of past production events. In summary, simultaneous seasonal information about gut contents and phytoplankton species composition in the study area is needed to establish the degree of particle selectivity in the feeding process, and whether the occurrence and abundance of food items are due to higher availability of potential food after phytoplankton growth.

The results of this study agree closely with recent findings of studies on biologic aspects of this species. Valero et al. (2000) studied the growth pattern of *Zygochlamys patagonica* at Reclutas bed. As was already found for several species of scallops from shelf and coastal areas (Barber & Blake 1991, Ciocco et al. unpubl.), growth of different body components of the Patagonian scallop are not simultaneous: maximum shell growth occurred in July, maximum gonadal growth was obtained in June, and maximum somatic (muscle) growth occurred in November. In view of this pattern, it is possible to link the period of maximum muscle growth with that in which scallops showed higher cell abundance in gut contents, both of which occur in November. Consequently, we hypothesize that somatic (muscle) growth of *Zygochlamys patagonica* located in the Reclutas bed occurs during the period of higher food availability in the bottom, which follows the period of spring phytoplankton growth in the upper layer of the water column and its subsequent sinking to the bottom before the development of the seasonal thermocline.

COMPARISON OF THE PARASITES AND PATHOGENS PRESENT IN A CULTIVATED AND IN A WILD POPULATION OF SCALLOPS (*ARGOPECTEN PURPURATUS* LAMARCK, 1819) IN TONGOY BAY, CHILE

KARIN B. LOHRMANN,[1]* ANDREW R. BRAND,[2] AND STEPHEN W. FEIST[3]
[1]Universidad Católica del Norte, Facultad de Ciencias del Mar, Cas. 117, Coquimbo, Chile; [2]Port Erin Marine Laboratory, University of Liverpool, Port Erin, Isle of Man, IM9 6JA, United Kingdom; [3]CEFAS Weymouth Laboratory, Barrack Road, The Nothe, Weymouth, Dorset DT4 8UB, United Kingdom

ABSTRACT Cultivation of the "ostión del norte", *Argopecten purpuratus*, is an important economic activity in the 3rd and 4th Regions of Chile. Studies of disease were undertaken on wild scallops to gather baseline information on healthy populations. However, as cultivated scallops are kept at higher densities than the wild populations, the occurrence and prevalence of parasites and tissue pathology differed as indicated in this study that compares the types of parasites and their prevalence in wild and cultivated scallops from Tongoy Bay, a major center for scallop cultivation. In January 1999, 151 cultivated and 154 wild scallops were examined histologically and via scanning electron microscopy (SEM). The same parasite taxa, as well as granulomas, were found in both populations, but their prevalence differed. The granulomas were small, with no apparent etiology, but the cultivated population harbored significantly more lesions than the wild population. The only parasites found were a prokaryote in the digestive gland and the ciliate protozoan *Trichodina* sp. on the gills of the scallops. *Trichodina* did not seem to elicit a host response and its prevalence was significantly higher in the cultivated scallops. The prokaryote, a rickettsiales-like organism (RLO) was observed as basophilic inclusions in digestive gland tubule epithelial cells. The intensity of infection was low, but significantly higher in the wild stock. No host reaction was seen, and the prevalence showed no significant difference between the two populations. The infection with RLOs was therefore independent of the source of the scallops, unlike the *Trichodina* or the granulomas, which were significantly more prevalent in the cultivated population.

KEY WORDS: scallop, parasite, long-line culture, rickettsiales, *Trichodina*

INTRODUCTION

Argopecten purpuratus, the "ostión del norte" (northern scallop) is distributed on the Eastern Pacific coast from Sechura, Perú (6°S), to Tongoy Bay, Chile (31°S) (von Brand et al. 2002), and is harvested and cultivated in both countries. In Chile, the most abundant beds are in the 4th Region, in the bays of Tongoy, Guanaqueros, and Coquimbo. These populations almost disappeared through overfishing, prompting a total harvesting ban for this species in 1986 and this ban is still in force for wild populations. In the early 1980s, *A. purpuratus* culture became established (DiSalvo et al. 1984, Illanes–Bücher 1987) and currently the 3rd and 4th Regions produce 97% of the cultivated scallop production of Chile (Aquanoticias 2000).

Tongoy Bay is the single most important bay for production of cultivated scallops. A serious disease outbreak here could have significant consequences for this industry, so a survey was undertaken to gather baseline information on parasites and tissue pathology present in healthy members of the cultivated population. There is no information available on any diseases of *A. purpuratus* from Tongoy Bay, but some metazoan parasites have been reported for this species in other bays in Chile and Perú. Mateo et al. (1975) described germ sacs and cercaria of a hemiuroidean in the gonad of *A. purpuratus* in Perú, causing castration of heavily infected scallops. In Chile, Oliva et al. (1986) described two larval cestodes located in the gonads of *A. purpuratus* in Antofagasta. One of the cestodes belonged to the family Phyllobothriidae, and the other possibly belonged to the family Oncobothriidae. In Coquimbo, Lohrmann et al. (1991) described a metacercaria of a fellodistomid trematode in the labial palps of *A. purpuratus* and an unidentified larval cestode in the intestine of a few animals of this species (Lohrmann & Smith 1993).

As there is still a small natural bed of *A.* purpuratus at the southern tip of Tongoy Bay, both wild and cultivated scallops are available for examination in this bay. The wild scallops from this natural bed live on the sea floor in depths of up to 15 m, at a density of 1 to 2 scallops m^{-2} (Stotz & González 1997). Cultivated scallops are kept in pearl nets at densities of about 166 individuals m^{-2} for scallops at a size below 50 mm, and 19 individuals m^{-2} in lantern nets at sizes above 50 mm (Illanes 1986). Since the cultivated scallops are kept at greater densities than the natural populations, it might be assumed that the occurrence and prevalence of parasites and other pathogens may differ. This investigation was carried out on wild and cultivated scallops, to test for differences in the prevalence of parasites and tissue pathology between the two populations of *A. purpuratus*.

MATERIALS AND METHODS

In January 1999, 151 cultivated, and 154 wild scallops were obtained from Tongoy Bay (Fig. 1). The 12-month-old cultivated scallops had been hatchery-produced, and transferred to the sea at age one month. They had been kept at a density of 19 scallops m^{-2} in lantern nets hanging from long lines at a depth of about 10 m from the surface. The natural scallops were obtained from a small bed located near the fishing community of Puerto Aldea, which is located at the southern tip of Tongoy Bay (Stotz & González 1997). These scallops were adults, but their ages were not known. They were collected by "hooka" diving (this consists in delivering air to the diver through a hose from a compressor in the boat), from a depth of 8 to 10 m. Each sample of scallops was transported to the central aquaculture laboratory of the Universidad Católica del Norte in Coquimbo, where they were placed in tanks with running seawater at ambient temperature. They were processed in batches of 50 scallops daily, starting on the day after their arrival.

The soft tissues of the scallops were taken out of the shells, and

were fixed for histology in Davidson's fluid (Shaw & Battle 1957), including the gills, digestive gland, gonad, kidney, mantle, and the adductor muscle. They were prepared for histology using standard methods and stained with haematoxylin and eosin (H & E). Giemsa and Ziehl-Neelson methods were used as appropriate to detect parasites and ceroid-like pigment respectively. Slides were analyzed and photographed using a Nikon E600 Eclipse photomicroscope. For assessing the intensity of infection of rickettsiales-like organisms (RLOs) and trichodinids, the most heavily infected area of the histologic section was selected, and the number of parasites present was counted at a magnification of 400 times, with a field diameter of 1,240 μm. Three categories of intensity were defined: grade I (very light) one parasite present, grade II (light), two to four parasites present, grade III (moderate), five or more parasites present.

For scanning electron microscopy (SEM), sections from selected wax blocks were cut at 12 μm, and mounted on coverslips. Sections were de-waxed in three changes of xylene, passed through three changes of 100% ethanol (modified from Toner et al. 1992), and critical point dried using CO_2. Samples were mounted on double-sided adhesive tape and ion sputtered with gold. The sections were viewed and photographed using a JEOL TS 300 microscope. Measurements of individual rickettsiales-like organisms and *Trichodina* were taken from SEM photographs.

For analyzing the prevalence of each parasite, a 2 × 2 contingency table was constructed with the frequency counts of each parasite in the wild and the cultivated scallops, and a χ^2 test for goodness of fit was applied. The intensities of infection were compared using the Mann Whitney rank sum test (Zar 1999).

RESULTS

From the total of 305 scallops analyzed, surprisingly few pathogens were detected. These included rickettsiales-like organisms (RLOs) and ciliates (*Trichodina* sp.). Small, granuloma-like tissue lesions were also detected. These are described in more detail later.

Rickettsiales-Like Organisms (RLOs)

Rickettsiales-like organisms (RLOs) were detected in digestive gland tubule epithelial cells in the form of spherical basophilic inclusions, with a diameter ranging between 7 and 14 μm. Occasionally, the inclusions were also seen in the lumina of the digestive tubules (Fig. 2A). In the interior of each inclusion there were darker staining bodies, which at the scanning electron microscope (SEM) level could be discerned as rod-shaped, and of fairly uniform size (Figs. 2B & C), ranging from 0.8 to 1.3 μm in length, and 0.38 to 0.46 μm in width. The inclusions seemed to be enclosed by a thin membrane, separating the RLOs from the cytoplasm of the host cell (Fig. 2B). The prevalence of these RLOs was 41% in hatchery-reared scallops and 37% for wild scallops (Table 1) but this difference was not statistically significant (P = 0.6247). The intensity of infection in both populations is shown in Table 1. A significant difference (P = 0.001) was detected in RLO intensity between populations, the natural population showing a higher proportion of scallops with degree II and III of infection.

Trichodina *sp.*

Trichodina sp., a ciliate protozoan, was found associated with the gills of the scallops (Fig. 3A). It was dome-shaped, with a horseshoe-shaped macronucleus (Figs. 3A & B). It measured 19 to 23 μm in height, and the basal disc was 14 to 18 μm in diameter. The basal disc was surrounded by a ciliary girdle (Figs. 3A & B). This trichodinid was always closely associated with the gill filaments, but no pathologic changes to the gill were detected. The prevalence was 56% for farmed scallops, but only 5.1% for wild scallops (Table 2), and this difference was highly significant ($P <$ 0.001). The intensity of infection is shown in Table 2 for both populations of scallops. The difference in intensity between the cultivated and the wild population was not statistically different.

Granulomas

In the base of the gills, small tissue lesions were found embedded in the connective tissue. These consisted of a central focus of pigmented material resembling ceroid that appeared to be contained within host cells and was surrounded by a thin capsule of fibroblast-like cells (Fig. 4). These lesions are hereafter referred to as granulomas. No evidence of infectious agents was detected in association with these granulomas. The prevalence was 12% in cultivated scallops, and 2.6% in the natural stock (Table 3) and this difference was highly significant (P = 0.0034).

DISCUSSION

In scallops, RLOs have been described as basophilic inclusion bodies in the gills of *Placopecten magellanicus* (Gulka et al. 1983), *Argopecten irradians* (Leibovitz et al. 1984, Elston 1986, Karlsson 1991), and *Pecten maximus* (Le Gall et al. 1988, Le Gall et al. 1991). They have also been found in the kidney of *Argopecten irradians* (Morrison & Shum 1983, Karlsson 1991, McGladdery et al. 1993), as well as in the digestive gland (McGladdery et al. 1993). The basophilic inclusions of *A. purpu-*

Natural	57/154	37	22	32	46

ratus were similar in size and structure to the rickettsial inclusions described by Morrison and Shum (1983) in the kidney of *A. irradians*, or in digestive gland tubules of clams by Elston and Peacock (1984). For the RLOs from *A. purpuratus* only one life cycle stage was found that indicates they are most likely rickettsiales and not chlamydiales-like organisms. Using SEM, the morphology and surface characteristics were discerned. However, as no other SEM images of RLOs were found in the literature, a comparison with other RLOs was not possible.

Since the prevalence of this organism showed no significant difference between the cultivated and the wild populations, host density does not seem to be an important factor in its transmission.

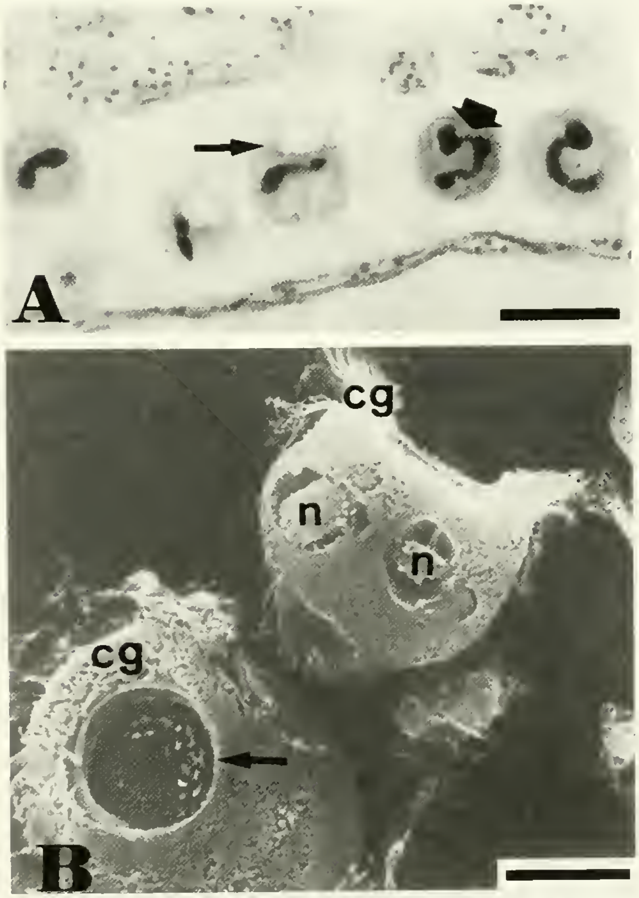

Figure 3. *Trichodina* sp on the gills of *A. purpuratus*. A: Light micrograph of a few individuals in different orientations. The horseshoe-shaped nucleus (short arrow) can be clearly seen, as well as the ciliary girdle (arrow). Stain: H & E. Bar: 50 μm. Natural	4/154	2.6

The RLOs observed in *A. purpuratus* do not seem to cause any harm, because there is no host response. Infections with RLOs are common in bivalves, where they usually cause only mild effects, if any (Lauckner 1983, Comps & Tigé 1999). However, RLOs were reported to have caused a few serious diseases but the relationship between the presence of RLOs and the mortalities was not experimentally demonstrated. In 1983, a mass mortality of *Placopecten magellanicus* occurred in Rhode Island, USA and a rickettsia-like organism was found in the gills and other tissues of these scallops (Gulka et al. 1983). Mass mortality due to branchial RLOs was also reported for *Pecten maximus* in Brittany, France by Le Gall et al. (1988), for the giant clam *Hippopus hippopus* (Norton et al. 1993), and for the clam *Venerupis rhomboides* from Spain by Villalba et al. (1999). With such limited knowledge it is important to undertake further studies on RLOs transmission and their effect on scallops of different ages and culture conditions such as density, temperature and depth.

Trichodina sp. ciliates are very common in bivalves (Lauckner 1983, Bower et al. 1994). They have been described from the following scallop species: *Mizuhopecten yessoensis* (Stein 1974, in Lauckner 1983), *Chlamys farreri* (Kuidong et al. 1995) and *Placopecten magellanicus* (McGladdery et al. 1993). In invertebrates, trichodinids are considered to be harmless commensals, feeding on bacteria (Lauckner 1983). However, they are present in large numbers in weakened animals (Bower et al. 1994), and also in organisms from areas polluted with chemicals and bacteria (Boussaïd et al. 1999). Boussaïd et al. (1999) found that *Crassostrea gigas* heavily infected with *Trichodina* exhibited an inflammatory response of the gill, and numerous desquamated epithelial cells, haemocytes, and tissue debris of host origin was observed surrounding the parasites. They also stated that an excessive mucus production covered the gill lamellae. This could interfere with the respiratory function of the gill, and may result in the death of the oyster (Boussaïd et al. 1999). A significant difference in prevalence of *Trichodina* was found between farmed (56%) and wild *A. purpuratus* (5.2%). This may be a consequence of the crowding of the scallops, their proximity facilitating the transfer of this commensal.

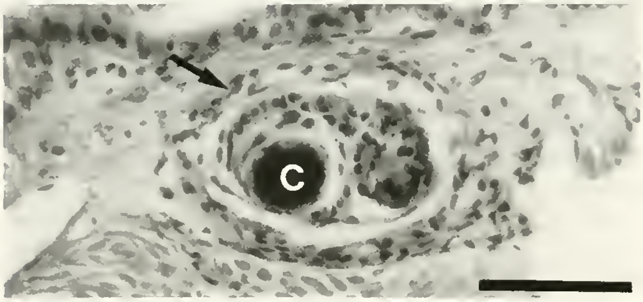

Figure 4. Light micrograph of one granuloma located in the base of the gills. Some degrading material and ceroid (c) can be observed, encircled by fibroblast-like cells (arrows) encapsulating it. Stain: H & E. Bar: 50 μm.

The granuloma-like tissue lesions found at the base of the gills are similar to lesions (that they called "swirl" encapsulation) observed by McGladdery et al. (1991) in bay scallops *Argopecten irradians* infected by what was thought to be a *Perkinsus* species. Goggin et al. (1996) made an assessment of these lesions, and concluded that they were not produced by a *Perkinsus* species, but were a general response to a foreign agent. In this study, the very low prevalence and intensity of the lesions precluded ultrastructural investigations that are needed to determine the etiology of the granulomas. However, Gonzalez et al. (1999) identified apparently identical lesions in *A. purpuratus* from Valparaíso, which were heavily infected with a protistan. Macroscopically, infected animals presented small dark brown pustules in the mantle, which was also retracted. Based on one electron microscopy image of the protistan they suggested that it could be an apicomplexan. However, details were indistinct and this finding needs to be confirmed. Since pathogen involvement cannot be ruled out as a cause for these granulomas and there was a significantly higher prevalence in cultivated stocks, further investigations are needed to identify their cause.

From the results of this study it can be concluded that both cultivated and natural *A. purpuratus* from Tongoy Bay barbored very few putative pathogens, and those that were present, were the same for the two scallop groups. The main difference between the two groups of scallops was the density at which they lived: 1 to 2 scallops m^{-2} for natural scallops in Puerto Aldea, and 19 scallops per m^{-2} for the cultivated scallops. They also differed in the location, with natural scallops living on the seabed and cultivated scallops in cages suspended in mid-water. The increased density can favor transmission of pathogens in two ways, either providing hosts that are in close vicinity, and/or increasing stress. Overcrowding can reduce food availability or increase the levels of toxic waste products, all of which contribute to stress (Newell & Barber 1988). Stressed organisms have less energy available to defend themselves from disease and this is recognized as an important factor that can trigger disease in otherwise healthy animals (Lauckner 1983, Newell & Barber 1988, Sindermann 1990).

It is surprising how few potential pathogens were harbored by these two populations of scallops, since some metazoan parasites have been previously found in *A. purpuratus* in other northern Chilean bays. Although the scallops examined during this study were from healthy populations, the threat of disease is always present. Any pathogens that are new to *A. purpuratus* could have a devastating effect on both cultivated and natural stocks. Pathogens may be involuntarily carried by fouling organisms on boats, in the ballast water of big ships, or by transporting scallops or other bivalves from other regions to Tongoy Bay. Newly introduced parasites can cause epidemics if the host's innate defense mechanisms are not able to destroy it, or if the host is not able to defend against a novel parasite strategy (Figueras & Fisher 1988). It is therefore recommended that *A. purpuratus* stocks be regularly assessed for disease agents, so as to identify any different pathogen from those known to be present in these populations.

ACKNOWLEDGMENTS

The authors thank Alejandro Abarca for providing the cultivated scallops, and Sergio González and the fishermen from Puerto Aldea for providing the natural scallops. Thanks to Wolfgang Stotz for the map of Tongoy Bay.

ABSTRACT It has been previously reported that the saucer scallop, *Amusium balloti*, either lacked the ability to produce byssal threads or could do so only briefly. This present study reports our main conclusion that in the early spat stages, *A. balloti* does indeed secrete byssus, albeit at a time different from most scallops. We found that *A. balloti* first attaches by a byssus only after metamorphosis (indicated by the presence of dissoconch shell), and we found no evidence of the byssal attachment before or during early metamorphosis. By the time spat reach a shell height of 1–2 mm they secrete two or three fine byssal filaments. Byssal attachment is maintained until the spat reaches 4–5 mm, around the stage where they develop the ability to swim. This pattern is unlike that found in most other scallops that initiate byssal production and attachment before metamorphosis. We also describe post-settlement behavior of *A. balloti*. The newly settled postlarvae (~200 μm shell height) crawl along the substratum by using their foot. During attachment, spat change their positions daily, moving an average of 17 mm per day. In culture, a gentle water jet and hypersaline bath (40‰) effectively detached spat, with the majority rapidly reattaching.

KEY WORDS: *Amusium balloti*, byssal attachment, aquaculture, scallop, captive breeding

INTRODUCTION

The broad stages whereby free swimming planktonic molluscan larvae undergo transition into spat is similar in most scallops species, and commences when competent larvae contact and attach to a substrate by secreted byssal threads (Bourne et al. 1989, Beninger & Le Pennec 1991). Metamorphosis and postlarval life follows, when the larvae lose their velum (swimming organ) and produce functional gills. Many species, such as *Chamys asperrimus*, retain the ability to form byssus throughout life, while other scallops, like *Pecten maximus*, cease to form byssus at around 15 mm shell height and live free of attachment on the sea bed (Brand 1991). *Amusium balloti* (Bernardi 1861) is one of these latter, free-living scallops, but one that was also previously thought to either lack the ability to produce byssal threads or to attach for any significant time, even as spat (Rose et al. 1988, Cropp 1992, Sumpton et al. 1990, Robins–Troeger & Dredge 1993).

Amusium balloti, commonly known as the saucer scallop or swimming scallop is a fast growing scallop that inhabits subtropical and tropical waters off the east and west coasts of Australia and is an important component of the multi-species trawl fishery in these areas. Some individuals recruit to the fishery (i.e., reach legal harvest size of 90-mm shell height) when 6 months old, although most attain this size in 9 to 11 months (Gwyther et al. 1991). *Amusium balloti* has been the subject of a number of studies on larval development (Rose et al. 1988), wild collection (Sumpton et al. 1990, Robins–Troeger & Dredge 1993) and hatchery production (Cropp 1992), with a view to developing the species for aquaculture or stock enhancement. An essential component of either of these latter activities is a reliable, relatively cheap and large source of spat. While most successful scallop culture operation worldwide utilize wild-sourced spat due to lower cost, hatchery production is an option, and offers some advantages, such as genetic selection. However, both wild and hatchery production of bivalve spat depend on attachment to some form of substrate for collection and handling (Bourne et al. 1989, Wang et al. 1993).

According to Rose et al. (1988), newly settled *A. balloti* spat crawl actively using their foot, but never appeared to attach permanently to substrata provided. Cropp (1992) determined that newly settled spat lacked a firm and long-term byssal attachment, but retained a strong and active foot that allowed them to crawl on the substratum and detach and swim in the water column at will. During hatchery production this apparent lack of permanent byssal attachment resulted in significant numbers of cultured spat accumulating on the tank floor after dropping from suspended collector bags. If left on the tank floor, associated fecal matter and algal detritus would kill the young spat (Cropp 1992). The conclusions drawn from these hatchery observations were further supported by data from spat collectors in the field. Attempts to obtain spat by deploying collectors during the spawning and settlement season of *A. balloti* resulted in very low numbers of captured spat (Sumpton et al. 1990, Robins–Troeger & Dredge 1993). The most likely explanation given for this lack of success was that *A. balloti* either had a brief or non-existent byssal attachment stage.

Here we present data demonstrating that *A. balloti* does produce byssal threads, but unusually for a scallop, does not do so until the dissoconch shell is produced, well after metamorphosis and postlarval stages. We also document, for the first time, the processes of byssal attachment and provide data on detachment and reattachment methods, and movement of *A. balloti* spat.

MATERIALS AND METHODS

General Specifications

Hatchery conditioned broodstock were induced to spawn by air-drying and heat shock using standard methods (Bourne et al. 1989). After fertilization the embryos were kept at 20°C in a 500-L tank until hatching. Larvae were reared at 20 ± 1°C until ready to metamorphose (i.e., competent). Competent larvae were allowed to settle in screen chambers, which were constructed by gluing nylon mesh (160 μm aperture) on to PVC pipe (250 mm diameter),

---

and housed in a hatchery downweller system operated at 21 ± 1°C, pH 8.1–8.2 and 33–35‰ salinity. The rearing water was changed three times each week, followed by feeding with equal amounts of Tahitian *Isochrysis aff. galbana*, *Pavlova lutheri* and *Chaetoceros calcitrans* based on their dry weight at a density of approximately 15,000 cells ml^{-1}.

Qualitative Observations of Byssal Attachment and Movement

Three times per week postlarvae (i.e., after initiation of metamorphosis, but before evidence of a dissoconch shell) and spat (evident dissoconch shell) were placed into petri dishes and their movement was observed microscopically. After being left for approximately 30 min the attachment status of the immobile postlarvae and spat was determined by subjecting individuals to gentle water current produced by squeezing water from a Pasteur pipette. Postlarvae and spat that were moved by the gentle water current were considered to be unattached spat. Those that did not were considered to be byssally attached and were photodocumented (Sony, Mavica).

Spat attachment and movement was also qualitatively assessed by hanging small pieces of nylon mesh (tied to 2 × 3 cm PCV plates for support and weight) in three different ways in each of 3 replicate screen chambers (see General Specifications), each holding 1,000 to 2,000 spat. Specifically, mesh was: (1) suspended vertically 1cm from bottom of the screen chamber; (2) placed vertically in contact with bottom of the screen chamber; (3) placed in a Petri dish (5 cm in diameter with 1 cm side), that was suspended 1 cm from the bottom of screen chamber. In all cases, mesh or Petri dish was at least 1cm distant from the walls of the screen chambers. After 24 h mesh/PVC plates/petri dishes were inspected for settled spat and observed using a stereomicroscope. This experiment was performed twice when spat had a shell height between 1 and 2 mm.

Spat Detachment

Detachment of byssally-attached spat was investigated using two different treatments, high salinity water and a water jet. The high-salinity treatment consisted of exposing attached spat in a screen chamber to 40‰ seawater. After 5 min, detached animals were removed by very gentle rinsing, and counted. This procedure was repeated after 15, 30, 60, 90, and 120 min. This procedure was replicated using 3 screen chambers at the same time. The salinity was raised by adding rock salt (Olsson's) and measured using Horiba Water Checker (Model U–10, HORIBA Ltd., Japan). A control group using 33‰ salinity was also assessed using the same procedure. Spat detachment using a water jet was assessed using a small aquarium pump at a rate of 2,500 L/h (nozzle size: 0.8 cm). The jet was directed onto spat attached to the screen chambers suspended in water at 33‰ salinity. Detached spat were rinsed from the chamber and counted.

For all treatments, spat were hatchery reared at a water temperature of 21°C. Prior to the start of the experiment, any loose spat were gently rinsed from the screen chambers, leaving only attached spat at approximately 750–2,000 per chamber, or 1.6–4.4 spat/cm^2. Spat shell height was 1.2 mm (±0.05, SE). Following experimental procedures, 10 detached spat from each treatment were subsequently held in 400 ml-plastic dishes in normal seawater (33‰) to determine treatment effects on survival, which was assessed by inspection under a stereomicroscope 24 h after detachment.

Spat Reattachment

After being detached by water jet as described above, 10 spat were held in plastic dishes holding approximately 400-ml seawater at 21°C, 33‰, and pH 8.2. The size range of the spat was 1–1.5 mm. Spat were left to reattach for 5 min. after introduction to the dish and attachment status was determined by subjecting spat to a gentle water current from a Pasteur pipette. Scallops moved by the water current, were considered unattached. Reattachment was assessed after 5, 15, 30, 60, 120, 240, 360, and 720 min. using this procedure. Three replicate samples were used. Survival was also determined during this trial by microscopic inspection, immediately following reattachment assessment.

Quantitative Measurement of Spat Movement

Individual spat (shell height 2 mm ± 0.06, SE) were held in plastic dishes (32 in total) containing 400 ml seawater at 23°C, 34‰ and pH 8.2. Spat were left for 1 h (i.e., sufficient time to ensure reattachment as indicated by earlier results), and then the position of each spat was marked with permanent ink on the underside of the dish. Spat position was marked again every 24 h for seven days and the straight-line distance between the most recent and previous position recorded. At the same time the attachment status was checked as before and survival status of unattached spat was assessed by microscopic inspection. Water was exchanged daily to enhance water quality, and to minimize the effects of water exchange on spat attachment and movement, approximately 1,000 ml seawater was allowed to flow through each dish in one hour. Equivalent proportions of Tahitian *Isochrysis aff. galbana*, *Pavlova lutheri* and *Chaetoceros calcitrans*, based on dry weight at a final concentration of 15,000 cells ml^{-1}, was added to the flowthrough seawater to provide feed.

Statistical Analysis

GenStat (Payne et al. 2000) was used for all analyses, and differences between treatment means were evaluated for significance using least-significant difference testing (at a significance level of 0.05). The water jet detached 100% of the spat in the screen chamber within 2 min. Hence, this treatment had zero variation and was not included in the statistical analysis of detachment, and only control (normal seawater 33‰) and hypersaline (40‰) treatments were statistically compared. As the numbers of the attached spat varied among the individual screen chambers, the results of various detachment treatments were compared on the basis of percentage of total number of spat detached (i.e., at 120 min). Percentage detachment values were normalized by the angular transformation (arcsine of the square root of the proportions). The transformed data were analyzed using one-way ANOVA, with 3 replicate screen chambers per treatment. In addition to analysis of the total number of detached spat at 120 minutes, percentages of detachment in each cumulative interval were also subject to repeated measures ANOVA. For reattachment of young spat, the number of reattached animals was converted to the percentage and normalized by the angular transformation in each treatment, then also analyzed by one-way ANOVA. For movement of young spat, the distances of movement were analyzed by using two-way ANOVA, with the two treatments being "days" and "spat". The proportions of attached (vs. moved) animals were analyzed by using generalized linear regression analysis (McCullagh & Nelder 1989), using the binomial distribution and logit link, with the same treatments being fitted.

RESULTS

Qualitative Observations of Byssal Attachment and Movement

Newly settled postlarvae crawled actively using their foot. Non-active or immobile postlarvae were not observed to attach, and were easily moved by a gentle water current. Spat initially attached to the substratum with a fine and transparent byssus that was difficult to detect using a stereomicroscope, although its presence could be inferred by resistance to the water current. Upon reaching 1 to 2 mm, the byssus became thicker and could be observed microscopically (Fig. 1).

Shortly after byssal detachment by water jet, spat typically retracted into their shell for several seconds to minutes. Subsequently a spat would extend its foot from the byssal notch, using it to explore and crawl or attach to the substratum. Spat typically explored and crawled for several minutes before stopping, then continuing to explore the surrounding area with the foot. The cornet of the foot then pressed against a substrate, and seconds later the foot was retracted into the shell leaving a byssal filament that fixed the scallop to the substratum. *Amusium balloti* spat usually secreted two or three byssal threads. If disturbed, the spat would extend its foot again to explore the surrounding area and secrete another byssus, or release existing threads, and would crawl away using its foot and shell adduction. At about 4–5 mm, spat started to swim and ceased byssal attachment.

Inspection of PVC plates, nylon mesh and petri dishes indicated that 3 to 10 spat (out of 1,000 to 2,000) attached to the PVC plates or nylon mesh in contact with the bottom screen. No spat were found on PVC plates or nylon mesh that were off the bottom screen and no spat were caught in any of the petri dishes.

Spat Detachment

Based on the total number of spat detached after 120 min, one-way ANOVA indicated that hypersaline seawater (40‰) induced a significantly greater proportion (98%) of detachment compared with washing in normal seawater (33‰) (75%) ($P < 0.01$). The water jet (normal seawater) detached 100% of the spat in 1 or 2 min. Analysis of time intervals within the 120 min period (Fig. 2) indicated there was an interaction between time and treatments ($P < 0.01$), which occurred in 30 and 60 min intervals. Using salinity treatments, most detachment occurred during the first 60 min ($P < 0.01$). No mortality was observed within 24 h of detachment using any treatment.

Spat Reattachment

The rate of spat reattachment over time was significantly different (One-way ANOVA, $P < 0.01$; Fig. 3). Reattachment increased linearly, reaching a plateau of around 90% at 60 min, and remained stable up to 720 min. No mortality was recorded following this experiment.

Qualitative Measurement of Spat Movement

The average daily distance moved by spat over seven days was 17 mm, and tended to be greater in mid trial ($P < 0.01$, Fig. 4). However, there were large differences in distance moved between spat ($P < 0.01$). Figure 5 shows the average daily movement of individual spat over seven days with corresponding standard deviations. The longest mean daily distance travelled was 38 mm and the shortest mean distance was 1 mm. All animals moved at least once in seven days. Generalized linear regression analysis showed that for total numbers of attached animal and moved animals there was no statistical difference between different days ($P > 0.2$). However, individual spat showed differences in the proportion of times they were observed to be attached or to have moved over the seven days ($P < 0.05$).

DISCUSSION

Our investigation demonstrated that *A. balloti* consistently secreted a transient byssus, contrary to, and clarifying previous reports (Rose et al. 1988, Sumpton et al. 1990, Cropp 1992, Robins–Troeger & Dredge 1993). However, unlike most scallops (Sastry 1965, Bourne et al. 1989, Benigner & Le Pennec 1991), there is no evidence of the byssal attachment in *A. balloti* before and during early metamorphosis. The first appearance of byssal threads occurs after the spat begins to synthesize the dissoconch shell. Spat of shell height less than 1 mm do attach to the substratum, although it is difficult to detect byssus even under microscopic inspection because it is very thin and transparent (future electron microscopy may resolve this issue). The thickness and visibility of threads increases as the animal grows.

We do, however, find similarities between *A. balloti* and the reported behavior of other pectinids during byssal secretion (Benigner & Le Pennec 1991), specifically the crawling, and exploration phases prior to secretion, and the process of secretion itself.

Amusium balloti spat of 2–3 mm shell height secreted only 2 or 3 transient byssal filaments under our experimental conditions. Compared with other scallops *A. balloti* appears to have a much reduced byssus attachment. Gruffydd (1978) estimated the number

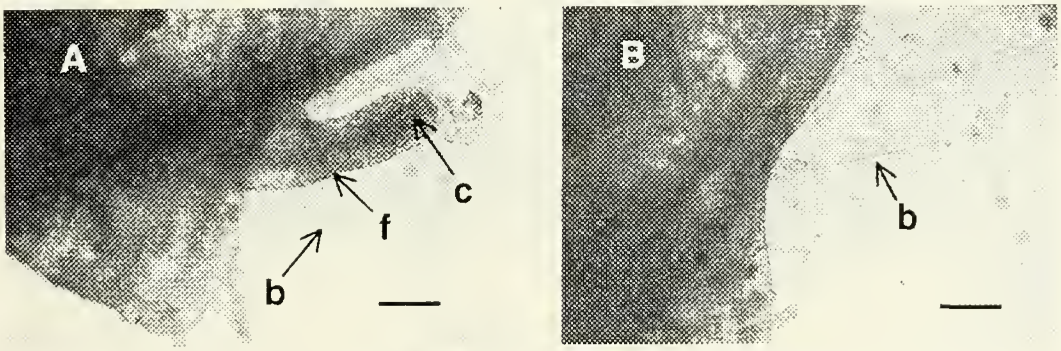

Figure 1. The foot, cornet, and byssus of *Amusium balloti* spat (shell height 2 mm) (A) Foot extended. (B) Foot retracted. b, byssal; f, foot; c, cornet. Scale bar = 10 μm.

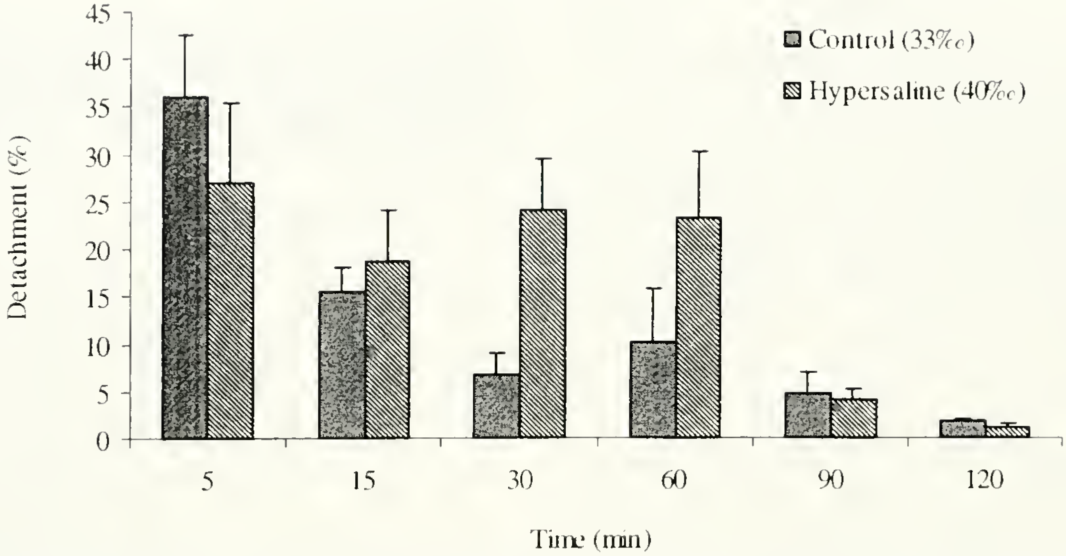

Figure 2. Sequential proportional detachment (mean and standard deviation of *Amusium balloti* spat (shell height 1.2 (±0.05 SE) mm) from settlement screens after exposure to normal (33‰) and hypersaline (40‰) seawater at cumulative time intervals of 5, 15, 30, 60, 90, and 120 min.

of byssal filaments secreted by *Chlamys islandica* to be 10–30, while *Placopecten magellanicus* juveniles secrete 3–7 filaments (Caddy 1972). *Amusium balloti* spat lose byssus when they reach a shell height of 4–5 mm, which is smaller than for most other scallops. For example, *Pecten maximus* ceases byssal attachment at 15 mm, *Argopecten gibbus* at 6–10 mm, (Brand 1991) and *Argopecten irradians* at 20–25 mm (Pohle et al. 1991). Other scallops such as *Chamys asperrimus* (Brand 1991) and *Chlamys farreri* (Wang et al. 1993) retain the ability to form byssus throughout life.

In culture, 1–2 mm *A. balloti* spat can crawl from the bottom to substrata (mesh and PVC plates) that are in contact with the bottom, although this appears to be uncommon. With our experiment design we found no evidence that spat can swim and attach to substrata raised above the bottom. However our experiment design did not categorically exclude the possibilities, either, that at this age spat were able to swim, but not able to attach to screen off bottom, or, that spat could swim but were not able to swim vertically more than 2 cm from the bottom. Future video surveillance techniques may overcome some of these technical limitations. Observations indicated that spat begin to swim at 4–5 mm, apparently losing the ability to synthesize new byssal filaments at the same time. With continued growth, spat demonstrate the active swimming noted in adults. According to Joll (1989), *A. balloti* is the fastest and longest distance swimmer amongst the scallops.

Results also indicated that most spat moved every day, although continuous movement patterns were not recorded. Since it is likely that spat movement is not in a single direction and perhaps more than once a day, our estimates of daily migration are likely to be underestimates of the actual distances moved. The change in

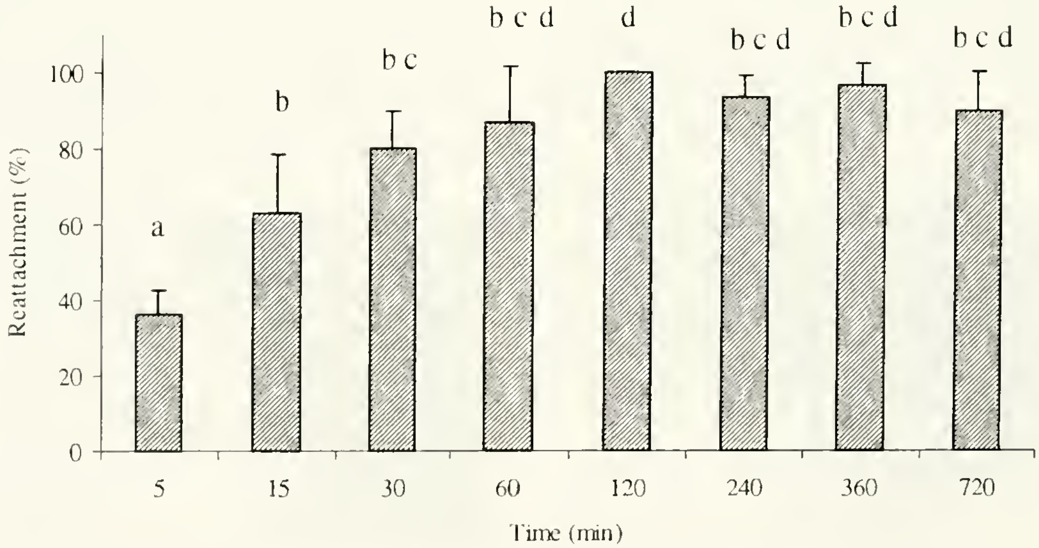

Figure 3. Reattachment rate (percentage with standard deviation) of *Amusium balloti* spat (shell height 1.5 (±0.05 SE) mm) Over 720 min following water jet detachment. Values sharing same superscript letter do not differ significantly ($P > 0.05$, ANOVA)

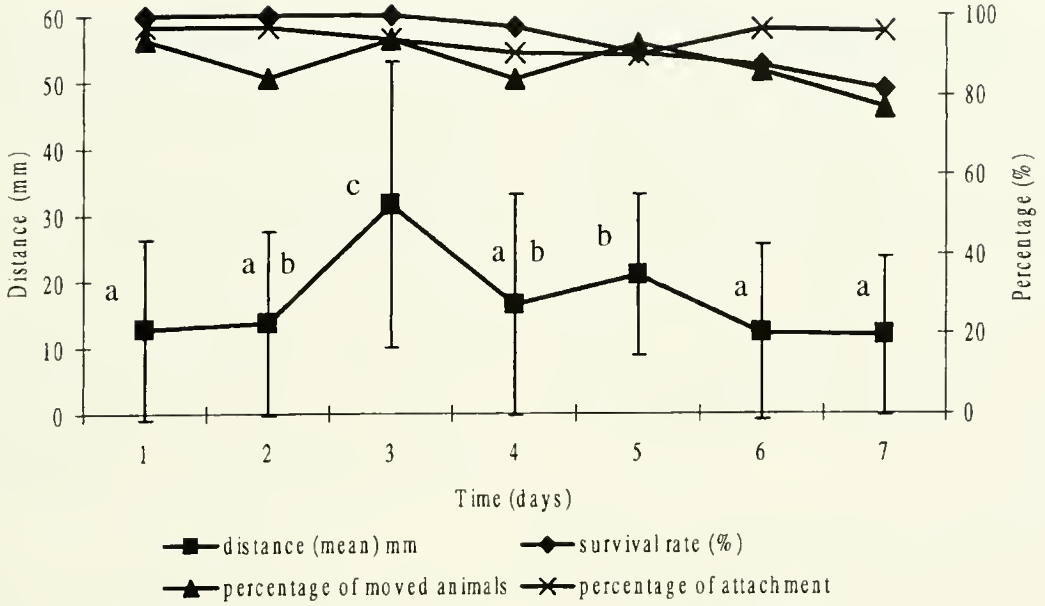

Figure 4. *Amusium balloti* spat (shell height 2 (±0.06 SE) mm), mean movement distances with standard deviation, daily proportions of moved and attached animals, and daily survival rates over seven days. Values sharing same superscript letter do not differ significantly ($P > 0.05$, ANOVA)

attachment rates over time for *A. balloti* young spat are similar to those reported for *Chlamys opercularirs* (L) (Paul 1980) and *Placopecten magellanicus* (Caddy 1972). The time required for most *A. balloti* spat to reattach is also similar to that reported for these species of scallop, with approximately 80% to 90% reattached after 30 and 50 min respectively (Caddy 1972, Paul 1980).

Scallops appear to be susceptible to the effects of siltation, particularly in relation to gills (Naidu & Scalpen 1976, Tettelbach et al. 1988). It has been suggested that byssal attachment to elevated substrates, by both juvenile and adult scallops, may help avoid burial by fine-grained sediments in areas of high near-bottom turbidity, as well as a means of avoiding predators (Bricelj & Shumway 1991, Pohle et al. 1991). *Amusium balloti* lives on medium to coarse sandy-mud seabed (Cropp 1994) where there is very fine sediment, but also no vertical substrate for juvenile attachment. Consequently *A. balloti* spat probably settle directly on the bottom with byssal attachment to coarse sand grains. As small spat, only a few filaments are required for them to attach onto the substrate and avoid being moved by currents, or perhaps concentrated and buried in areas of fine silt. The small number of filaments, in addition to minimizing the energy requirements of byssal production, would also enable more rapid detachment if the need arose, perhaps in response to predators. However, with the growth of young spat, sand grains are no longer effective anchors, even if the spat could secrete more and stronger byssal threads. Interestingly, after 4–5 mm, *A. balloti* spat rapidly develop a strong swimming capability, which is also likely to be an effective means of avoiding siltation and predation.

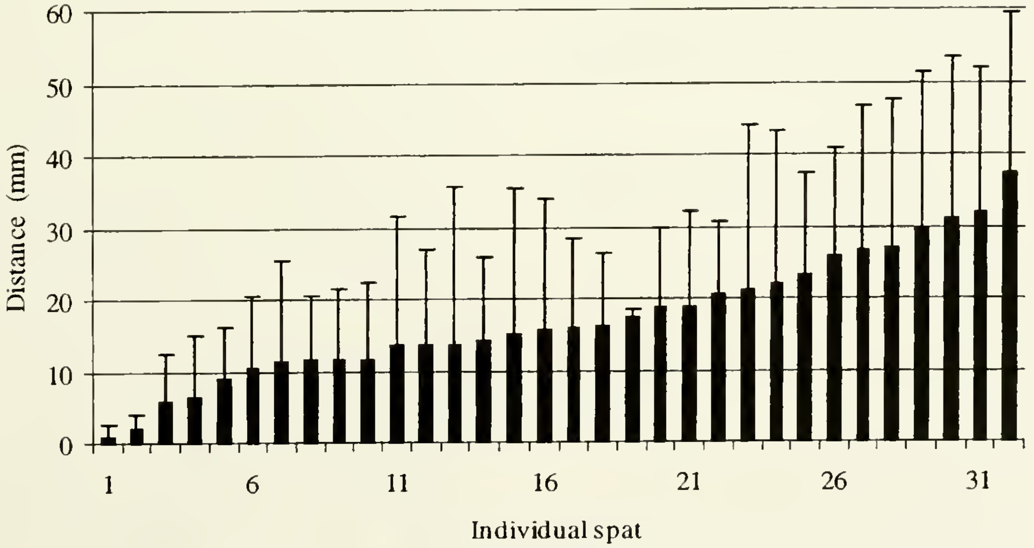

Figure 5. Mean daily movement of individual *Amusium balloti* spat ($n = 32$), (shell height 2 (±0.06 SE) mm), over 7 days, mean distance (mm) with standard deviation. Data arranged in ascending order.

Methods for artificial and controllable detachment of spat have important practical applications in hatchery production. Growing spat need to be frequently graded and transferred onto screens of successively larger surface area and mesh aperture sizes to reduce screen fouling and to offset increasing biomass (Heasman et al. 1994). In *Pecten fumatus*, mechanical methods, such as seawater jet and scrapers, can cause injury and subsequent high mortality, particularly in spat less than 5 mm shell height (Heasman et al. 1994) due to their more robust attachment. However, the delicate byssus of *A. balloti* is readily broken with a gentle stream of water does not cause mortality to the spat. A hypersaline (45‰) bath was found to be the most effective and safe means for inducing spat detachment in both *P. fumatus* (>95%) (Heasman et al. 1994) and *Pinctada maxima*, (>90%) (Taylor et al. 1997). This method was also effective for *A. balloti* with 40‰ salinity inducing 98% detachment within 2 h, compared with 75% in normal seawater (and after gentle rinsing).

A prerequisite for any aquaculture operation is the reliable, plentiful, and inexpensive supply of seed (juveniles). In most bivalve culture operations throughout the world, seed is obtained from the wild, although hatchery-produced spat is an alternative (Bourne 2000). Both approaches have been used successfully to produce scallop spat and in all documented cases, procurement of scallop relies on the attachment of spat via byssal threads to a solid substratum (Bourne et al. 1989, Ito 1991, Wang et al. 1993, Neima 1997, Bourne 2000). The results of this study demonstrate that *A. balloti* secrete byssus, consisting of a few fragile filaments. In addition, although spat are usually attached to a substratum by the byssus, they do move frequently. These characteristics explain why wild collection is unsuccessful, with water movement eventually removing most spat from collector bags, and supports the conclusion of Robins–Troeger and Dredge (1993), that fishery enhancement (and aquaculture) will be reliant on hatchery-reared spat.

The results of our present study also suggest that to culture *A. balloti* spat in the hatchery, we cannot use standard methodologies reliant on a robust byssal connection. However, this problem can be overcome by using screen chamber settlement systems. Downweller and upweller screen chamber settlement systems have been used successfully to rear many species of bivalve, such as oyster, clam, (Utting & Spencer 1991) and scallop (Heasman et al. 1998). Our work provides the first foundations for the development of a more reliable and commercial-scale hatchery production method for *A. balloti*, which has not previously been demonstrated. The potential for subsequent aquaculture or stock enhancement through large-scale hatchery production of spat may then be realized.

ACKNOWLEDGMENTS

The authors thank Ms Jan Rose for supply of microalgae, Mr. Mike Dredge and various fishermen for the supply of broodstock and to Mr. David Mayer for advice on statistical analysis. We also thank staff at the Bribie Island Aquaculture Research Centre and Dr. David Hewitt for their generous help in setting up the scallop hatchery. The authors thank Dr. Michael Heasman, Dr. Wayne O'Connor, Dr. Zhaoping Wang and an anonymous referee for helpful comments and advice.

INTRASPECIFIC VARIATION IN THE REPRODUCTIVE CYCLE OF THE TEHUELCHE SCALLOP *AEQUIPECTEN TEHUELCHUS* (PELECYPODA, PECTINIDAE), IN SAN MATÍAS GULF, PATAGONIA, ARGENTINA

MAITE NARVARTE* AND MARINA KROECK
Instituto de Biología Marina y Pesquera "Almirante Storni," CC 104, (8520) San Antonio Oeste, Río Negro, Argentina

ABSTRACT The reproductive cycle of the tehuelche scallop, *Aequipecten tehuelchus*, from San Matías Gulf was studied for a two year period. Scallops were collected at monthly intervals from August 1997 to July 1999. Muscular and gonosomatic indexes were estimated and histologic sections of the gonad were prepared and used to determine gametogenic stages and to estimate the mean oocyte diameter. Gonosomatic index (GSI) data revealed a bimodal pattern, but the spring-summer spawn was larger and more synchronized than the autumn spawn. GSI and histologic observations had similar patterns. Massive spawning began in December. Gametogenesis lasted from June through late winter (September). The tehuelche scallop is a partial spawner. The spawning schedule showed between-year fluctuations, starting at any time during September through October, depending on the year. Partial spawnings and gonadal recovery alternated along the summer, until March. Spawning was followed by the reabsorption of unspawned gametes. A resting stage in the reproductive cycle occurred from late summer (March) to mid-autumn (May). In 1 of the two years studied, an early sexual maturation matched low temperatures. This suggests that in San Matías Gulf the reproductive cycles are not clearly synchronized with seasonal cycles of superficial seawater temperature and that other factors, presumably the amount of food supply, may be responsible for an anticipated gonadal maturation.

KEY WORDS: reproductive cycle, intraspecific variation, Aequipecten tehuelchus, san Matías Gulf

INTRODUCTION

The tehuelche scallop *Aequipecten tehuelchus* (D'Orb., 1846) is one of the most important commercially fished bivalves in eastern Patagonia (San Matías and San José gulfs). Landings have fluctuated from 4,700 to 100 tons during the last 30 years. Fishery measures include minimum commercial size, rotation of fishing areas, and selection of catch on board (Orensanz et al. 1991). The fishery operates during winter months to obtain maximum yield and to prevent capture during reproductive periods.

The tehuelche scallop is hermaphroditic (Christiansen & Olivier 1971). As in other pectinid species, the male gonad is white-yellow and the female gonad is orange ("coral"). Gamete development is easily viewed within the acini, and light varies with the gametogenic stage (Barber & Blake 1991). Christiansen et al. (1974) delineated the reproductive cycle of a San Matías Gulf population based on irregular samplings in the region. Fecundity ranges from 2 to 17 million eggs for scallop sizes of 35–90 mm (Orensanz et al. 1991). The reproductive cycle of the populations from San José Gulf (43°S) was studied by Lasta and Calvo (1978). Partial spawnings begin in late spring and pre- and post-spawning stages coexist as far as the end of the summer. Despite the high value of this fishery in San Matías Gulf (41°S), the reproductive cycle was not studied in detail until this work.

There is extensive literature on the gametogenic cycle and the timing of spawning in many bivalve species (Giesse & Pierce 1974, Sastry 1979, Newell et al. 1982, Barber & Blake 1991). For several pectinid species in the northern hemisphere, spawning occurs at higher temperatures and later in the year in southern populations (Barber & Blake, 1991) and is often more synchronized at higher latitudes (Bricelj et al. 1987).

The objective of this study is to describe the reproductive cycle of the tehuelche scallop of San Matías Gulf and to compare the reproductive patterns between years for the same population.

MATERIALS AND METHODS

Specimens of tehuelche scallop were collected from the northern bank of the San Matías Gulf (Orengo, 40°52′S; 64°32′W) (Fig. 1), at a depth of 18–24 m, between August 1997 and July 1999. Monthly samples of 20 specimens, with a mean shell height of 67.05 mm (SD: 10.1), were used to determine the gonosomatic index (GSI) and muscular index (MI) before fixation. Scallops were dissected; the shells removed; and the total weight (TW), soft parts wet weight (SPW), muscular weight, and gonad wet weight (GW) were recorded. The GSI was calculated using the equation (Giesse & Pierce 1974, Jaramillo et al. 1993):

$$GSI = \frac{GW \times 100}{SPW}$$

Mean GSI was estimated for each monthly sample. To analyze multiyear trends in reproduction, data collected in 1997 and 1999 were coupled to a GSI data set already available for the Orengo area from 1989 and 1991, and both data sets were related to sea water temperature. Minimal average values following high average

---

*Corresponding author. E-mail: maitenarvarte@canaldig.com.ar values were considered as indicators of spawning (Jaramillo et al. 1993, Avendaño & Le Pennec 1997).

The mean muscular index (MI = wt. of adductor muscle/TW × 100) was estimated monthly in a similar way than GSI and was compared with GSI data.

The gonads from those 20 specimens were then processed for histologic analysis. The whole gonad was fixed in Davidson's solution, stored in ethanol (70%), and then dehydrated using a series of increasing ethanol solutions (Howard & Smith 1983). Then, the samples were embedded in paraffin and sections 5- to 7-µm thick were cut and stained with Harris hematoxylin and eosin.

Gonad tissue was quantitatively examined using the schemes of Lasta and Calvo (1978), Dibacco et al. (1995), and Pazos et al. (1996) to assess developmental stages. The percentage of each gonadal stage was analyzed. The definition of each stage (early-mid mature, ripe, partial spawn, spawning and recovery, and spent) is provided in Table 1. Photomicrographs were taken using a standard microscope at magnifications of 100 and 400×. Oocytes were measured and analyzed according to Dibacco et al. (1995). Mean oocyte diameter was estimated by measuring the diameter of 250 oocytes of each individual. This process was repeated for five individuals from the total monthly sample. Only those oocytes with clear nucleolus were considered for the analysis.

The GSI and adductor MI indexes were compared by means of a simple ANOVA using data that had been subjected to an arcsine transformation $[\sqrt{(p)}]$ (Sokal & Rohlf 1979). The maximum values of the oocyte diameter were compared between years using a simple ANOVA.

RESULTS

Gonosomatic Indices

During this two year study, major peaks in GSI were observed in January and December 1998. Peaks were followed by decreases in GSI, representative of spawning events (Fig. 1). Maximum GSI was significantly different ($F_{1,39}$ = 88.88, $P < 0.001$) between these two reproductive periods. Average values of GSI ranged between 27.58 (SD: 9.93) and 4.83 (SD: 0.85) from January to July 1998, and from 15.30 (SD: 5.17) to 4.01 (SD: 1.11) from December 1998 to April 1999.

GSI increased between July and October, indicative of early stages of gametogenesis. GSI then reached maximal values from November to January and subsequently dropped over a short period, which indicated a massive spawn. Spawning continued to April, when the last spawning events were detected and after which the GSI was annually the lowest (May through June). A resting period of 1–2 mo was observed after the autumn spawn.

The magnitude of spring and autumn spawning periods, estimated by observing the extent of drops and peaks of the GSI, varied interannually, particularly for the spring spawn.

Histologic Analyses

Sperm and oocytes were observed together in the gonoduct (Fig. 2a). The male portion spawns over a longer period than the female gonad (Fig. 2b) and, consequently, the female gonad development is what determines the reproductive viability. For this reason gonadal cycle was described only for the female portion of the gonad.

Oocyte Characteristics

Absence of vitello was typical of the development oocytes, as well as a defined nuclei (Fig. 2c). Mature oocytes had a diameter around 50–60 µm, with a high quantity of vitello around a conspicuous nuclei (Fig. 2d and 2e). Reabsorbed oocytes (both mature and non-mature) remained attached to the follicle wall or free inside it. They were easily distinguished by the loss of the round-polyedric shape, typical of mature oocytes, and by the diffuse contour of the cell membrane (Fig. 2f). The central portion of the gonad, or the transitional zone between female and male portions, had a high frequency of atresic oocytes mainly in the ripe stage during August–October 1997 (Fig. 2h).

TABLE 1.

Main histological characteristics of gonadal maturity stages of the tehuelche scallop. Gonadal stages were determined by histological analysis and scored using a modification of Lasta and Calvo (1978).

Stages	Description
Early maturation	Follicles are well-defined. The lumen may occupy up to 50% of the follicle.The interfollicular space is highly visible. *Male:* few layers of cells (germ cells and spermatogonia) along the follicle wall. *Female:* presence of germ cells, oogonia, and primary oocytes with diameters varing between 10 and 25 µm.
Mid-maturation	The follicles occupy up to 75% of the gonad. Follicular lumen is much reduced. Interfollicular space is still present but limited. *Male:* follicles are full of spermatocytes I and II and spermatids. *Female:* stalked oocytes I, 25 to 40 µm, protrude into the follicular lumen but still attached to the wall (peduncled oocytes).
Ripe	The follicles are completely full of ripe gametes, and there is no interfollicular space. *Male:* spermatozoa occupy almost 100% of the follicles. They are in order and oriented with the flagella toward the centre of the follicle. *Female:* follicles are full of free oocytes up to 50 µm diameter. They have polygonal shapes, being pressed against each other.
Spawn and recovery	Ripe gametes are being released through the gonoducts. Presence of a second series of germ cells attached to the follicular wall. *Male:* presence of spermatocytes I and II, and spermatozoa are disordered in the follicular lumen. *Female:* presence of oocyte I attached to the wall and polygonal oocytes free and disordered in the follicular lumen.
Partial spawn	Follicles remain full of mature gametes, but some of them look lax because some gametes were released. Some phagocytes are present in the interfollicle space. *Male:* spermatozoa are disordered and separated in the follicular lumen. *Female:* remained oocytes still have polygonal shapes and they are free or attached at one side of the follicle.
Spent	Most follicles are empty. Interfollicular spaces become very noticeable. Phagocytic cells are very abundant. Residual gametes may or not be present, but with no signs of gametogenesis.

Gonadal Phases

Gonadal phases, considered as the percentage of individuals of each gonadal stage over the monthly sample, differed between 1997 and 1998 and 1998 and 1999 (Table 1, Fig. 3).

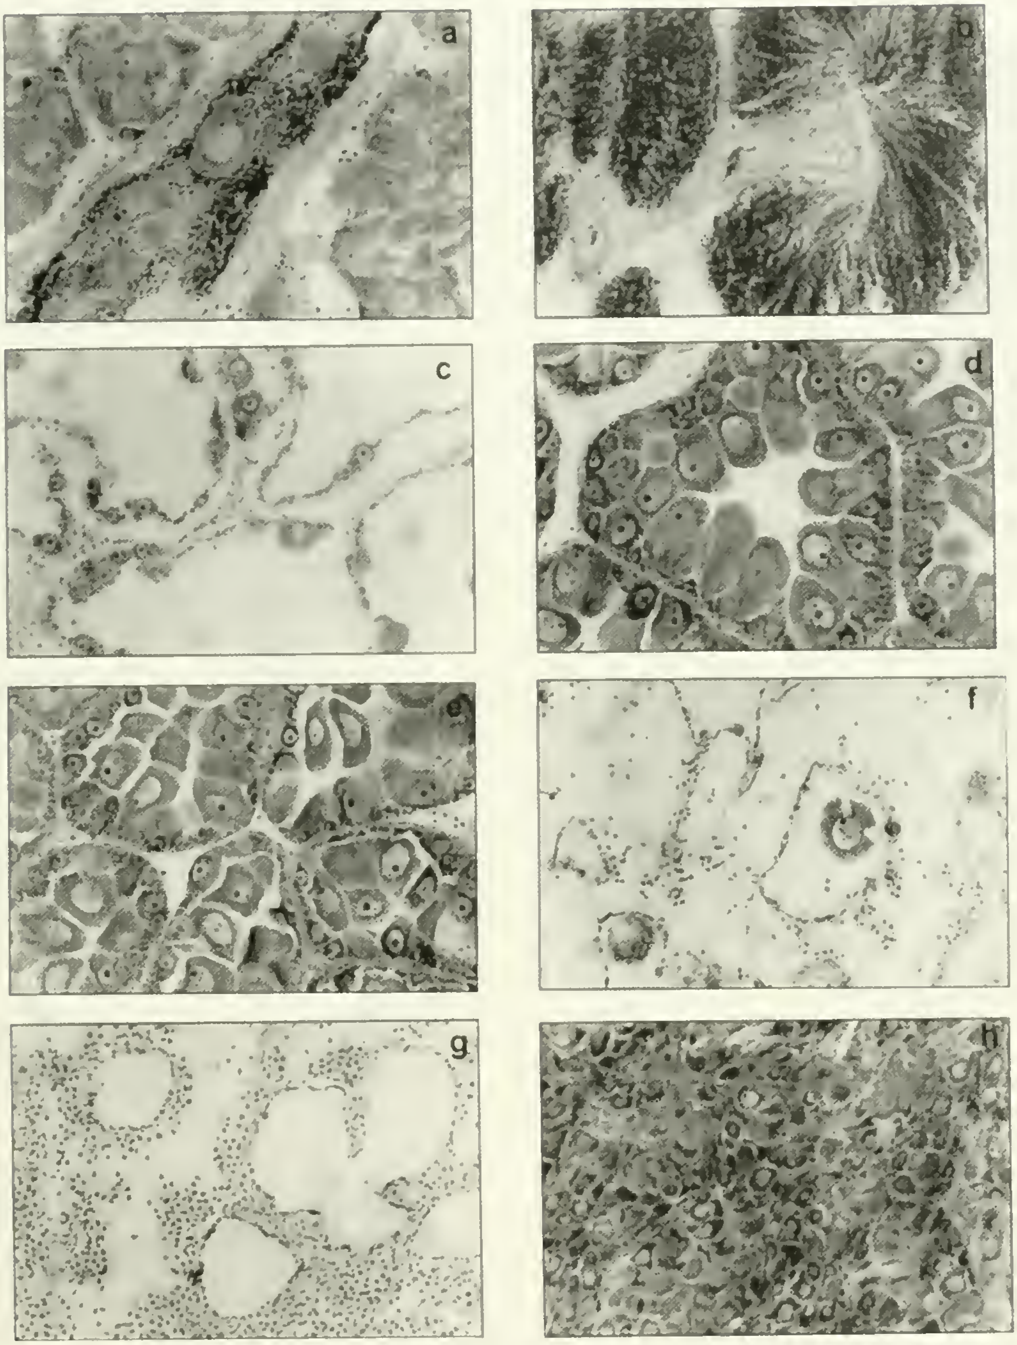

Figure 2. Photomicrographs of gonads of *Aequipecten tehuelchus* at different stages of a seasonal reproductive cycle. a, Sperm and oocytes in the same oviduct; b, partial male spawning; c–e, maturation; f, partial spawn; g, spent; h, atresic oocytes.

In 1997, 87% of the female gonads were "ripe" in August. Ripeness continued into the spring months, involving 90–100% of the total sample. The remaining individuals were spawning and recovering. A high percentage of individuals with atresic oocytes (80% in August–October) were considered ripe. A massive spawning (all individuals) occurred between December 1997 and January 1998, with individuals in partial spawning and recovery during this month. Partial spawns were observed in more than 90% of the population in February through March 1998 and most of the individuals were spent in May through July (Fig. 3).

In August 1998, the prevalent stage was mid maturation (90%). Proportions of total maturation during spring months (September through December 1998) were lower in magnitude than in the previous season, ranging from 55–85% of the sample. All individuals were in recovery in December 1998 and January 1999, indicating a spawning event had occurred. The same stage was observed in 70% of the individuals in February. Spent stages appeared gradually, increasing between March and June 1999 (Fig. 3).

Oocyte Diameter

Mean oocyte diameter reached its maximum value in December of both 1997 and 1998. Significant differences in the oocyte

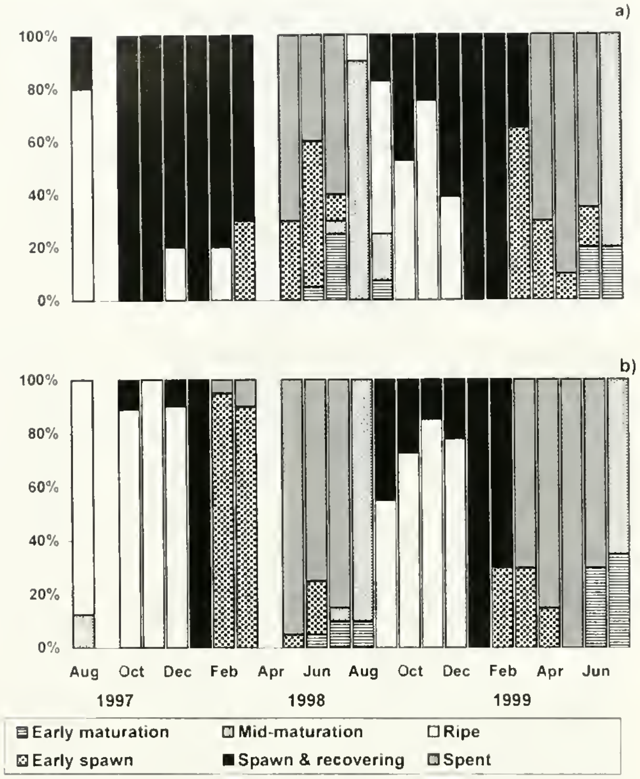

Figure 3. Diagram of the seasonal percentage distributions of the different gonadal phases in the tehuelche scallop gonads (a, male portion; b, female portion), during August 1997 to July 1999.

diameter were found between years ($F_{1,8} = 10.63$, $P < 0.05$) (Fig. 4). Maximum mean value in December 1997 was 41.98 µm (SD: 12.89), whereas a value of 36.04 µm (SD: 16.33) was found in December 1998.

Frequency distributions of oocyte diameters are presented in Figure 5. Mature oocytes were representatively observed in August 1997. Proportion of mature oocytes decreased in October and increased in November. The highest fraction of mature oocytes was observed in December of both years.

Mature oocytes were almost totally absent in January 1998 and the gonad was full of immature oocytes, indicating an intense proliferation. Diameter of these oocytes increased in February and they disappeared from the gonad in February and March. Two modes (10 and 35 µm) were present in March 1998.

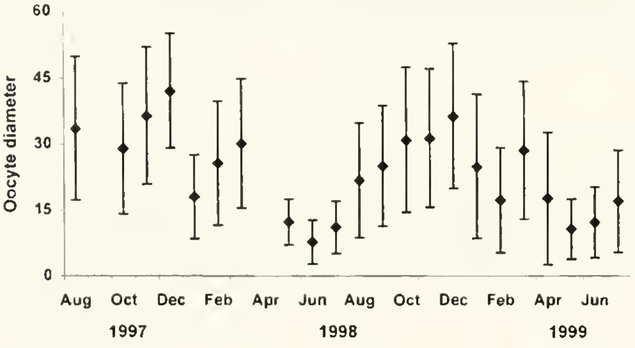

Figure 4. Mean oocyte diameter of tehuelche scallops, *Aequipecten tehuelchus*, in Playa Orengo, San Matías Gulf during August 1997–July 1999. Datapoints are mean values ± SD (*n* = 5 per sampling date).

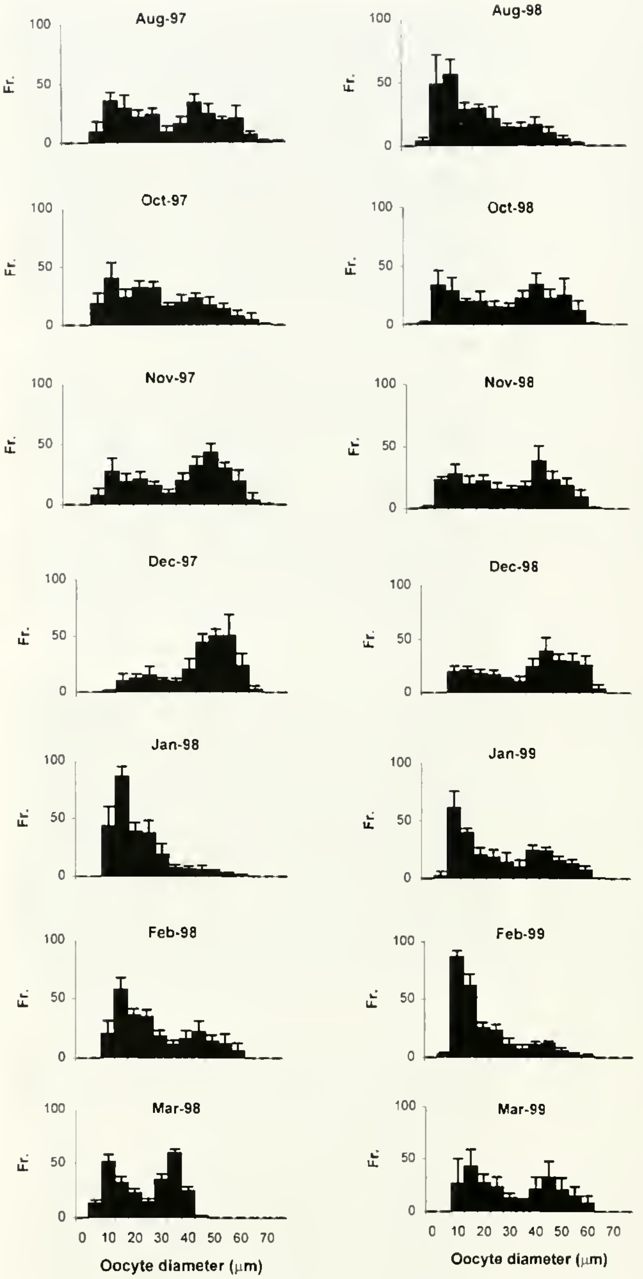

Figure 5. Frequency distribution of oocyte diameters of *A. tehuelchus* during the period from 1997 to 1999 (columns: mean values; bars: SD; *n* = 5 individuals per sampling date).

Prevalent stages found in August and September 1998 matched the initial cell series (early maturation). The co-existence of two generations of cells from September 1998 to March 1999 was characteristic of partial spawnings with recovery. A great fraction of mature oocytes disappeared from December 1998 to January 1999. In January and February, intense oocyte proliferation was observed. Numbers of mature oocytes increased again in March 1999 and decreased abruptly in April, indicating a fall spawning.

Inter-Year Variations of GSI and Its Relation With Water Temperature

Water temperature records of the 1989 and 1991 period showed slight variations between years. Differences between 1997 and

1998, however, were greater (Fig. 6a). Records of winter 1997–summer 1998 varied less ($\Delta \approx 1$°C) than records of 1998 and 1999. The highest monthly increases ($\Delta T > 1.3$°C) were recorded from September to December for the period 1997–1998 and from September to January in 1998–1999.

Figure 6b represents the variations of GSI during 1989–1991 and 1997–1999 seasons. Inter-year variations were similar for the first period. Maximum mean values oscillated between 16.15 (SD: 4.28) and 17.56 (SD: 6.02). During the 1997 and 1999 periods, differences between years were greater, ranging from 27.58 (SD: 9.93) to 15.30 (SD: 5.17).

Muscular Energy Reserves

MI reached its maximum mean value during winter-spring months, before the start of the reproductive season of 1997 to 1998 and 1998 to 1999 (Fig. 7). No differences in the MI were found between 1997 and 1998, for August, October, and November ($P > 0.05$). MI increased between January and July before gonadal development (Fig. 7).

DISCUSSION

The GSI of *A. tehuelchus* from the San Matías Gulf, studied over 2 consecutive years, indicated that this species undergoes its maximum reproductive activity during the spring–summer months. A small spawning occurred in autumn. Even when this pattern was repeated during the study period, seasonality and duration of spawnings were not identical between successive years. In both the 1997 to 1998 and 1998 to 1999 seasons, a massive spawning occurred between December and January. A second, lower-magnitude spawning occurred in March through April 1999. Even though a fall spawning was not supported by GSI in 1998, evidence of spawning was clearly observed in the oocyte frequency distribution and mean oocyte sizes.

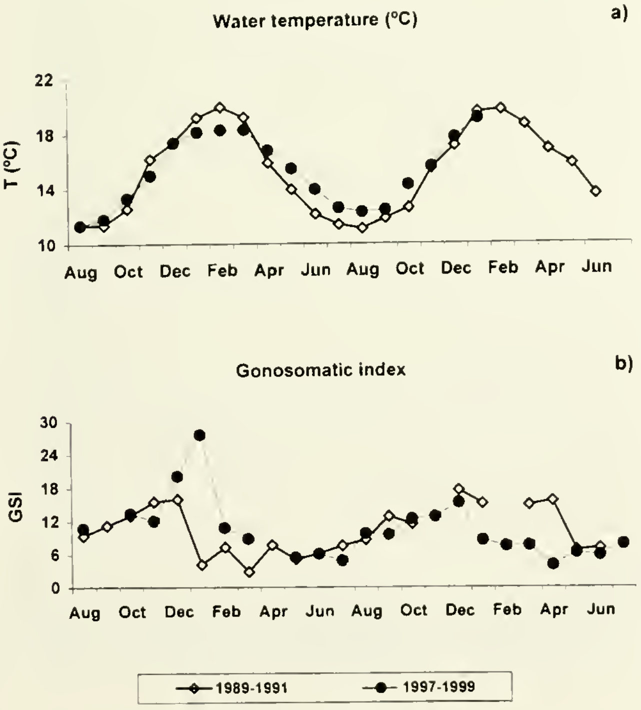

Figure 6. Inter-year variations of (a) the seawater temperature (T, °C) and (b) GSI during two study periods, 1989 to 1991 and 1997 to 1999.

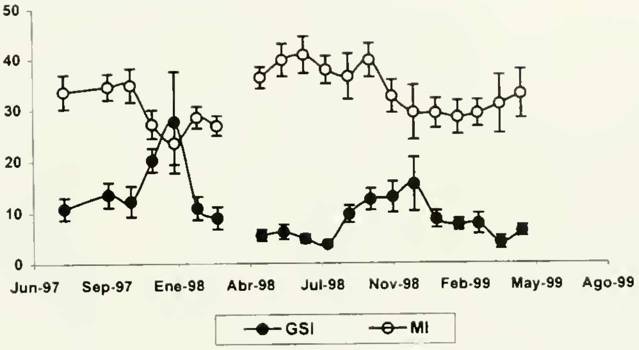

Figure 7. Variations of MI and GSI indexes from August 1997 to June 1999.

Temporal patterns of the reproductive condition of the tehuelche scallop in this study revealed some other differences between histological analyses and GSI monitoring. The main spawning in 1997 to 1998 season was detected from January to February by GSI and from December to January by histologic studies. In addition, the microscopy study on the female gonad of *A. tehuelchus* revealed the coexistence of different components of the oocyte series in those successive years. Therefore, the tehuelche scallop has asynchronous maturation and continuous spawnings within the same reproductive season.

The existence of an early mature stage in August was confirmed by the oocyte diameter frequency distribution. Nevertheless, the great percentage of atresic oocytes in August–October suggests that spawning did not occur. Greater than 50% atresia has also been observed in other pectinids (Lubet et al. 1987a, Lubet et al. 1987b, Avendaño & Le Pennec 1997, Román et al., unpublished data). Dibacco et al. (1995) suggested that during unfavorable environmental conditions, bivalves may have a mechanism to reabsorb and use the high energy content of mature oocytes. As in other pectinids (Motavkine & Varaksine 1983, Beninger 1987, Dorange & Le Pennec 1989, Avendaño & Le Pennec 1997), the highest levels of atresia in *A. tehuelchus* were observed just before spawning. These authors have suggested that atresia should be related with an energy deficiency, caused by low food availability. This could have occurred during the winter months in 1997 in San Matías Gulf, when lower water temperature was recorded.

Histologic observations of the female gonad during the fall spawning of both reproductive seasons showed a high relative proportion of oocytes in early stages, whereas larger oocytes were observed undergoing lysis. Metabolites produced by lysis of mature oocytes by phagocytic cells, present in large quantities at the end of the reproductive period, would implicate an important energy contribution for the recovery after the reproductive season. This phenomenon was previously observed for a variety of pectinids (Dibacco et al. 1995, Avendaño & Le Pennec 1997). Accordingly, we could infer that the second spawning of each season was smaller than the first, and constituted a minor contribution to that year class.

The utilization of the adductor muscle energy reserves for reproduction was cited for other pectinids (Barber & Blake 1991). Variations of MI observed along two annual cycles in this study showed a similar pattern, in which the energy stored in the adductor muscle is then diverted to the reproductive system, to satisfy energetic demands for the synthesis of gonad components (Gould et al. 1988). When the MI was compared between years, no clear variations were observed between 1997–1998 and 1998–1999. Therefore, energy demands from the muscle seemed to be similar. However, the extraordinary GSI values in 1997–1998 suggest a higher energy availability for the gonad development. Because muscular reserves are limited by muscular degradation, other exogenous mechanisms could help to sustain the energy budget for this development. A higher food availability during the spring 1997 was probably responsible for this extraordinary gonadal development. Thompson and MacDonald (1991) have indicated that temperate species such as *Placopecten magellanicus* are exposed to phytoplanktonic "blooms" in early spring and therefore have a short period of energy reserve accumulation. This early investment for reproduction would depend of the environmental conditions following the bloom (Dibacco et al. 1995).

de Vido de Mattio (1984) and Orensanz (1986) indicated that energy for gonadal development for *A. tehuelchus* in the San José Gulf seems to come more from food than from the energy stored in the muscle. In the San Matías Gulf, a decrease of MI before spawning indicates that this population uses both energy sources, food and muscle. As was observed in other pectinids (Langton et al. 1987, Barber & Blake 1991, Dibacco et al. 1995, Rheault & Rice 1996, Avendaño & Le Pennec 1997), exogenous factors, such as temperature and food availability, may produce great variations in the gonadal development and the spawning time of *A. tehuelchus*.

AKNOWLEDGMENTS

This work was supported by funds from the Europe Union–Argentina Agreement (1996–1999). The authors thank the personnel of the IBMP "Alte. Storni" for their cooperation and assistance. We specially thank Sandro Acosta, Tony Brochado, and Elda Cerecera for assisting with field and laboratory activities, and Marcela Pascual, José M. Orensanz, and an anonymous reviewer for their constructive criticism of the manuscript.

ABSTRACT A study was conducted on the reproductive and reserve storage cycles in *Aequipecten opercularis* (L., 1758) from deep waters (50–60 m) in the Ría de Arousa (Galicia, NW Spain). The reproductive cycle was studied by visual inspection of the gonad, the use of the gonad condition index, the gonad dry weight of a standard queen scallop 50-mm height, the average oocyte diameter and the percentage of the gonad occupied by oocytes. The same results were obtained with each of these methods. Following a resting period in autumn, which varied in length depending on the year, there was a period of recovery in winter, followed by a spawning period lasting until the end of summer. There were several partial spawnings, followed by recovery periods until the gonad was totally spent. Accumulated reserves in the adductor muscle (glycogen and proteins) and digestive gland (lipids) were used up during gametogenesis. The weight and condition indices of both organs and their reserve substrate contents showed parallel changes throughout the two years of the study.

KEY WORDS: *Aequipecten opercularis*, Ría de Arousa, breeding season, reproduction, energy reserves

INTRODUCTION

Aequipecten opercularis (L., 1758) is distributed along the North Atlantic coast, ranging between 30°N and 70°N, and also extends to the Mediterranean and the Adriatic Sea (Brand 1991). There is one commercial fishery of this species in Galicia, which in the 1960s caught up to 700 tonnes year^{-1}, although nowadays the catch rarely exceeds 100 tonnes year^{-1}.

Despite the commercial interest in *A. opercularis* in Galicia, investigation of the reproductive biology of natural populations in this region has not been performed. Only the reserve storage cycle and breeding season have been previously been described, by Román et al. (1996), for cultured queen scallop in the Ría de Arosa.

Mason (1983) and Barber and Blake (1991) reviewed the periods of gametogenesis in queen scallop populations in the North Atlantic. However, the information provided is scant and the reproductive behavior of geographically separated populations of the same species may vary (MacDonald & Thompson 1988, Bricelj et al. 1987, Devauchelle & Mingant 1991).

As gametogenesis, the storage and use of energy reserves in scallops is also cyclical and underlies the reproductive cycle. The importance of stored reserves in the reproductive cycle of pectinids in temperate waters is well documented (see Barber & Blake 1991 for a review). In general, protein and/or glycogen are stored in the adductor muscle and lipids in the digestive gland. Barber and Blake (1981) reported that in *Argopecten irradians*, the relative importance of different parts of the body as energy storage sites is highly adaptive, and results from genetic divergence or non genetic adaptation to different environments within the geographical range of the species.

This study is part of an investigation of the feasibility of cultivating *A.opercularis* in Galicia from spat obtained from natural environments using collectors. Studies of the reproductive behavior of this species are required to optimize spat collection for commercial purposes. The main objectives of this study are to describe gametogenesis, the breeding season, seasonal changes in weight of reserve storage organs and their biochemical composition in relation to the reproductive cycle, and the influence of environmental factors on gametogenesis and spawning.

MATERIALS AND METHODS

Study Area

The largest population of queen scallops in the Ría de Arosa are found in "The Channel" (Fig. 1), at a depth of between 50 and 60 m. The study was therefore centered on this area, although disperse, smaller banks are found in shallower waters.

Environment

From January 1996 until December 1997 weekly recording was made of temperature, salinity and chlorophyll ***a*** at a depth of 45 m using a CTD. From March to September 1996 fortnightly determinations were made of the particulate organic matter, by filtering a sample of 2 L of seawater, collected from a depth of 50 m, using pre weighed Whatman GFC/C filters (Whatman International Ltd., Maidstone, England). After drying at 60°C for 24 h, the filters were weighed then reweighed after combustion at 450°C for 12 h. The organic matter content was calculated as the difference between the two weights.

Animals

Adult specimens of *A. opercularis* were collected between January 26,1996 and November 18, 1997. Captures were made at fortnightly intervals in "The Channel" from a commercial fishing boat, by trawling. The animals measured between 35 and 65 mm in height, which corresponds to age year classes 1 and 2. The gonads of 10 scallops were placed in Bouin's fixative immediately following capture. The fixative was removed by frequent washing with 70% ethanol saturated with lithium carbonate and then stored in 70% ethanol until being processed. Classic histologic techniques were used; gonad was embedded in paraffin and serial sections of ovary (5 μm) stained using modified Wheatley's stain. Histologic study was only made of ovary tissue, using stereological methods (Paulet & Boucher 1991, Pazos et al. 1996) with a Visilog 5.1.1 image analyzer. The average diameter of the oocytes (Dm) and the

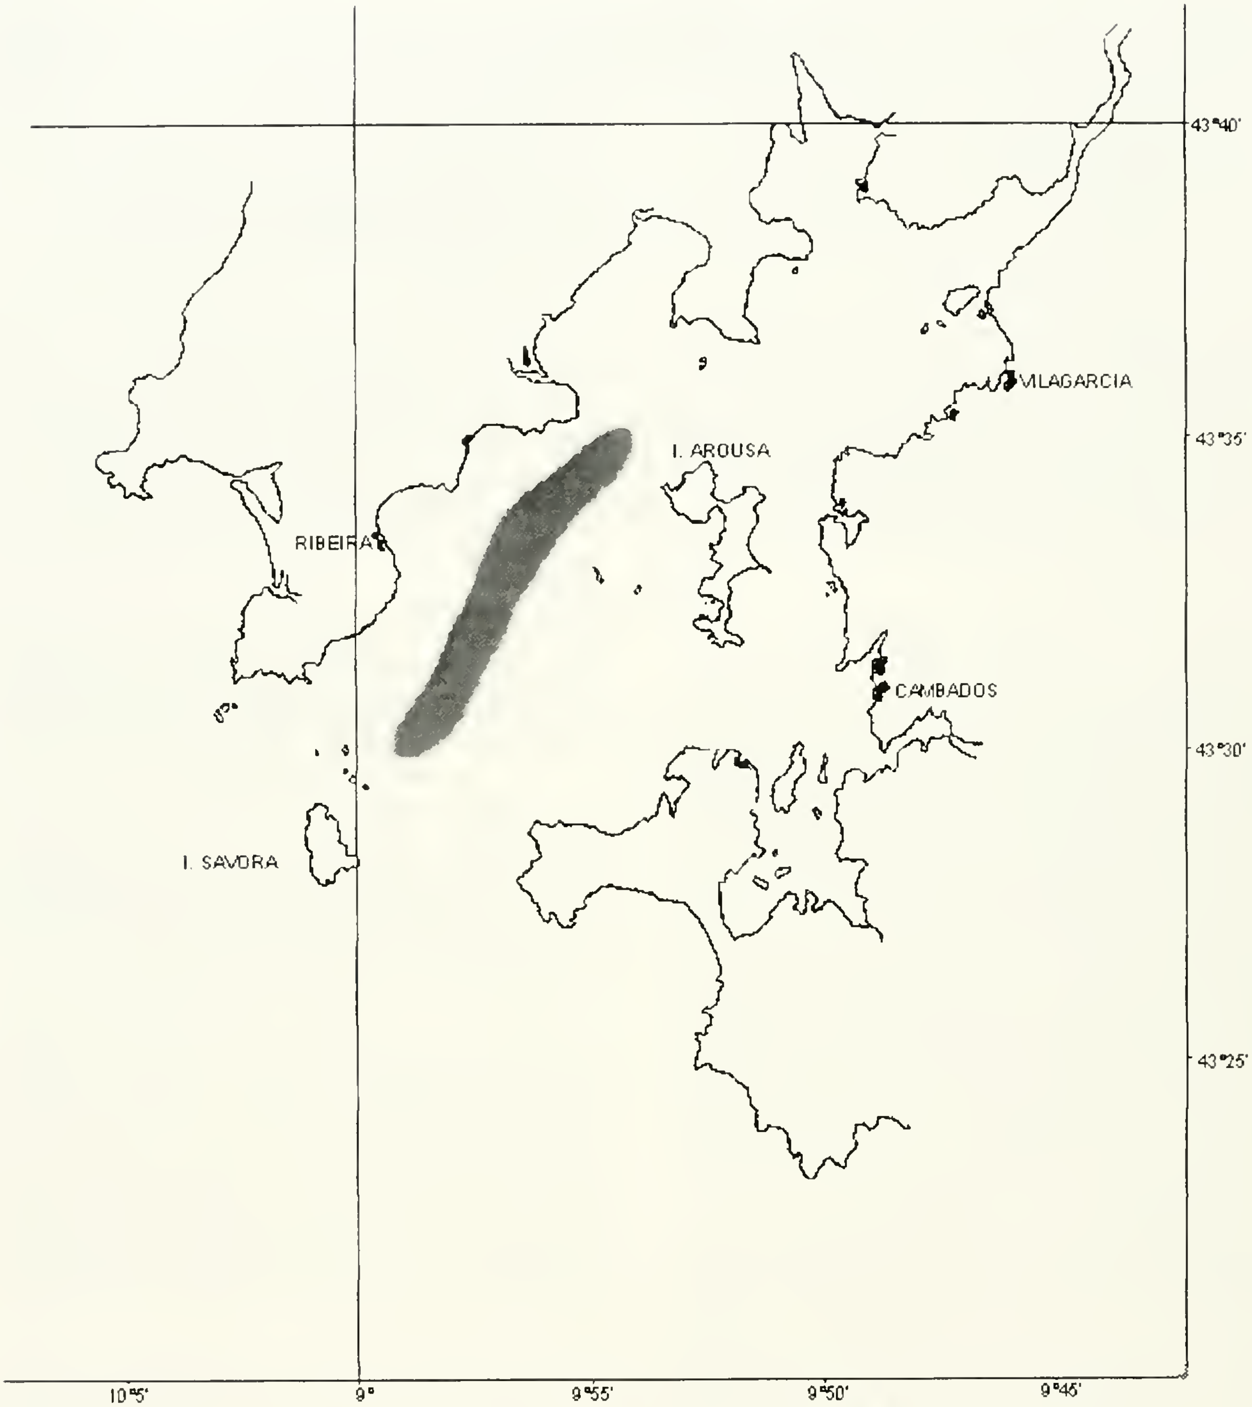

Figure 1. The Channel (shadowed area) in the Ría de Arosa.

percentage volume occupied by oocytes (OVF = % of ovary occupied by non atretic oocytes) were calculated.

Another 30 animals were transported to the laboratory in a coolbox and then maintained under running water for 18 h to allow sand to be expelled. The specimens were then opened and the soft tissue separated into 4 components: gonad, adductor muscle, digestive gland, and remaining tissues. After draining for 10 min on filter paper, the wet weight (WW) was determined; an aliquot of each organ was used to determine the dry weight (DW 100°C, 24 h). We recorded the appearance of the gonad, noting if transparent and colorless or if there were two clearly differentiated areas of color (white or cream in the testicle, orange or red in the ovary).

The height of the shell was measured to the nearest 1 mm, using calipers. The shells were dried (100°C, 24 h) and weighed. Condition indices were calculated for gonad (Gci), digestive gland (DGci), muscle (Mci) and remaining tissues (RTci) using the following equation:

CI organ = 100 × DWorgan/DWshell (Lucas & Beninger, 1985).

Regression equations were used to describe the relationships between shell height and the dry weight of each component, and the weight of each component for a standard animal having a shell height of 50 mm was calculated according to Taylor and Venn (1979).

Aliquots of muscle, digestive gland and gonad were lyophilized before biochemical analyses were carried out (glycogen and protein content of muscle and total lipid content of digestive gland and gonad) following previously described techniques for lipids and glycogen (Román et al. 1996). Protein contents were determined from the N content, measured using an elemental analyzer Carlo Erba 1108. The amount of N was multiplied by 6.25 to estimate the amount of proteins (Ansell 1974, Beninger 1982). Grams of lipids in gonads and digestive gland and glycogen and protein in muscle were estimated by multiplying the percentage of each reserve substrate by the previously calculated standard dry weight of each component.

Statistical Methods

One-way ANOVA was used to test for significant differences among the average values of the condition indices, Dm and OVF. The normality of the distribution of the variables was tested using the Kolmogorov–Smirnof test and the homogeneity of the variables using Bartlett's test. Where necessary, arcsine transformations ($x' = \arcsin\sqrt{x}$) were carried out. Correlation coefficients were calculated for the relationships among gonad indices, Dm and OVF, and among the condition indices of the reserve storage organs, the standard dry weight and biochemical composition.

RESULTS

Environment

The temperature varied little throughout 1996, ranging between 12.7°C and 14.4°C. In 1997 very high temperatures of 17 to 18°C were recorded in May and June. High values of 16.5 to 17°C were also recorded from the end of October until the middle of November. The chlorophyll ***a*** content was low in both years, ranging between 0.6 and 1.3 μg L^{-1}; the lowest values were registered between October 1996 and May 1997 and did not rise above 0.8 μg chlorophyll ***a*** L^{-1}. Particulate organic matter ranged between 0.3 and 2.7 mg L^{-1}. Salinity remained practically constant at 35.7–35.8‰ throughout most of the sampling period, with slight decreases occurring in winter to below 35.5‰. The minimum value, 34.2‰, was recorded in November 1997 (Fig. 2).

Gonad

During winter and spring of 1996 the gonads were well differentiated, with testicle and ovary clearly visible in all specimens. From July 23, 1996 onwards there was an increasing percentage (reaching a maximum value of 90% on September 10) of queen scallops with spent gonads, which were flat, colorless and watery; histologic analysis revealed empty follicles in the undeveloped gonads. In these queen scallops that were in a period of sexual repose, the average diameter of the oocytes and the percentage volume occupied by oocytes was considered to be zero (Fig. 3).

Following the period with the maximum percentage of sexually reposing animals, there was a period of gonad recovery, which involved only part of the population, peaking (at 60%) on October 26, then a new minimum (30%) was observed on November 19. From December 1996 onwards there was a new period of gonad recovery, which this time involved the whole population, reaching full development on January 28, 1997. Following a decrease observed on February 12, which affected 40% of the population, all animals had developed gonads. This situation persisted until the end of summer, then from August 12 until October 28, 1997 all of the population was in sexual repose and displayed spent gonads. In 1997, gonad recovery took place between October 28 and November 19.

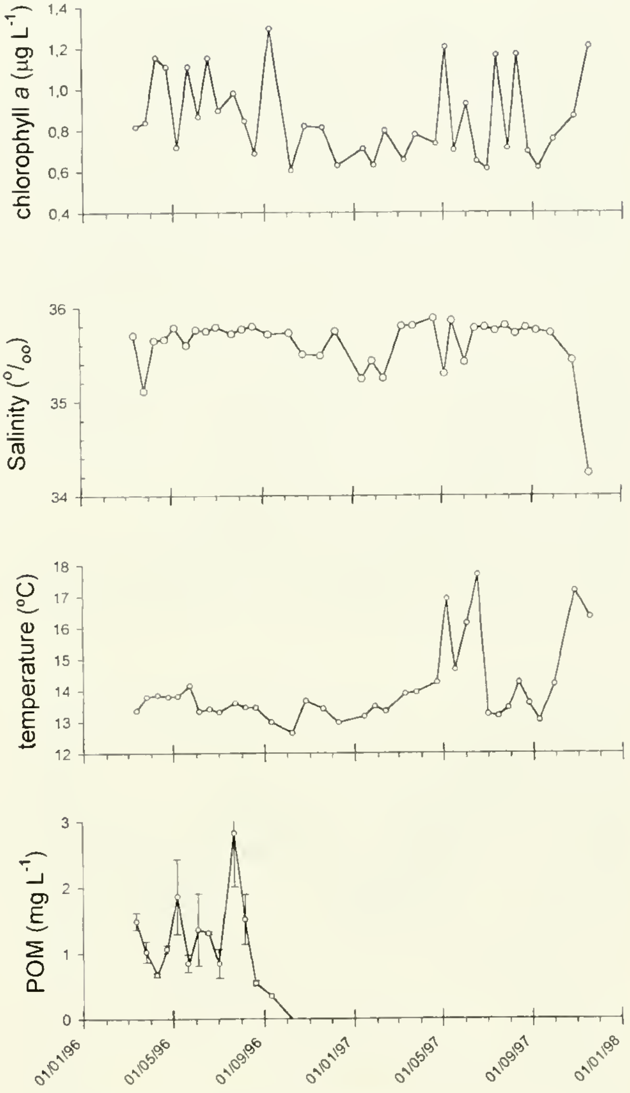

Figure 2. Environmental conditions in The Channel.

The value of the gonad condition index (Gci) ranged between 0.1 and 2.0 (Fig. 3). Maximum values corresponded to the period between March 13 and 26 1996 followed by a significantly lower value on April 10. There were then a series of recoveries followed by decreases to significantly lower values on June 4, July 2, and August 20; minimum values were recorded coinciding with gonads being totally spent. There was a new peak (significantly higher) on October 20, the gonads then became totally spent before undergoing recovery from November 19 onwards. The peak recorded on January 28, 1997 was followed by a significant decrease on February 12 and then again, as in 1996 there were a series of recoveries and decreases, with significant decreases observed on March 25, May 17, July 1, and August 12, which coincided with the

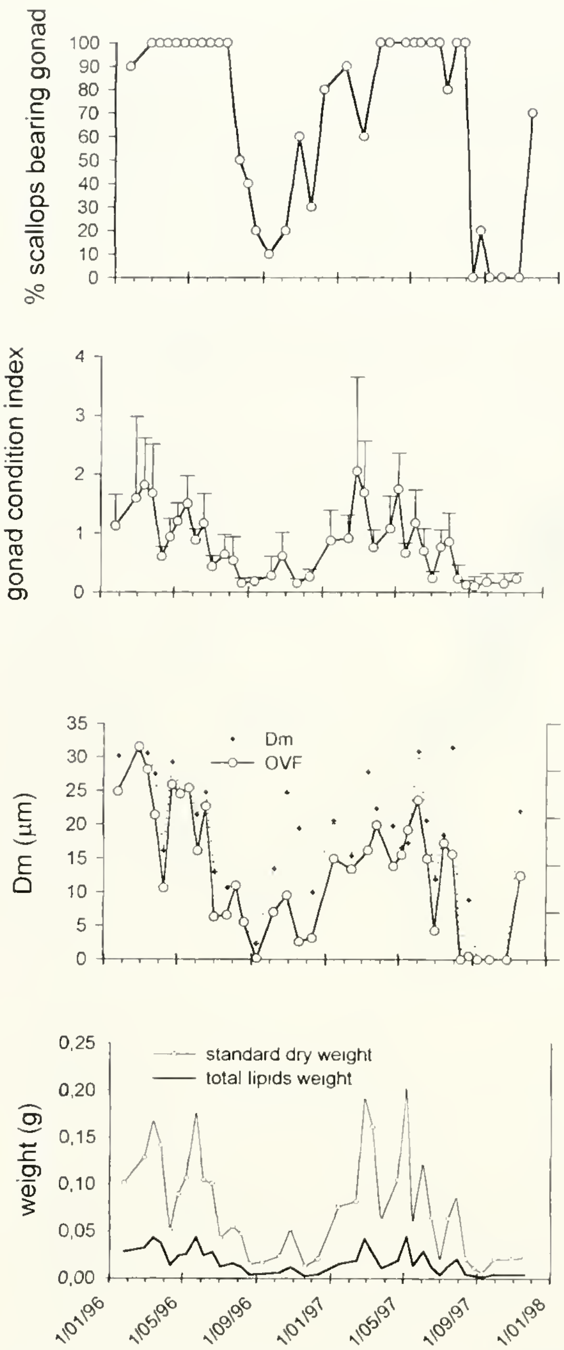

Figure 3. From top to bottom, a) percentage of scallops bearing gonad, b) gonad condition index, c) oocyte mean diameter and percentage volume of the ovary occupied by oocytes, and d) gonad dry weight of a standard 50 mm height scallop and lipid content of the gonad.

gonads being totally spent; recovery did not take place until November 19. The decreases were assumed to be associated with spawning.

Changes in the average diameter of the oocytes and of the percentage volume of the ovary occupied by oocytes (OVF) were similar (Fig. 3). Maximum values occurred in winter (February to March 1996) then a sharp decrease was observed on April 10, 1996. The values had significantly increased by April 24 and there was then a gradual decrease until reaching minimum values between September 10, and October 8, 1996, with two recoveries observed on June 19 and August 6. There were significant increases in both Dm and OVF between December 16 and January 14, coinciding with gonad recovery. In 1997 there were 4 peaks observed on January 28, March 10, June 3, and July 29 followed by decreases, which only on the latter date was not followed by gonad recovery.

The changes in all of the parameters studied followed the same pattern and each parameter was significantly correlated with the others: Gci vs. Dm (r_s = 0.588, $P < 0.0001$); OVF vs. Dm (r_s = 0.772, $P < 0.0001$), and Gci vs. OVF (r_s = 0.716, $P < 0.0001$).

The gonad dry weight of a standard queen scallop ranged between 0.006 and 0.204 g. The seasonal variations are shown in Figure 3. Although the mean percentage value of the total weight was low (9.0%) the range of values varied greatly, between 0.7% and 23.0% of the dry weight of the animal. There was a large variation in weight, which followed the pattern of variation of Gci.

Biochemical Composition of the Gonad

The percentage values of lipid contents are shown in Table 1. The total lipid content of the gonad of a standard queen scallop varied in a similar way to the Gci and to the standard DW, with maximum and minimum values coinciding with the maximum and minimum values of the condition index and the standard dry weight (Fig. 3).

Somatic Tissues

Seasonal changes in the standard dry weight of the muscle and the digestive gland, as well as in their respective condition indices and in their reserve substrate contents (lipids in digestive gland, glycogen and proteins in adductor muscle) are shown in Figure 4. Somatic growth began in early summer and was demonstrated by increases in dry weight, condition index and specific reserve substrate content, which reached maximum values between autumn and winter. There was then a decrease in the values of all of these parameters.

Adductor muscle accounted for most of the weight of the queen scallop, on average 54.5%; the mean dry weight of the muscle varied between 35.6% and 68.1%, representing the greatest variation in the weight of the animal. The dry weight of the muscle of a standard animal varied between 0.273 and 0.993 g, (i.e., the mean dry weight varied by up to 3 times). The condition index of the adductor muscle (Mci) varied in a similar way, ranging between 3.3 and 8.5.

Digestive gland accounted for a small proportion of the total weight of the animal (mean, 10.3%, range 6.9%–14.2%). Although the weight varied more than that of the muscle, ranging between 0.042 and 0.198 g, (i.e., varying by almost 5 times) the condition index (DGci) ranged between 0.5 and 1.7 (i.e., it varied by more than three times).

The dry weight of the remaining tissues accounted for, on average, 26.0% of the weight of the animal, ranging between 17.3% and 39.1% of the somatic components of the standard queen scallop. The dry weight of the remaining tissues of the standard specimen ranged between 0.144 and 0.310 g (i.e., it varied by approximately two times).

The percentage amounts of glycogen and proteins in the muscle and of lipids in the digestive gland in the gonad are shown in Table 1.

In January 1996, high values were recorded of standard dry weight of muscle, Mci, percentage, glycogen, and total protein and

glycogen content; these then decreased rapidly and minimum values were registered at the beginning of spring. During summer and autumn there was rapid somatic growth, with maximum weight values in November. Values of all parameters then began to decrease and the cycle was repeated, with minimum values occurring at the beginning of spring 1997, before beginning to increase once again. The percentage amount of proteins in the muscle showed a more irregular pattern of variation, with frequent oscillations between 70% and 80% between March and September. Following a minimum of 65% in November the values began to increase showing a similar pattern to that of the previous year.

The changes in standard dry weight of the digestive gland, DGci, percentage lipids, and total lipid content showed parallel variation, with the pattern being very similar to that observed for the studied muscle parameters. The greatest differences were that in both years growth of the digestive gland began later than that of the adductor muscle and also that in May of both years there was a sharp increase in growth, only found in the muscle in 1997.

There was no clear pattern of variation for the remaining tissues, or any correlation with the other somatic components.

There were highly significant positive correlations among condition index, standard dry weight and lipid content of the digestive gland and among condition index, standard dry weight and glycogen and protein contents of the muscle (simple regression, $P < 0.01$). Likewise, there were statistically significant correlations between the muscle and digestive gland condition indices ($P < 0.01$), between the "standard" dry weight of the muscle and of the digestive gland ($P < 0.01$) and between the lipid content of the digestive gland and glycogen and protein contents of the muscle ($P < 0.01$). Only the percentage amount of proteins in muscle correlated negatively with the other parameters.

Spearman's correlation analysis did not reveal any significant correlation between environmental variables and the parameters used to study reproduction and the cycle of reserve storage.

DISCUSSION

In this study we describe the spawning cycle and the cycles of storage and use of reserves in a population of *A.opercularis* from relatively deep waters (50–60 m) in the Ría de Arousa.

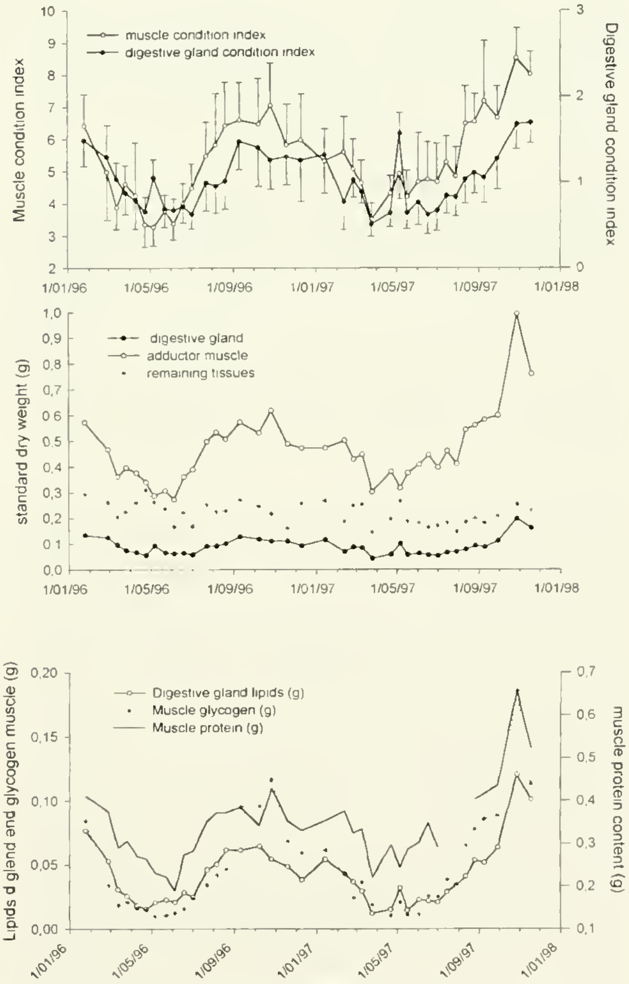

Figure 4. From top to bottom, a) muscle and digestive gland condition indices, b) dry weight of the somatic components of a standard scallop 50 mm height, and c) biochemical composition of the specific reserve substrates of the organs of energy storage.

Spawning Cycle

The spawning cycle of *A. opercularis* was studied by visual observation (presence or absence of developed gonad) as well as by quantitative (Gci) and qualitative methods (Dm and OVF) (Barber & Blake 1991).

Despite the simplicity of the first method, its use provided a general idea of when spawning took place—from winter until the middle of summer—there being a gradual decrease in the number of specimens with gonad as the summer progressed, culminating in the gonads being totally spent. There then followed a period of gonad recovery in autumn. Taylor and Venn (1979) also found the maximum number of spent scallops in summer in the Clyde Sea Area, although both the time of appearance of animals without gonad and the recovery period were earlier than found in the present study. It is possible that the rough estimate provided by this method would only be applicable in species or populations with very marked seasonal variations and in which gonads become totally spent.

The consistency of the results obtained by the different methods of establishing the different processes involved in the reproductive cycle (Gci, OVF, Dm) may be because Gci decreases due to release of mature, larger oocytes. As a result, there is an obvious decrease in the diameter of the remaining oocytes and of the percentage space occupied by them. Furthermore, as seen in the graphs outlining the changes in Dm and OVF (Fig. 2), increases in Gci coincided with cytoplasmic growth and vitellogenesis, (therefore larger oocyte diameter and greater percentage space occupied).

Spawning was indicated by the decrease in the Gci, the decrease in the mean diameter and the percentage space occupied as well as by the increase in the percentage number of spent gonads and the decrease in "standard" dry weight and lipid content.

Optimization of spat collection in natural environments depends on knowledge of the reproductive cycle, the changes in which must be monitored over time. The consistency of results independent of the method used allows monitoring of the reproductive cycle of this species without the need for use of sophisticated, expensive techniques by, simply recording the changes in Gci.

Following spawning, we recorded a period of gonad recovery, characterized by undifferentiated gonads, without gametes, as previously described by Allarakh (1979), who observed a very short recovery period of less than a month. In this study, this period lasted for 1 month in 1996 (September 10 to October 8) and for almost 2 months in 1997 (September 9 to October 28). In 1996 the period of sexual repose was shorter because there was partial maturation in autumn (from October 8), which was not observed in 1997. In both years gonad recovery, which involved the whole population, started at the end of autumn or beginning of winter and was rapid, as the first spawning took place in January; there were then a series of successive periods of maturation and spawning that lasted until the middle of summer. As the summer progressed, the number of individuals participating in reproduction gradually decreased (1996), or all suddenly displayed spent gonads (1997).

We conclude that the reproductive strategy of this species consists of a very protracted spawning period with frequent partial release of mature oocytes, followed by recovery due to the rapid maturation of oocytes present in the follicles, by vitellogenesis. These ovocytes are in turn spawned while a new cohort of oocytes matures. The successive recovery and spawning periods involve gradually less oocytes, until the gonads are totally spent; the final spawning is therefore not the most important. The whole population participates in reproduction during the period of greatest gametic activity, from February to July, but between August and January, only part of the population is involved.

Descriptions of the reproductive cycle of *A. opercularis* in northern areas, revised by Mason (1983) and Barber and Blake (1991), are mainly based on visual observation of gonads, although Taylor and Venn (1979) used the dry weight of gonad to describe the spawning cycle in Clyde Sea area; only Allarakh (1979) used histologic methods to study the reproductive cycle in scallops from Rade de Brest. In general these studies describe partial spawning taking place at different times, and the main spawning in autumn. Allarakh (1979) for example, described three natural spawnings in Rade de Brest, the first two in January to February and June to July and the third in September, ending with gonads being totally spent. Soemodihardjo (1974) and Paul (1978) reported various spawning periods in the Isle of Man, two partial spawnings in winter (January to February) and spring or the beginning of summer (May to July) and the main spawning in autumn (August to October). Amirthalingam (1928) observed spawning between January and July in Plymouth but did not record any spawning activity in autumn.

Our results are generally consistent with those of the authors cited, although the more frequent sampling and the inclusion of histologic analyses allowed confirmation that partial spawning takes place more often than previously described in other populations and that the final spawning that resulted in the gonads being totally spent, is not the most important, but merely the last before gonad recovery. In summary, partial spawning forms part of the sexual strategy consisting of staggered maturation of 4 to 5 cohorts of oocytes that are shed when mature, throughout a long breeding season that may span from January to July.

The generally small number of oocytes obtained by artificial stimulation of these animals is possibly due to this behavior (Le Pennec, 1982).

Conversion of the measurements obtained to those of a standard 50-mm animal allowed us to compare our results with those of Taylor and Venn (1979). In one of the two years of their study, these authors recorded a lower standard dry weight of gonad than in this study (range between 0.087–0.105 g), whereas in the other year the values were similar (0.170–0.198 g). In this study, the maximum values ranged between 0.168–0.204 g. This may be partly due to the lower frequency of sampling by Taylor and Venn (1979), who may have recorded dry weight values as they were rising or falling but not while at their maximum values, as we have observed considerable increases and decreases in weight within 15 days. A similar explanation may be given for the greater number of spawnings that were observed.

The lipid contents of scallops from the Ría de Arousa (maximum levels of 0.043 and 0.045 g in 1996 and 1997, respectively) were considerably higher than in those from the Clyde Sea Area (0.013–0.026 g).

Spawning took place at approximately the same times in both years, despite the large differences in temperature observed. Temperature therefore probably does not affect spawning, as previously thought by other authors; Broom (1976) investigated the possible relationship between spawning and changes in temperature, but with inconclusive results.

Cycles of Storage and Use of Reserves

By autumn somatic growth was completed, the muscle and digestive gland had reached their maximum weights and had maximum levels of reserves, the breeding season was over and gonads were spent. A new period of gonad growth began in November and from this time onwards in both years, the accumulated reserves began to diminish.

This decrease was associated with gametogenesis and the main spawning that affected the whole population during most of the breeding season. The final, partial, spawning that affects only part of the population, is apparently carried out using external energy enough to maintain gonad growth, without having to use the reserve energy stored in organs. In both years accumulation of reserves began (at the end of spring for muscle and at the beginning of July for digestive gland) even though spawning was still taking place.

The variation in the weights and indices of digestive gland and muscle indicate their status as reserve energy storage organs; the variation in the lipid content of the digestive gland and of glycogen and protein in the muscle indicate that these are the substrates used as energy reserves.

Although the percentage amount of protein in the muscle always remained high (64–80%), a large amount of protein was used (ranging between 0.189 and 0.657 g). The glycogen content varied greatly (3–18%), but the total amount used was relatively small (ranging between 0.010 and 0.185 g). As a consequence of fluctuations occurring during the cycle of storage and use of reserves, the weight of the muscle varied between 0.273 and 0.617 g and between 0.301 and 0.993 g in the first and second years, respectively. Observations were consistent with those of Taylor and Venn (1979) who describe a marked seasonal variation in the weight of the adductor muscle, with minimum values at the end of winter, gradual increases during spring and summer and maximum values in September to October, the weight sometimes doubling between March and October. According to these authors, and in agreement with our results, the seasonal variation in weight is due to changes in protein and carbohydrate contents.

Taylor and Venn (1979) attributed the variations in lipids of the remaining tissues to the digestive gland, although they did not carry out specific analyses of this organ. Observed in the Ría de Arousa were large variations in the lipid content of the digestive gland (minimum values of 0.012 and 0.016 g and maximum values of 0.133 and 0.198 g in 1996 and 1997, respectively), thereby confirming their speculations.

In contrast with the findings of Barber and Blake (1981), who observed that *Argopecten irradians concentricus* uses different substrates (glycogen, protein or lipids) of different origin (muscle or digestive gland) depending on the phase of gametogenesis, *A. opercularis* apparently uses all of its reserves simultaneously (muscle glycogen and proteins, as well as digestive gland lipids). However, these authors indicate that which are the important substrates, where they are stored and how their use is related to reproduction varies among species and among different populations of the same species. It should also be taken into account that *A. irradians concentricus* is semelparous, and has a straightforward reproductive cycle, with one spawning after which the animal dies, whereas *A. opercularis* is iteroparous, and spawns several times in one year for several years.

KARYOTYPE ANALYSIS AND CHROMOSOME BANDING OF THE CHILEAN–PERUVIAN SCALLOP *ARGOPECTEN PURPURATUS* (LAMARCK, 1819)

GONZALO GAJARDO,* MARGARITA PARRAGUEZ, AND NELSON COLIHUEQUE
Laboratory of Genetics & Aquaculture, Universidad de Los Lagos, P. O. Box 933, Osorno, Chile

ABSTRACT The Chilean–Peruvian scallop, *Argopecten purpuratus*, is the southernmost representative of the genus and has become an aquaculture commodity in Chile as a result of 20 y of culture practice promotion after natural beds were almost exhausted by overexploitation. Chromosome preparations of *A. purpuratus* D-larvae from three samples, two from commercial hatcheries, and one from the few remaining wild populations were subjected to karyotype analysis by the usual measurements of chromosome pairs, Ag-NOR staining, as well as by the Hoechst 33258/Actinomycin D counterstain and restriction endonuclease banding techniques. The species has a modal diploid number of $2n = 32$, and the karyotype consists of 11 pairs of telocentric and five pairs of subtelocentric chromosomes, NF=32. The banding techniques, attempted for the first time in the species, served as a good complement for identifying a number of homologous chromosomes. The NOR was located terminally on the short arm and in the pericentromeric region in three chromosome pairs. The Hoechst 33258/Actinomycin D counterstain revealed tiny fluorescent heterochromatic areas in the centromeric region of chromosome pairs 1, 2, 4, 5, 6, 7, 8, 9, 11, 15, and 16, whereas a quenching zone was observed in chromosome pair 6. Endonuclease restriction banding revealed pericentromeric and telomeric bands in one chromosome pair (*Alu*I) and interstitial bands in other two chromosome pairs (*Hae*III). The karyotype and banding pattern provided in this work are likely to help an industry seeking for improved stocks. Such information will be also valuable for further investigating both intra- and interspecific genomic relationships in the Chilean Pectinids, where the number of species karyologically screened is still very limited.

KEY WORDS: *Argopecten*, karyotype, Chilean scallop, genetics, banding

INTRODUCTION

Classic techniques for chromosome analysis generally have permitted accurate assessment of chromosome numbers and morphology in a wide variety of aquatic invertebrate species (Thiriot-Quiévreux 1994). Yet the number of species investigated from the cytogenetic point of view is rather scarce, i.e., no more than 200 of approximately 15,000 species in the Bivalvia class (González-Tizón et al. 2000). Recent molecular and banding techniques have contributed to a better identification of whole or chromosome parts, and hence to a more detailed characterization of the genome organization in different organisms. Analysis of the distribution and composition of heterochromatin and identification of the nucleolar organizer regions (NORs) are among these advances (Insua et al. 1998; González-Tizón et al. 2000). In commercially exploited species, these techniques have enabled the obtaining of better karyotypes, although not fully standardized, allowing more reliable intra- or interspecific comparisons of genetic resources either for basic studies (evolutionary inferences) or for practical purposes (taxonomy, chromosomal manipulations).

The Chilean–Peruvian scallop, *Argopecten purpuratus*, is a functional hermaphrodite inhabiting sedimentary substrates in sheltered bays along the Pacific Ocean from Paracas Bay, Peru (13° South) to the Gulf of Arauco, Chile (37° South). The species used to be a commercially important member of the subtidal macro-invertebrate fauna along the northern part of the Chilean coast until overfishing almost exhausted natural beds. Since 1982, *A. purpuratus* has been farmed successfully and currently represents an important aquaculture product (Gajardo & Núñez 1992). Because of its economic importance, the species has been transplanted to southern Chile, where it does not occur naturally. Von Brand et al. (1990) ascribed it to the genus *Argopecten* instead of *Chlamys* as previously described based on the fact that both diploid number ($2n = 32$) and chromosome types (4 m+ 14 m-Sm+ 6St+ 8t) were shared with other Pectinids, particularly *Argopecten irradians* (Wada 1978). Instead, most *Chlamys* species studied so far exhibit a diploid number of $2n = 38$ and few bi-armed chromosomes (Komaru and Wada 1985).

A. purpuratus is replaced by other *Chlamys* species in the southern Chilean coast, such as *Chlamys patagonica*, *Chlamys amandi*, and *Chlamys vitrea*. As part of a broader effort aimed at the genetic characterization of *Argopecten purpuratus*, this study seeks to provide a more reliable karyotype description and chromosome pairing based on the chromosome index and banding analysis of this important aquaculture commodity. The information provided is likely to help in future cytogenetic studies of intra- and interspecific karyotype comparisons of Chilean scallops.

MATERIAL AND METHODS

Chromosome Preparations

Argopecten purpuratus D-larvae were obtained by artificial hatching of ripe animals from three different sources. Two samples were from commercial hatcheries, Cultivos Marinos Internacionales S.A (Caldera), northern Chile (24° South), and Germont S.A in southern Chile (Calbuco; 51° South), whereas the Quintay sample corresponds to animals collected in Laguna Verde (33° South). This latter location is one of the few natural beds remaining in the Central coast of Chile, close to Valparaiso.

TABLE 1.

Diploid chromosome number determination in three populations of *A. purpuratus*.

Locality	No. of Cells Observed	Chromosome Number 25	26	27	28	29	30	31	32	Modal 2n
Caldera	48	2	1	3	4	3	7	5	23	32
Calbuco	49			1	1	5	8	11	23	32
Quintay	28			1	2	4	4	5	12	32

* Values with a different letter are significantly different (Tukey, $P < 0.05$).

The splash method was developed in our laboratory for D-larvae (24–48 h after hatch) according to the following protocol: initial colchicine (0.05%) treatment of a pool of D-larvae from each locality in sea water for 2 h, then mechanical disruption of cells, including centrifugation at 1000 rpm/10 min, hypotonic treatment in distilled/ seawater (1:1), washing to eliminate hypotonic solution (centrifuge at 800 rpm/10 min), fixation in methanol-acetic acid (3:1) for 20 min, and washing (centrifuging twice at 800 rpm/ 10 min). The pellet was re-suspended in 0.5 mL of cold fixative methanol/acetic acid (3:1) and a drop splashed onto clean slides and stained in 4% Giemsa. For diploid number determinations, between 28 and 49 of the best metaphase plates (without overlapping) were studied. These were then photographed on a Nikon Labophot microscope (with epifluorescence) for chromosome counting. In all populations, between 5 and 10 suitable cells were used for the estimation of the centromeric index (CI) following the protocol of Levan et al. (1964). Chromosome measurements were obtained and mean and standard deviation for CI were calculated for each chromosome. Total chromosome relative length (expressed as percentage) and the relative length of short (SA) and long arms (LA) over the total length of haploid complement were also obtained. Chromosome differences within and between karyotypes were evaluated from karyo-ideograms elaborated on SA and LA relative lengths (Spotorno 1985). Confidence intervals were established for SA and LA for each chromosome pair to assess the significance between comparisons. For chromosome arm number (NF) determinations, subtelocentric and acrocentric chromosomes were considered uni-armed according to Matthey (1945). This karyotype descriptor (NF), which only considers the main arm of a chromosome, is quite reliable as very often the size of the short arm of a subtelocentric chromosome is variable due to technical artefacts during spread preparations.

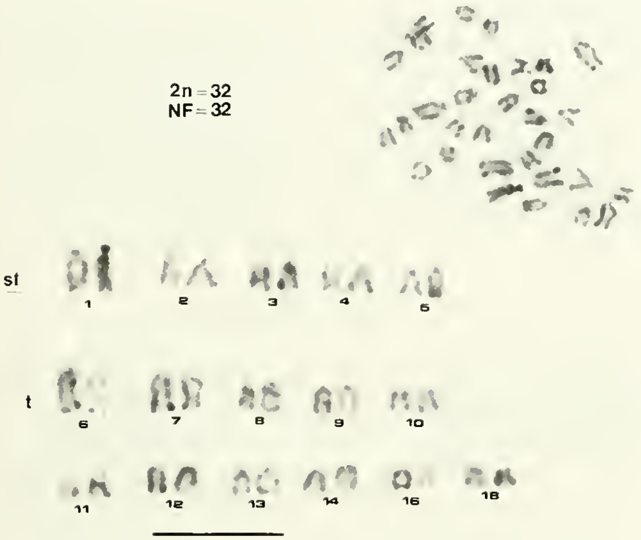

Figure 1. Karyotype of *Argopecten purpuratus*. $2n = 32$; NF = 32. Bar represents 10 microns.

Banding Methods

Howell and Black's (1980) silver-NOR staining method was used to identify NOR-bearing chromosomes. The counterstain-

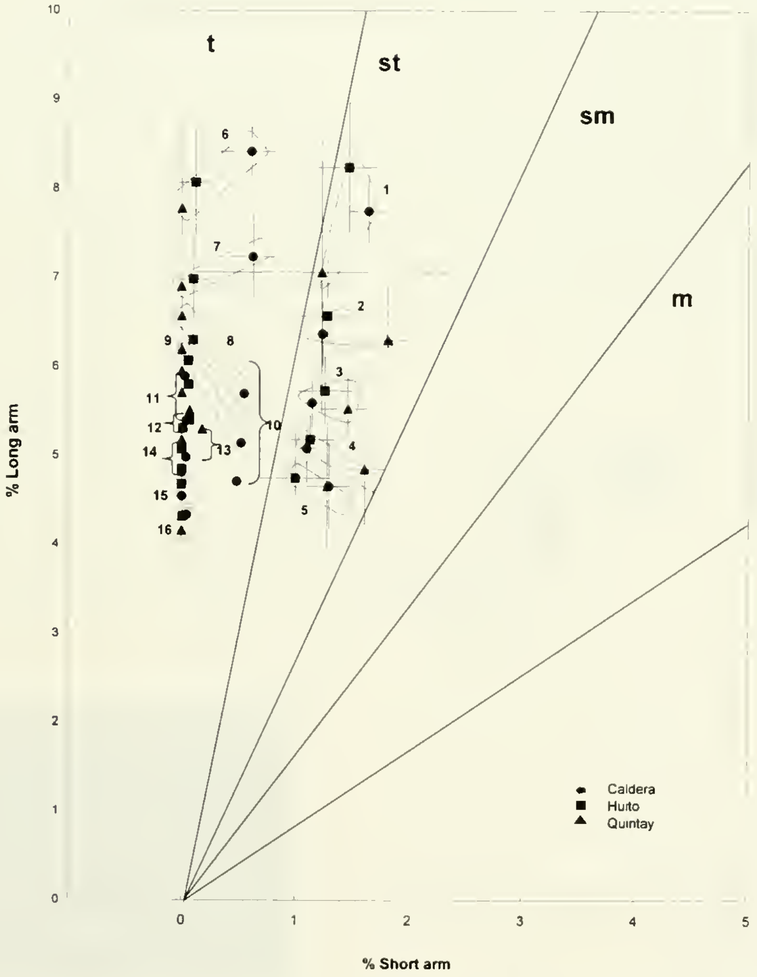

Figure 2. Karyo-idiogram for three populations of *A. purpuratus*. Diagonal lines separate chromosome morphologies in metacentrics (m), submetacentrics (sm), subtelocentrics (st), and telocentrics (t). Dotted lines show those chromosome pairs (identified by numbers) of the studied population that are easily distinguished from the rest. Each point in the karyo-idiogram represents a mean value (in percent) of the relative length of the short and the long arm of 16 homologous pairs. Bars represent 95% confidence intervals of the mean for short and long arms.

enhanced chromosome banding technique (Hoechst 33258/ Actinomycin D; Schweizer 1981) was used to identify heterochromatic regions. Metaphase plates were photographed using a Nikon epifluorescence microscope (filter block UV-2) with a Kodak T-Max 100 ASA film.

For restriction endonuclease (RE) banding, RE enzymes suspended in the appropriate buffer were added to one drop of an air-dried cell suspension and covered with a coverslip. Enzyme concentration and digestion time depended on each endonuclease type, as follows: for *Eco*RI, 0.5 U/μL for 5 h; for *Bam*HI, 0.5 U/μL for 8 h; for *Alu*I, 0.3 U/μL for 7 h; and for *Hae*III, 1.7 U/μL for 5 h. Slides were incubated in a moisture chamber at 37°C, washed in distilled water, and stained in 4% Giemsa solution for 10 min.

RESULTS

The modal diploid number of 32 was established for all three *A. purpuratus* populations screened (Table 1). The CI revealed that all karyotypes had similar chromosomal constitutions (5 pairs of subtelocentrics and 11 pairs of telocentrics (Table 2 and Fig. 1). The karyo-ideogram showed that various chromosome pairs could be easily identified because of size differences (pairs 1 to 7). Interpopulational chromosome differences were evident, particularly for the short arm (ANOVA, $P < 0.05$) for chromosome pairs 2, 4, 6, 7, 8, 9, and 10 (Table 2 and Fig. 2).

The Ag-NOR staining revealed three pairs of NOR-bearing chromosomes (Fig. 3) with NOR location varying, i.e., it was pericentric in the long arm of one pair and telomeric in the short arm of two other pairs (see Fig. 3). The number of NOR-bearing chromosomes was in agreement with the number of nucleoli observed in the interphase nucleus (3 to 6, Fig. 3b).

The Hoechst/Actinomicin D counterstain (Fig. 4) revealed a tiny positive fluorescent heterochromatic block in the centromeric area of chromosome pairs 1, 2, 4 to 9, 11, 15, and 16 (Fig. 4). This stain produced a quenching zone in the middle of the long arm of pair 6, which corresponded to an A-T low-content chromatin sequence, according to the pair specificity of the Hoechst 33258. Figure 5 shows the pattern after restriction endonuclease digestion. Only two REs, *Alu*I and *Hae*III, produced a banding pattern in such a way that pericentric and telomeric bands were evident in one chromosome pair (*Alu*I) and interstitial bands in two pairs (*Hae*III).

DISCUSSION

This work confirms the chromosome number of $2n = 32$ reported for *A. purpuratus* (Von Brand et al. 1990; Canello et al. 1992; Alvarez-Sarret & Lozada 1992; Winkler et al. 1993). However, the chromosome formulae obtained (5 st + 11 t chromosome pairs) differs from that reported by Von Brand et al. (1990), who indicated the presence of 2 m pairs, 7 m-sm pairs, 3 st pairs, and 4 t pairs in the karyotype. Such a difference is likely to be produced by the fact that in the latter study the karyotype was tentatively arranged using the size criteria without the chromosome measurements required to determine the centromeric position. Our results consistently show, in all three samples that were analyzed, a chromosome complement of sub-telocentric chromosome types (see Fig. 2). *A. purpuratus*, along with other related species, such as *A. irradians irradians* (Wada 1978) and *C. nobilis* (Komaru and Wada 1985), are among the few Pectinids sharing a diploid number of 32. Instead, the majority of species studied (i.e., genus *Chlamys*, *Pecten*, *Patinopecten*, and *Placopecten*) exhibit $2n = 38$ (Thiriot-Quiévreux 1994; Insua et al. 1998), with *Aequipecten opercularis* ($2n = 26$) being the exception (Beaumont & Gruffydd 1974).

Molluscs and crustaceans are among the most primitive groups considering those karyologically compared by Thiriot-Quiévreux (1994). Nevertheless, a typical diploid number does not emerge in most groups, Ostreidae being a special case in which a diploid number of $2n = 20$ is common and very likely the ancestral one. Some marine species frequently exhibit greater numbers of chromosome than those of freshwater species, although in some cases, for example, within the bivalvia, both an increase and decrease are evident. The diploid number in most animal species ranges widely, between 12 and 40 (White 1978). Whereas evolution to higher chromosome numbers in certain aquatic organisms is often paralleled by an increase of subtelocentric and telocentric chromosomes, probably by fission of chromosomes (see review by

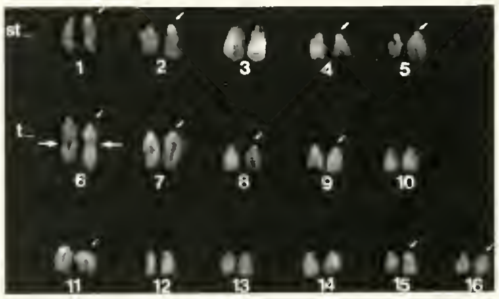

Figure 4. Hoescht 33258/ Actinomycin D counterstain. Intense fluorescent bands are indicated by small arrows. Large arrows depict a less fluorescent area in chromosome pair 6.

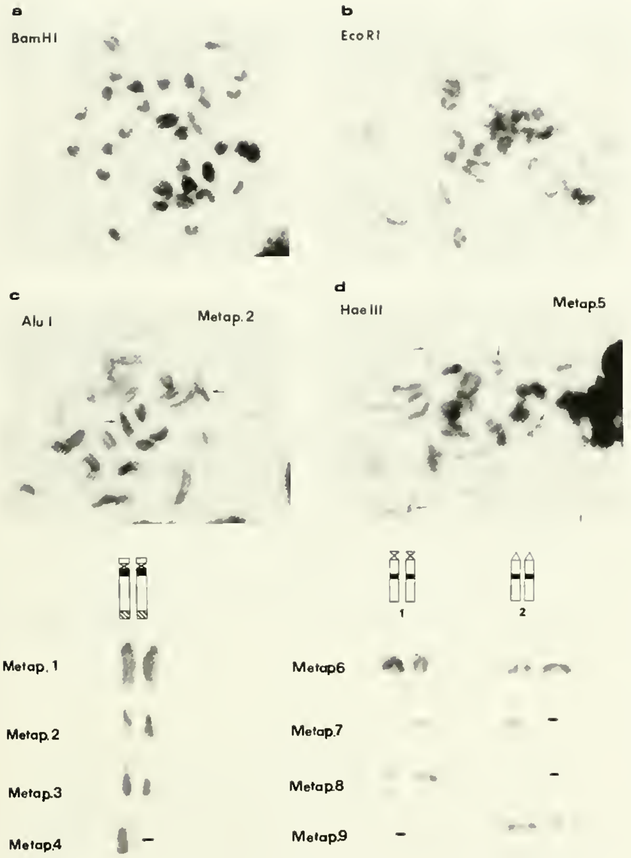

Figure 4. RE digestion: (a) *Bam*HI (no digestion); (b) *Eco*RI (no digestion); (c) *Alu*I (+ digestion), photo depicts a pericentromeric band in one pair of subtelocentric chromosome (arrows); (d) *Hae*III (+ digestion) depicts an interstitial band in two chromosomes. Below, banded chromosomes obtained from different metaphase plates.

Thiriot-Quiévreux, 1994: 379). Such phenomenon is likely to be related with specialization or adaptation to a certain type of marine environment. As mentioned previously, the diploid number in Pectinids varies between 26 and 38; hence, the chromosome formulae observed for *A. purpuratus* could be considered a derivative state within the group. Although it is debatable whether such a trend could yet be inferred in a group with few species exhibiting standardized, or comparable, karyotypes, it is worth mentioning that *A. purpuratus* is one of the southernmost *Argopecten* representatives. Indeed, this group originated in the tropical/subtropical region of the Caribbean and Atlantic (Von Brand et al. 1990). *A. purpuratus* along with *A. opercularis* (Beaumont & Gruffydd 1974) are among the few Pectinids of 14 species karyotyped so far with $2n = 32$ and $2n = 26$, respectively (see Insua et al. 1998).

Our results (2n and NF) and similar information from other species within the group (reviewed by Méndez et al. 2000), suggest that NF (Matthey 1945) is a valuable descriptor for species comparisons and to evaluating factors affecting chromosome shape variations such as chromosome rearrangements (White 1978). Because of technical procedures, the size of the short arm can vary widely and this can be deduced from the deviation observed between the average values of the centromeric index (CI) in Table 2 as well as from the presence or absence of short arms in the telocentric chromosomes.

The combination of classic and banding techniques used in this work allowed a better description of the karyotype and a more reliable pairing of certain homologous chromosomes. Reproducible banding patterns are still uncommon in aquatic invertebrates; hence, chromosome markers described in this work, for the first time in *A. purpuratus*, are considered valuable for an improved and reliable characterization of the species karyotype and its variations. Three NOR-bearing chromosome pairs were preliminary identified in the karyotype with the NOR regions, varying its location in the chromosomes (Fig. 3). Further analysis of these chromosome regions (using chromomycin A3 and a rDNA probe) will be required to clarify a probable polymorphism for both number, position, or NOR size in *A. purpuratus*. The three NOR-bearing chromosome pairs observed in this work are within the range reported for Pteriomorphia subclass (1–4 pairs; Martínez-Lage et al. 1997; Insua et al. 2000). The Ag-NOR number reported for *A. purpuratus* is higher in comparison with *A. opercularis*, which shows only one pair (Insua et al. 1998).

The combined use of fluorescent dyes and RE digestion allowed the detection of different kinds of chromatin in *A. purpuratus*, suggesting specific DNA composition of certain chromosome sectors. The Hoechst 32258/Actinomycin D counterstain highlights heterochromatic areas in humans (Schweizer 1981) and lower vertebrates (Colihueque et al. 2001). Although we observed highly fluorescent areas in the *A. purpuratus* karyotype, these were restricted to the centromeric regions of few chromosomes, indicating that heterochromatin is not common in this species (see Fig. 4). However, the differential response to digestion with restriction enzymes is also evidence of chromatin differences in *A. purpuratus* chromosomes. For example, the positive detection (no bands), at least preliminarily, of sites for *Alu* I (AGÅCT) and *Hae*III (GC↓CC; see Fig. 5) indicates that these target sequences should be highly repeated for the digestion to be evident (Sánchez et al. 1991). It should be stressed, however, that heterochromatic areas are few and mainly restricted to the centromeric areas as revealed by the fluorescent banding. Digestion with RE of fixed metaphase plates is not so common in invertebrates, with the exception of *Drosophila* (Mezzanotte 1986). Therefore, the results of this work confirm the finding of Martínez-Lage et al. (1994), who indicated that the digestion of bivalve chromatin produces specific chromosome bands (Fig. 5). However, the pattern of digestion is simple and restricted to few chromosomes similar to what is observed in fishes (Sánchez et al. 1991) and mammals (Burkholder 1989).

The farming of the Chilean scallop was greatly promoted by the fact that natural beds were almost depleted. Nowadays, a blooming, fast-growing industry is still far from realizing its potential because of the limited, or unreliable, production of quality seeds (Gajardo & Núñez 1992). This is in part related with proper broodstock management. By providing a better karyological description (quantitative measurements and banding pattern of chromosomes), this work offers a reliable and comparable way to evaluate the chromosome formulae of *A. purpuratus* and hence, a proper way for comparing probable differences among the few wild populations remaining, or hatchery stocks, if any can be identified yet. This is expected to assist to the management, improvement and conservation of this economically valuable resource. At the same time, it will help in the understanding of the processes affecting chromosome evolution in this species as well as in the bivalvia class.

ACKNOWLEDGMENTS

Support from the European Union, INCO-DC project (contract no. IC18-CT97-0188) is greatly appreciated. We are indebted to Dr. Josefina Méndez, University Da Coruña, Spain, for suggestions and valuable literature. Two anonymous reviewers made constructive comments to improve the original manuscript.

MOLECULAR CLONING AND CHARACTERIZATION OF A FRUCTOSE-1,6-BIPHOSPHATE ALDOLASE cDNA FROM THE DEEP-SEA SCALLOP *PLACOPECTEN MAGELLANICUS*

MOHSIN U. PATWARY,[1]* AKELIA WAUCHOPE,[1] TIMOTHY W. SHORT,[2] AND EDWARD J. CATAPANE[1]
[1]*Department of Biology Medgar Evers College of the City University of New York 1150 Carroll Street Brooklyn, New York 11225;* [2]Queens College and the Graduate Center of the City University of New York, 65-30 Kissena Boulevard, Flushing, New York 11367

ABSTRACT The deep-sea scallop *Placopecten magellanicus* is an important member of commercial fisheries along the coast of Northeastern United States and Atlantic Canada. A cDNA encoding a glycolytic pathway enzyme fructose-1,6-biphosphate aldolase was isolated from a sea scallop adductor muscle-specific cDNA library and sequenced from both directions. The full-length cDNA is a 1627 base-pair (bp) long sequence that has a 62 bp 5′ untranslated region, a 1092 bp open-reading frame, and a 473 bp 3′ untranslated region including a 24 bp polyA tail. The open-reading frame encodes a 39.3 kDa protein with 363 amino acids. The protein has 183 nonpolar, 94 polar uncharged, and 86 polar-charged amino acids. Several amino acids show bias for codons with G/C at their third position. The cDNA has 28 unique restriction sites, including common restriction enzymes such as *Sac*I, *Bam*HI, *Taq*I, and *Bst*EII. The aldolase is a highly conserved protein with 66% sequence identity with that of *Schistosoma mansoni*, 65% with that of *Drosophila melanogaster*, 62% with that of *Homo sapiens*, and 57% with that of *Oryza sativa*. Southern blot analysis indicates that aldolase in sea scallops belongs to a family with 4 to 10 putative genes. Northern blot analysis shows that this gene is expressed only in adductor muscles. Hybridization of an aldolase cDNA probe to genomic DNA from several individuals revealed restriction fragment length polymorphisms at several loci, indicating potential use of this cDNA as a marker in genetic studies of sea scallops.

KEY WORDS: aldolase, cDNA, sea scallops, restriction fragment length polymorphisms, codon bias

INTRODUCTION

Fructose-1,6-biphosphate (FBP) aldolase, technically known as D-glyceraldehyde-3-phosphate lyase (EC 4.1.2.13), is a long-lived, ubiquitous, glycolytic pathway enzyme. In glucose metabolism, it catalyzes cleavage of FBP into two 3-carbon molecules, glyceraldehyde 3-phosphate and dihydroxyacetone phosphate (DHAP), and in gluconeogenesis, it catalyzes the reaction in reverse order. This enzyme is also involved in gluconeogenesis and in the Calvin Cycle in plants. In the Calvin Cycle of higher plants, aldolases were reported to be bifunctional (Flechner et al. 1999) because they catalyze both the reversible condensation of DHAP to glyceraldehyde 3-phosphate and DHAP and erythrose-4-phosphate to sedoheptulose-1,7-biphosphate. Cytosolic aldolase in strawberry was found to be related to fruit ripening (Schwab et al. 2001).

The aldolases are distinguished as two classes based on their two distinct mechanisms of catalyzing glycolytic reactions, requirement of divalent cations in catalysis, subunit structures, pH optima, and substrate affinity (Rutter 1964). The two classes of aldolases share very little in their sequence homology (Alefounder et al. 1989, Plaumann et al. 1997) and are considered to be independent evolutionary lineages (Flechner et al. 1999). The class I enzymes are tetramers of 40 kDa identical subunits, each with an active site (Lys 229) located in the core of the enzyme (Lai et al. 1974, Samson et al. 1997). These enzymes have the same molecular weight and subunit structure and catalyze the overall reaction through Schiff base formation with ketoses of sugar substrates and can be inhibited by borohydride reagents (Sawyer et al. 1988). Although they are prevalent in animals and higher plants, they also occur in green algae and a few prokaryotes grown under autotrophic conditions (Sauve & Sygusch 2001). The class II enzymes are usually dimers with certain exceptions where they are tetramers, and are found in bacteria, yeast as well as other fungi and some green algae grown under heterotrophic conditions (Rutter 1964, Plaumann et al. 1997). These aldolases are EDTA sensitive, stabilize the enol intermediate of the reaction by using a divalent cation, usually Zn^{2+} or Fe^{2+}, and their activities are enhanced by monovalent cations.

In vertebrates, there are three classes of class I enzymes: aldolase A (isolated from muscle), aldolase B (isolated from liver), and aldolase C (isolated from brain). This work deals with the class IA group. The classes have immunologic differences, different kinetics, different chromosomal locations, and different gene sequences. Some class I enzymes are expressed only in specific tissues. For example, aldolase A is present in muscle and red blood cells; aldolase B in the liver, kidneys, and small intestine; and aldolase C in neuronal tissues (Penhoet et al. 1966, Penhoet et al. 1969, Tolan et al. 1987). These enzymes were reported to be three distinct proteins, yet are structurally closely related. Their functions are different, but homologous. In invertebrates, so far no such tissue specificity of an aldolase gene has been reported.

The sea scallops are an important fishery in the Northeastern coastal regions of the US and in Atlantic Canada (Black et al. 1993). This species has been the subject of several genetic studies in recent years (Volckaert & Zouros 1989, Patwary et al. 1994a, Patwary et al. 1994b, Patwary et al. 1996, Patwary et al. 1999, Pogson 1994, Pogson & Zouros 1994, Gjetvaj et al. 1997). As a part of our continuing effort to characterize cDNAs in this species, we report here a first bivalve full-length FBP aldolase cDNA and show that it is potentially useful as a probe in genetic studies of sea scallop and other related species. The cDNA information would also contribute to enhancing the understanding of structure-function relationships of aldolase genes in bivalves.

MATERIALS AND METHODS

Sea scallops were obtained from commercial beds in Nova Scotia and from the Marine Biology Supply Center, Woods Hole, MA. The methods of DNA extraction and cDNA library construction are as described by Patwary et al. (1996).

Isolation of FBP Aldolase cDNA Clones

As described earlier (Patwary et al. 1999), a small portion of adductor muscle-specific Uni-ZAP XR cDNA library was plated and 130 plaques were randomly cored and stored at 4°C in SM buffer. Bluescript clones containing cDNA inserts were rescued according to the supplier's protocol (Stratagene, La Jolla, CA). inserts were partially sequenced from the 5′ end, and one of these clones was identified as a truncated aldolase cDNA. An additional 150 plaques were randomly cored from a set of new plates and stored in SM buffer. The cDNA inserts from each of these recombinant Uni-ZAP XR lambda clones were separately amplified (Patwary et al. 1996) by polymerase chain reaction (PCR) using SK and KS primers (Stratagene), the PCR products were fractionated in agarose gels, and the they were transferred onto positively charged nylon membranes using standard protocols (Sambrook et al. 1989). The blots were hybridized with aldolase cDNA labeled with ^{32}P-dCTP as previously described (Patwary et al. 1999), exposed to X-ray films, and two positive clones were identified. These two cDNA clones, PmC 82 and PmC 83, were rescued into pBluescript from their recombinant uni-ZAP XR lambda vectors and sequenced completely from both directions. The 5′ truncated cDNA sequence end is obtained using a 5′RACE system version 2.0 (Invitrogen Corporation, Chicago, IL).

Preparation of RNA and Northern Blotting

Total RNA for northern blotting was extracted separately from several tissues pooled from at least six animals of both sex. The collected tissues were immediately fixed in RNA*later*^{TM} (Ambion Inc. Austin, TX) and stored at −20°C. Each pooled sample was ground in a separate baked mortar using a baked pestle. RNAs were extracted according to the protocol that came with Ambion's ToTALLY^{TM} RNA Kit. After quantification, RNA samples were precipitated by adding salt and 95% ethyl alcohol and stored at −180°C. The quality of RNA samples was checked in a formaldehyde gel containing ethidium bromide at the time of Northern analysis. Northern blotting, preparation of ^{32}P probe, prehybridization, and hybridization were performed as described in Patwary et al. (1999).

Preparation of Probe for Restriction Fragment Length Polymorphism (RFLP) Detection

To detect polymorphisms among sea scallops, the entire coding region of FBP aldolase cDNA was used as a probe. The cDNA was labeled with alkali-labile Dig-11-dUTP by PCR. The 25 μ PCR reaction was prepared on ice. The final concentration of PCR components were as follows: *Taq* polymerase buffer 1x; $MgCl_2$ 1.5 mM; dATP, dCTP, dGTP 100 μM each; dTTP 84 μM; dig-dUTP 14 μM; nested primers flanking coding regions 20 ng each; plasmids with cDNA insert 1 ng; and *Taq* DNA polymerase 1U. A Gene-Amp 9600 thermocycler (Perkin Elmer, Norwalk, CT) was used to perform PCR reactions. The thermocycler was programmed for 31 cycles. Cycle 1 was at 94°C for 4 min, followed by 29 cycles each of 94°C for 30 sec, 55°C for 30 sec, and 72°C for 2 min and the final cycle of 94°C for 30 sec, 55°C for 30 sec, and 72°C for 5 min. A small portion of the labeled PCR and unlabeled PCR (control) products were subjected to an agarose gel electrophoresis and the slower mobility of labeled PCR products in comparison to unlabeled control confirmed successful labeling. The probe was cleaned using nick columns (Pharmacia Biotech, Upsala, Sweden) and quantified by comparing hybridization with known dig-labeled DNA on a dot blot.

Preparation of Genomic Blots

Ten micrograms of each DNA sample was digested to completion with 40 units of appropriate restriction enzymes at 37°C. Spermidine to a final concentration of 5 mM was included in each reaction to improve digestion. A small quantity of each sample was fractionated in a mini agarose gel to verify the extent of digestion. The digested DNA samples were fractionated in 0.8% regular molecular biology grade agarose gels in TAE (0.04 M Tris-acetate, 0.0001 M EDTA) buffer together with dig-labeled molecular weight marker III (Boehringer Mannheim). The digested DNA samples were vacuum transferred to positively charged nylon membranes. DNA blots were rinsed in TAE buffer, air dried, and baked at 80°C for two hours before hybridization with the probe.

The blots were prehybridized in an oven at 40°C for three to four hours in hybridization buffer containing deionized formamide (50%), sodium citrate (SSC) and sodium chloride (5x each) *N*-lauroylsarcosine (0.1%), SDS (0.02%), blocking reagent (2%), and denatured yeast RNA (100 μg/mL). Hybridization with the probe was performed for 18 to 24 h in fresh buffer containing 10 ng/mL denatured probe. Blots were washed twice in 2x SSC, 0.1% SDS for 10 min, once in 0.5× SSC, 0.1% SDS for 15 min, and once or twice in 0.2× SSC, 0.1% SDS for 20 min. Detection of labeling was done according to the Boehringer Mannheim protocol.

RESULTS AND DISCUSSION

As a part of our ongoing effort to identify cDNAs that have potential as probes in genetic studies of sea scallops, over one hundred randomly selected phagemid clones with cDNA inserts were partially sequenced from the 5′ end. Through an amino acid sequence homology search (BLAST P) one of these clones was identified as the cDNA encoding FBP-aldolase. This cDNA sequence was highly truncated at the 5′ end and it was used as a probe to screen additional Uni-ZAP XR clones from the adductor muscle-specific cDNA library. Two clones designated PmC 82 and PmC 83 were isolated through this screening process. PmC 82 was determined to have the entire open reading frame (ORF). Clone PmC 83, although it is bigger than the first clone, is still shorter by several bases in the 5′ coding region. The clone PmC 82 is 1546 bp long excluding the polyA tail. It has only five base pairs in its 5′ untranslated region, a 1092 bp ORF and a 449 bp 3′ untranslated region. Figure 1 shows a full length cDNA that includes additional 57 bp at 5′ end obtained by using the RACE system. The ORF encodes 363 amino acid residues with a predicted molecular mass of 39, 343 Da. These amino acid residues are 183 nonpolar, 94 polar uncharged, and 86 polar charged. There are 45 alanine and 3 tryptophan residues in the sequence, and these two are the most heavily represented and least represented amino acids, respectively (Table 1).

The G/C content for the coding region of the cDNA is 57.7%, and the distribution of these two nucleotides in the gene at first, second, and third positions are 81%, 43%, and 71.4%, respectively. A similar distribution was also observed in the aldolase gene of *Thermus aquaticus* (Sauve & Sygusch 2001). The high G/C content at the third position of the codon tend to be higher than the overall G/C content in exons of many genes of other organisms including humans. There is a considerable bias in codon-usage for a number of amino acids in FBP aldolase gene. This bias is particularly prominent in the usage of codons for leucine, isoleucine, valine, glutamine, asparagine, lysine, and aspartic acid (Table 1). For example, 25 of the 31 leucine residues are encoded by two codons (CUC, CUG), although there are four

Figure 1. Nucleotide sequence of the sea scallop fructose-1,6-biphosphate aldolase cDNA and the deduced amino acid sequence of the enzyme. The nucleotide residues are numbered from the 5′ end. The amino acid residues are numbered from first in-frame methionine (M). The potential polyadenylation signal is bolded. Underlines indicate primers for amplification of 3′UTR. The star indicates the stop codon. Note that the 57 bp obtained by RACE system is added to the 5′ end of the clone PmC 82.

In each block, the first, second, third, and fourth columns are codons, three-letter abbreviations for amino acids, one-letter abbreviations for amino acids, and number of amino acid residues, respectively.

other codons for this amino acid. Likewise, one (CAG) of the two codons for glutamine code for 16 of the 18 residues of this amino acid. This conspicuous nonrandom usage of synonymous codons in the FBP aldolase gene in sea scallops is consistent with the bias found in highly expressed genes of several other organisms (Sharp & Li 1986, Sharp et al. 1988). This strong codon-usage bias may be the result of selection for translation efficiency and accuracy in highly expressed genes like FBP aldolase.

The number of FBP-aldolase amino acid residues in different organisms varies from 358 in *Oriza sativa* to 366 in *Caenorhabditis elegans*. However, a wide range of organisms such as *Drosophila*, rat, and *Xenopus* have 363 residues as in sea scallops. Based on the high amino acid sequence homology, we conclude that this is a subunit of class I aldolase. Because of its essential role in glucose metabolism, the primary structure of this enzyme has remained highly conserved across kingdoms. The rate of evolution of aldolase was estimated to be about 4% amino acid residue changes every 100 million years (Sawyer et al. 1988). The muscle-specific aldolase evolved at an even slower rate, with only about 2% amino acid residue changes per 100×10^6 years (Freemont et al. 1988). The BlastP search (Altschul et al. 1997) results show that the sea scallop aldolase is approximately 66% identical with that of *Schistosoma mansoni*, 65% with that of *Drosophila melanogaster*, 64% *Salmo salar*, 63% with *Gallus gallus* and *Xenopus leavis*, 62% with human muscle aldolase A, 62% with *caenorhabditis elegans*, 57% with *Oryza sativa*, and 55% *Plasmodium falciparum*.

The approximate number of genes encoding FBP-aldolase in sea scallop was established by Southern blot analysis. Hybridization of cDNA coding region probe with a blot containing DNA samples from a single sea scallop but digested with several restriction enzymes produced signals of varying intensity in all lanes (Fig. 2). From the number of signals we estimate that sea scallops have a family of 4 to 10 FBP-aldolase genes. Aldolase constitutes a medium-sized gene family in comparison to the estimated family size of 12–15 for the actin gene (Patwary et al. 1996) and 1 to 3 for the tropomyosin gene (Patwary et al. 1999) in sea scallops. The organization of FBP aldolase as a small multigene family was also observed in *Euglena* (Plaumann et al. 1997).

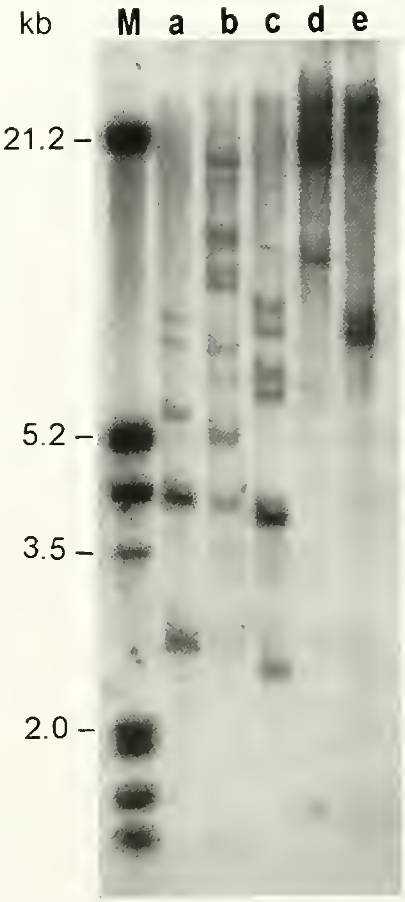

Figure 2. Detection of fructose-1,6-biphosphte aldolase gene in the sea scallops. In this Southern hybridization, digoxigenin-labeled aldolase coding region probe was hybridized to genomic DNA from a single animal. Each lane has 10 μg of DNA digested with *Eco*RI (lane a), *Eco*RV (lane b), *Hind*III (lane c), *Sal*I (lane d), and *Xba* (lane e). M is digoxigenin-labeled DNA molecular weight marker (Boehringer Mannheim).

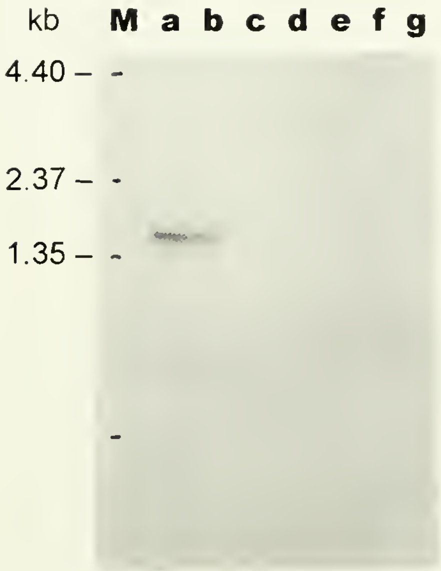

Figure 3. Northern blot analysis. A 3′ untranslated cDNA region was labeled with ^{32}P and hybridized to blots each lane with 12 μg of pooled total RNA obtained from adductor muscles (lanes a and b), gonads (lane c), hearts (lane d), livers (lane e), mantles (lane f), and gills (lane g). M is RNA molecular marker lane.

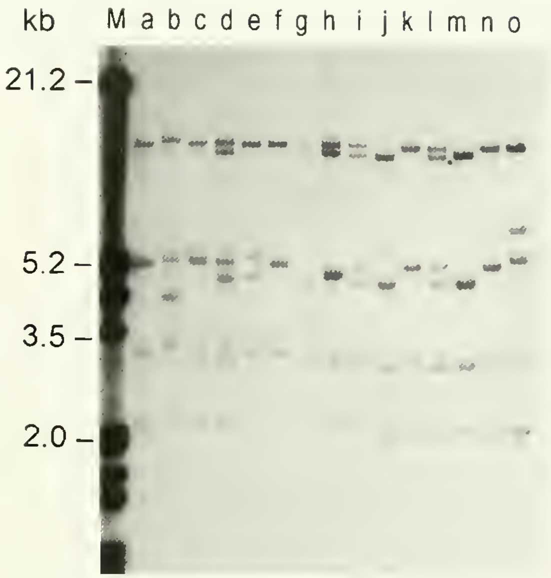

Figure 4. RFLPs in the region surrounding the aldolase genes in sea scallops. Each lane has 10 μg of genomic DNA from a different animal obtained from five different sea scallop beds (a–c from Yarmouth, d–f from Sable Island, g–i from Georges Bank, j–l from Browns Bank, and m–o from Newfoundland) digested with restriction enzyme *Acc*I and hybridized with the complete aldolase cDNA coding region. M is digoxigenin-labeled DNA molecular weight marker (Boehringer Mannheim).

Figure 3 shows that the size of sea scallop FBP aldolase messenger RNAs in the Northern blot corresponds closely to the length of the sea scallop FBP aldolase cDNA (Fig. 1). This result suggests that the clone PmC-82 represents a FBP aldolase cDNA with a very small truncation at its 5′ untranslated region. We have used the 3′ non-translated region of cDNA as a probe in Northern hybridization to determine the tissue specificity of aldolase expression, and obtained signals in the adductor muscle lanes only (Fig. 3). In absence of any indication of RNA degradation in the gel or in the blot, we conclude that the aldolase gene in question is expressed tissue-specifically in the adductor muscle of sea scallop. This finding suggests that, like vertebrates (Penhoet et al. 1966, Penhoet et al. 1969), sea scallops may have different class I aldolase genes expressed in different tissues. The extent of structural differentiation of these genes and the pattern of their distribution among different sea scallops tissues remain to be studied.

We examined the utility of FBP-aldolase cDNA as a probe to reveal polymorphisms. The probe revealed RFLPs in three loci in an *Acc*I-digested blot (Fig. 4) and in two loci in a *Dde*I-digested blot (data not shown). Pogson and Zouros (1994) and Pogson (1994) obtained three types of RFLPs in sea scallops when they used unidentified sea scallop cDNAs as probes. These were restriction site polymorphisms, polymorphisms caused by variable numbers of tandem repeats (VNTR) and complex fingerprinting patterns (Pogson 1994). In this study the FBP aldolase cDNA probe revealed restriction site polymorphisms at the approximately 15 kb and 3 kb loci and a VNTR type polymorphism at the 5 kb locus in the *Acc*I digested genomic blot (Fig. 4). Each of these loci has one or two bands, suggesting that the genomic DNA was completely digested and that the gene lacks restriction sites within it for the enzyme concerned. This finding of polymorphisms at multiple loci supports the presence of multiple copies of the aldolase gene probably distantly placed in the genome. Some of these genes possibly carry one or more variable sized introns and or VNTRs within their introns or in their flanking regions, producing multiple alleles at a particular locus. These results demonstrate that FBP cDNA is a useful addition to our collection of cDNAs that can be used as a probe to reveal RFLP markers for varieties of genetic studies in deep-sea scallops and possibly in other related bivalves. The isolation of the first bivalve aldolase cDNA may also assist in understanding the mechanism of aldolase function in this unique group of organisms.

ACKNOWLEDGMENTS

M. U. P. received support for the construction of the cDNA library from the Department of Fisheries and Oceans, Canada through a contract to the NRC Institute for Marine Biosciences, Halifax, Canada. The authors thank Dr. Ellen Kenchington, Department of Fisheries and Oceans, Bedford Institute of Oceanography, Dartmouth, Canada for initiating this contract with NRC-IMB. We acknowledge the support received from American Society for Cell Biology through a Visiting Professorship awarded to M. U. P. and from the Office of Academic Affairs, and Health Science Research Assistance Center, School of Science, Health and Technology, Medgar Evers College of the City University of New York.

COMPARATIVE ANALYSIS OF OOCYTE TYPE FREQUENCIES IN DIPLOID AND TRIPLOID CATARINA SCALLOP (*ARGOPECTEN VENTRICOSUS*) AS INDICATORS OF MEIOTIC FAILURE

ROSALÍO MALDONADO-AMPARO AND ANA M. IBARRA*

Centro de Investigaciones Biológicas del Noroeste, S.C., Aquacultural Genetics Laboratory, A.P. 128,
La Paz B.C.S. 23000, Mexico

ABSTRACT Differences between diploid and triploid female mollusks in their gametogenic process had previously centered on comparing the general gametogenic cycle, not the oocyte types in each ploidy class, which by their presence or absence might be used as indicators of completion of specific meiotic events. In this study we compared oocyte type frequencies at three different stages of the gametogenic cycle of triploid and diploid catarina scallops. Regardless of age of sampling (81 d, 118 d, 205 d of grow out), the most abundant oocyte type in diploids was always the vitellogenic, and in triploids the previtellogenic. The frequency of occurrence of vitellogenic oocytes in triploids was only 4.7–19% of that in diploids, and that for postvitellogenic oocytes was only from 0–8% of that in diploids. This indicates that the oocyte stage in triploids at which gametogenesis was largely arrested was the previtellogenic oocyte, at meiosis I. The principal cause for the meiotic arrest might be associated with problems during zygotene at the time of synapsis between the three homologous chromosomes in triploids as previously suggested by other authors.

KEY WORDS: triploid, oocyte-frequency, scallop, *Argopecten ventricosus*

INTRODUCTION

Previous research comparing diploid and triploid female mollusk gonad development have centered on comparisons of the gametogenesis cycle as described for diploids. Those studies have led to the general conclusion that triploid gametogenesis is retarded when compared with diploids (Allen & Downing 1986, Allen & Downing 1990, Allen 1987, Komaru & Wada 1989, Cox et al. 1996). Whereas some studies have based the comparative analysis of diploid and triploid gametogenic cycle in the qualitative occurrence of some particular type of oocyte at an age (Cox et al. 1996), a different approach to study the abnormal gonad development in triploid females is to estimate oocyte type frequencies in each ploidy class at different stages of the gametogenic cycle as it has been done for some fish species (Carrasco et al. 1998, Felip et al. 2001). The most common method of comparing diploids and triploids (by gametogenesis cycle) results in that it is not clear if the delayed gametogenesis in triploids is caused by a lower developmental rate of most oogenic stages, or by an inhibitory effect resulting in delay or an arrest of a particular stage so further development is impaired, or by both. What is clear is that a final consequence of the triploid condition at the end of the gametogenic cycle is the occurrence of partial or total sterility observed for most mollusk species, measured as the qualitative observation of low numbers of either spermatozoa or mature oocytes (Komaru & Wada 1989, Allen & Downing 1990, Guo & Allen 1994a, Guo & Allen 1994b, Cox et al. 1996, Eversole et al. 1996).

As with other mollusk species, in the functional hermaphrodite catarina scallop, *Argopecten ventricosus*, gametogenesis of triploid scallops is apparently delayed when compared with diploids, resulting in partial sterility of triploids. The partial sterility results in fecundity being largely reduced in triploid females, with the male gonad generally not developing further than the spermatocyte stage, and becoming replaced by female germinal cells later in the life cycle of triploids (Ruiz-Verdugo et al. 2000, Ruiz-Verdugo et al. 2001, Maldonado-Amparo & Ibarra 2002). However, as is the case with most other mollusk species, an oocyte stage at which gametogenesis is arrested has not been clearly identified. The objective of this study is to compare oocyte type frequencies between diploid and triploid catarina scallops at three different ages to define if such a stage exists.

MATERIALS AND METHODS

Definition of Oocyte Types and Their Size

Because oocyte types in catarina scallop have not been previously described, we first defined the oocyte stages based on those described by Dorange and LePennec (1989) and Saout (2000) for another scallop, *Pecten maximus*. The oocyte stages described by those authors included oogonia, previtellogenic oocyte, vitellogenic oocyte, and postvitellogenic oocyte. An additional oocyte stage was described for catarina scallop, mature oocytes, following the description from Longo (1983). The definition of meiotic stages occurring in previtellogenic oocytes of catarina scallop were based on those described for *Pecten maximus* by Saout (2000).

To obtain high definition photomicrographs of each oocyte stage, samples of diploid and triploid catarina scallop gonads were taken from five scallops of each ploidy group at 7 months old. These scallops were produced following the same methodology as Ruiz-Verdugo et al. (2000), inhibiting formation of the second polar body with cytochalasin-B (0.5 mg L^{-1}), and grown under the same conditions. All gonad samples were fixed similarly as for electronic microscopy studies (Komaru et al. 1994) to be able to obtain semi-thin (2 μm) sections, with the following modifications. The gonads were fixed in 2% gluteraldehyde in phosphate buffer (0.2 M) with an adjusted pH to 7.4 for 24 h. After this time, all samples were washed twice, each during 30 min, in a washing solution (9 g NaCl, 0.14 g KCl, 0.12 g $CaCl_2$, 0.2 g $NaHCO_3$, 2 g glucose, in 1000 ml distilled water). The samples were then progressively dehydrated passing them sequentially from 30% alcohol to absolute alcohol. The rest of the histologic process was the same as with H&E. Photomicrographs taken with an Olympus BX-41 microscope with an integrated camera (CoolSNAP-Pro Color) were digitalized and measurements of oocyte types diameters of each ploidy class were taken with the image analysis program SigmaScan Pro5, obtaining the area by digitalizing contours and estimating diameters. A total of 30 cells of each type were measured per ploidy.

Quantification of Oocyte Types

After defining the type of oocytes in catarina scallop, we proceeded to obtain oocyte types frequencies. The diploid and triploid catarina scallops used in the evaluation of numbers of oocyte types in this study were those used by Ruiz-Verdugo et al. (2000) for the study of gametogenesis between triploids and diploids. In that study oocyte types present in each ploidy class at different ages were not comparatively quantified. Those triploids were produced by inhibition of polar body 2 with 0.5-mg cytochalasin-B L^{-1}, and the scallops were reared for one year at Bahía Magdalena, B.C.S. Mexico.

Gonad samples from three ages were evaluated for both ploidy groups. Samples were taken at 81 d of grow out when vitellogenesis was beginning in diploids, at 118 d as an intermediate gametogenesis stage in which advanced vitellogenesis was evidenced by

Oogonia	4.57 (3.98–5.12) a	4.85 (4.08–5.46) b
Previtellogenic	6.95 (5.75–8.34) a	7.81 (7.24–8.76) b
Vitellogenic	37.34 (11.99–49.31) a	32.77 (10.29–55.54) a
Postvitellogenic	43.84 (35.25–50.54) a	50.35 (38.77–58.93) b

Different letters between columns indicate significant differences between ploidy classes.

the presence of large numbers of vitellogenic and postvitellogenic oocytes, and at 205 d of grow out when mature oocyte stages occurred in diploids and spawning had taken place in some scallops. For the quantification of each oocyte type the same digitalization process that was used for definition of oocyte types was followed. For each ploidy class 9 to 10 gonads (organisms) were randomly sampled, and for each gonad all oocyte types in 20 randomly selected acini were counted.

Statistical Analyses

Differences in size of oocyte types between ploidy groups were analyzed with a single factor (ploidy) analysis of variance for each oocyte type. Means were compared with a Duncan test. Differences in numbers of oocyte types between ploidy groups were analyzed with a multivariate mixed ANOVA model, in which scallops were a random effect, and age and ploidy were fixed effects. For the only fixed interaction (ploidy by age), *post hoc* comparisons were done between treatment means using a Tukey test (Sokal & Rohlf 1981). Significance for all analyzes was established at $P < 0.05$.

RESULTS

Oocyte Types in Catarina Scallop

The oocyte types occurring in diploid catarina scallop are depicted in Figure 1, and their mean sizes in Table 1. Those stages included oogonia (diameter 4.57 µm) attached to the acinus wall, previtellogenic oocytes with an average diameter of 6.95 µm in which the prophase I stages of zygotene-pachytene and diplotene could be distinguished (based on Saout 2000). The first association of oocytes to auxiliary cells characterized vitellogenic oocytes, with an average diameter of 37.34 µm, but ranging from 11.99 µm to 49.31 µm. Postvitellogenic oocytes, in which a clearly defined vitelline envelope was present, had an average diameter of 43.84 µm. Few mature oocytes, those in which the germinal vesicle was broken, were observed in these scallops, and therefore not measured.

In triploid catarina scallop (Fig. 2, Table 1), oogonia also attached to the acinus wall were significantly larger (4.85 µm) than those in diploids. Previtellogenic oocytes (diameter 7.81 µm) were also larger and differed from diploids in that they were the most abundant oocyte type, and in that they were surrounded by empty spaces, probably a consequence of cell lyses. Vitellogenic oocytes diameter (32.77 µm) in triploids was not significantly different from diploids, although in triploids most of the few observed vitellogenic oocytes were still pedunculated. Postvitellogenic oocytes (diameter 50.35 µm) were larger than in diploids and free in the lumen of the acinus. No mature oocytes were observed in triploid scallops.

Analyses of Numbers of Oocyte Types

Both, ploidy class and age were significant effects ($P < 0.0001$) in the analysis for frequencies of all oocyte types. There was a significant interaction between ploidy class and age, and also the triple (random) interaction effect was significant. At 81 d and 118 d of grow out, diploids had significantly less oogonia and previtellogenic oocytes than triploids, and more vitellogenic, postvitellogenic, and mature oocytes than triploids (Table 2). At 205 d diploid and triploids practically showed no oogonia, but diploids still had significantly less previtellogenic oocytes and more vitellogenic, post-vitellogenic, and mature oocytes than triploids. In triploids evaluated at this late age the most common oocyte type was still the previtellogenic oocyte.

Beside the differences within age for numbers of oocyte types between ploidy groups, and the difference in the most common oocyte type between diploid and triploid scallops at any age (Fig. 3), diploids had an increasing number of vitellogenic oocytes and a decreasing number of previtellogenic oocytes from 81 d (15.26 and 6.89, respectively) to 118 d (29.47 and 0.7, respectively). Triploid scallops had an increasing number of previtellogenic oocytes and a decreasing number of vitellogenic oocytes during the same period (27.82 and 2.19 at 81 d, and 85.53 and 1.4 at 118 d). There was a decrease in numbers of vitellogenic oocytes found in diploids from 118 d (29.47) to 205 d (24.64), which was paralleled

by an increase in mature oocytes (0.65 at 118 d, and 2.74 at 205 d). Among triploids there was a decrease in number of previtellogenic oocytes from 118 d (85.53) to 205 d (77.01), which paralleled an increase in numbers of vitellogenic oocytes (1.40 at 118 d, and 4.76 at 205 d).

The significance of the triple random interaction (ploidy, age, and organism) was caused by differences among diploid and triploid individuals in the number of the different types of oocytes each showed at the different ages evaluated, with the largest differences occurring among triploid individuals for the number of previtellogenic oocytes present per individual, followed by the number of oogonia and vitellogenic oocytes. In diploids, variation between individuals was seen especially for numbers of vitellogenic oocytes, but the variation was not as marked as that seen for previtellogenic oocytes among triploids (Fig. 4).

DISCUSSION

We have demonstrated in this study that in catarina scallop the number of late developmental oocyte stages (vitellogenic, postvitellogenic, and mature) is largely reduced in triploids when compared with those developing in diploids, and that the number of early oocyte stages in triploids, especially the previtellogenic oocyte, is in a large frequency from the beginning to the end of the reproductive cycle of diploids. A large reduction in fecundity, measured as number of mature or spawned eggs, as a consequence of triploidy has been observed for oysters and clams (Guo & Allen 1994c, Utting et al. 1996), as well as for the catarina scallop (Ruiz-Verdugo et al. 2001). The sporadic occurrence of vitellogenic oocytes in triploid scallops appears to be a random event, as significant variation between individuals was seen. The low number of vitellogenic oocytes translates into a reduction in fecundity of 86% at 81 d, 95% at 118 d, and 81% at 205 d of growth. However, when post-vitellogenic oocytes are considered, the reduction in fecundity was larger, 100% at 81 d, 99% at 118 d, and 92% at 205 d.

Because the first sampling analyzed already contained diploid scallops with advanced stages of development, not just the first oocyte stages, we were unable to determine whether there was an actual delay in triploid scallops in the initial occurrence of the first oocyte stages (oogonia and previtellogenic oocytes) when compared with diploids by oocyte frequency counts. In this study the scallops shell height at the earliest sampling (81d) was close to 3 cm (Ruiz-Verdugo et al. 2000), and it is known that the first age of sexual maturation for catarina scallop when grown at the same environment is a shell height of 2 cm (Cruz et al. 2000). Further studies at ages or sizes smaller than the ones sampled in this study are necessary to clarify whether there is an actual delay in early oogenesis of triploid scallops when compared with diploids.

In fish, studies comparing numbers of oocyte types between diploids and triploids (Carrasco et al. 1998, Felip et al. 2001), have

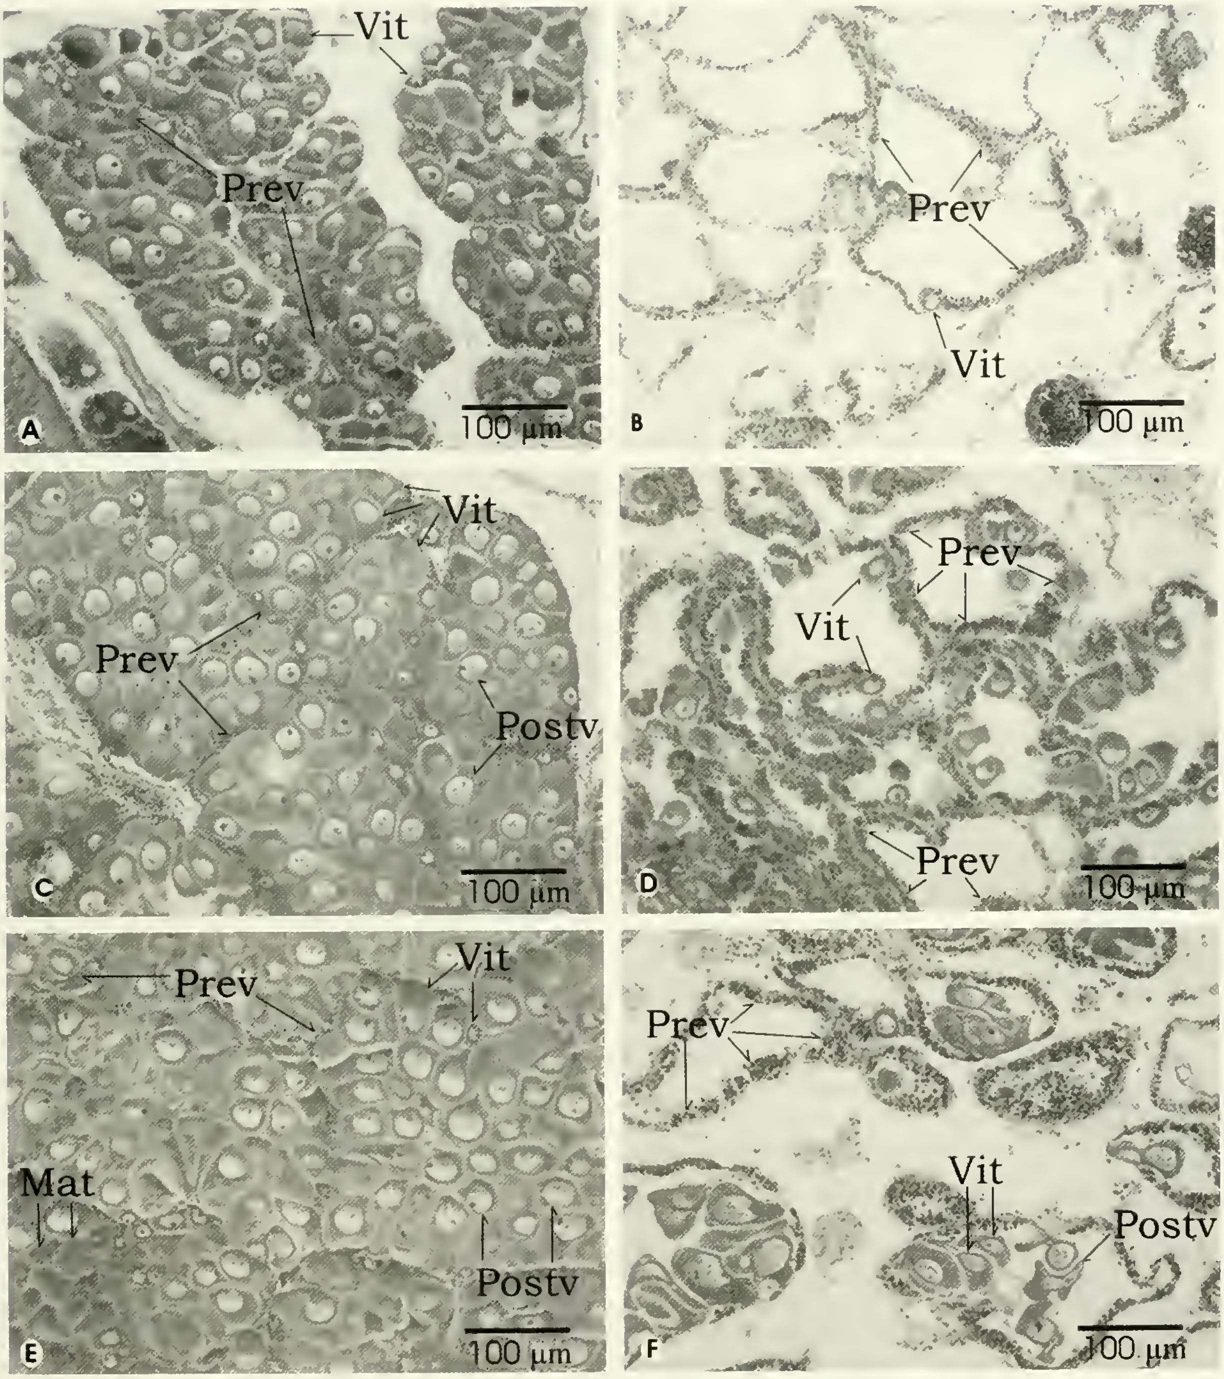

Figure 3. Diploid (left) and triploid (right) catarina scallop female gonad structure at 81 d (A & B), 118 d (C & D), and 205 d (E & F) of grow out. Light microscopy (×20). In diploids at 81 d (A) there were abundant vitellogenic oocytes (Vit), and few previtellogenic (Prev); by 118 d (C) postvitellogenic oocytes (Postv) were abundant; by 205 d (E) some mature oocytes (Mat) were also present. In triploids previtellogenic oocytes were the most common type at all ages although a few vitellogenic (B) were already present at 81 d, increasing in numbers by 118 d (D); some postvitellogenic oocytes were evident by 205 d (F).

also indicated that there is a difference between ploidy groups in the type of oocytes most frequently occurring, with the most common one in triploids being the previtellogenic oocyte. This points toward the first oocyte stage at which the triploid condition results in an inhibitory effect of further development being the previtellogenic oocyte, such that more advanced oocyte stages occur at much lower frequencies. In scallops it is known that only those previtellogenic oocytes that complete the pachytene stage and enter the diplotene stage of meiosis I will begin the process of vitellogenesis and become mature (Beninger & Le Pennec 1991, Dorange & Le Pennec 1989). Our results clearly point to the fact that oogenesis in triploid catarina scallop (*Argopecten ventricosus*) was arrested at the previtellogenic oocyte, and the reduced numbers of ooyete stages other than the previtellogenic type in triploids point to the halt of oocyte development at prophase of meiosis I, before the diplotene stage. In the male gonad part of this hermaph-

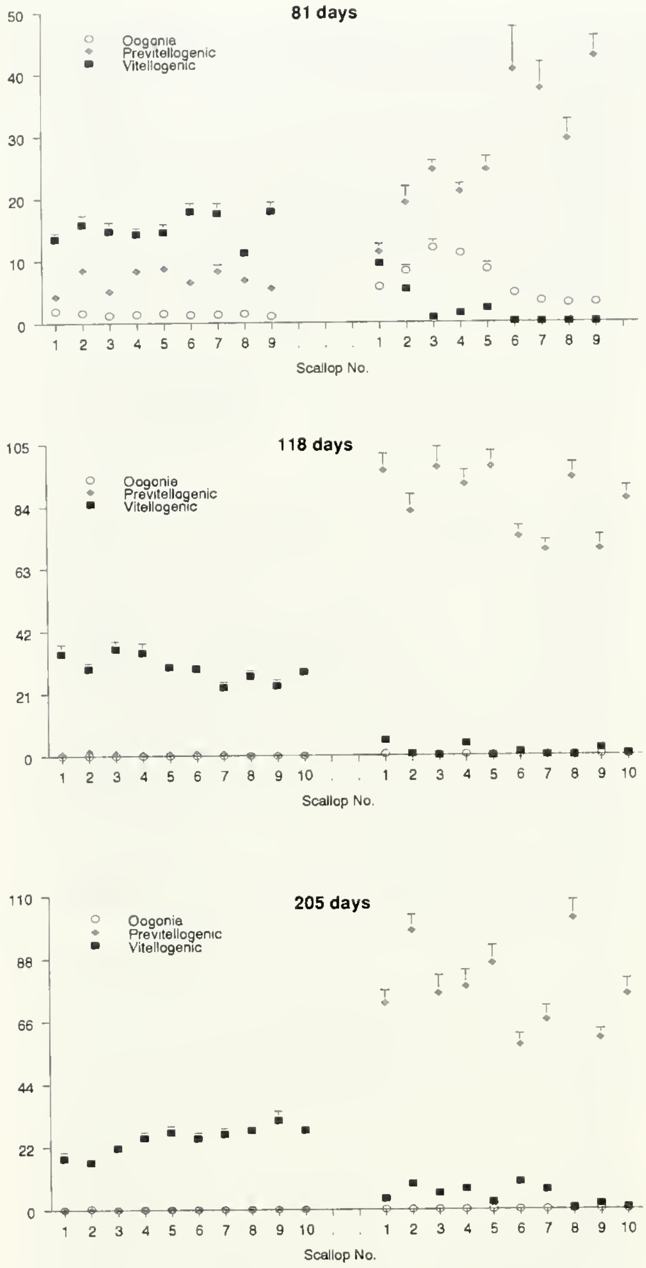

Figure 4. Frequencies of oocyte types (oogonia, previtellogenic, vitellogenic) per scallop in both, diploids and triploids, at each of the evaluated ages.

rodite species it is known that the halt in spermatogenesis occurs also at prophase I (Maldonado-Amparro & Ibarra 2002).

Until now, the cause of the sterility in triploid mollusks had been mostly ascribed to the inability of chromosomes to synapse, align, and segregate. However, at least for one species, the Pacific oyster, it has been demonstrated that synapses and segregation of chromosomes can occur in triploid oocytes even if in a lower number of oocytes than in diploids and in an abnormal fashion (Guo & Allen 1994c). In other mollusk species, including the catarina scallop, female triploids are known to be able to produce mature oocytes, even if in largely reduced numbers when compared with diploids (Guo & Allen 1994a, Utting et al. 1996, Ruiz-Verdugo et al. 2001). Among some species of male triploid mollusks, meiosis I and II are able to proceed through sperm formation although in reduced numbers when compared with diploids (Komaru & Wada 1990, Guo & Allen 1994a, Cox et al. 1996, Maldonado-Amparo & Ibarra 2002), and the produced sperm is generally aneuploid.

Because mollusks do not have to go through the completion of meiosis I to form mature oocytes, Allen (1987) proposed that the fact that oogenesis is arrested in triploid mollusks must be a consequence of meiotic difficulties arising at pre-synaptic or synaptic stages, after chromosome replication, rather than difficulties in pairing of homologous for segregation in metaphase I of meiosis. Our results support this same conclusion. The finding that few oocytes proceeded to the vitellogenic oocyte in triploids points toward the halt of meiosis being just before the diplotene stage at prophase I. The regulatory mechanisms to explain that arrest of meiosis remain to be investigated. One possible regulatory mechanism might be associated with the known "meiotic checkpoints" described for a number of organisms (Murakami & Nurse 1999, Murakami & Nurse 2000, Roeder & Bailis 2000, Tarsounas & Moens 2001), with the "recombination or pachytene checkpoint" being one of the most interesting ones to explain the arrest of meiosis in oocytes of triploid organisms, as it provides with a genetic, rather than just a mechanical mechanism for the observed arrest of further development. Meiotic checkpoints, also called "housekeeping mechanisms", are known to act by means of protein complexes signaling abnormal chromosome behavior, with effector proteins acting to delay or arrest the meiotic process (Roeder & Bailis 2000).

In conclusion, partial sterility in the female gonad of the catarina scallop is related to a halt in previtellogenic oocytes. As it is known that only those previtellogenic oocytes that complete the diplotene stage of meiosis I become vitellogenic, we conclude that the sterility is caused by problems during chromosome synapsis and recombination, that is, during the zygotene and pachytene stages of meiosis I. Why some oocytes are able to complete the vitellogenic process in spite of the demonstrated general arrest at previtellogenic oocyte is not known, but recent studies in triploids of other species point toward the existence of a correction mechanism of trivalent and tetravalent formation when homologous pair for recombination, which appears to be sex specific (Gui et al. 1991, Gui et al. 1992, Gui et al. 1995; Oliveira et al. 1995, Zickler & Kleckner 1999), and explains triploids differences between sexes in sterility.

LOW TEMPERATURE, BUT NOT AIR EXPOSURE SLOWS THE RECUPERATION OF JUVENILE SCALLOPS, *PLACOPECTEN MAGELLANICUS*, FROM EXHAUSTING ESCAPE RESPONSES

MARTIN LAFRANCE,[1] HELGA GUDERLEY,[1]* AND GEORGES CLICHE[2]
[1]Département de Biologie, Université Laval, Québec, P.Q., Canada G1K 7P4; [2]Ministère de l'Agriculture, des Pêcheries et de l'Alimentation, Direction de la recherche scientifique et technique, P.O. Box 658, Cap-aux-Meules, P.Q. Canada G0B 1B0

ABSTRACT Marked changes in temperature as well as periods of air exposure are common during scallop seeding operations. We examined whether the escape responses of cultured juvenile sea scallops *Placopecten magellanicus* (35–45 mm shell height) of the size used for seeding were hindered by such stresses and how the performance of stressed scallops changed within the week following thermal change. Tagged cultured scallops were either transferred to 8°C or maintained at 18°C; escape responses from starfish were measured 8 times during the following 156 h. The second study combined the stress of air exposure (4 h) with that of transfer to colder temperatures. Transfer of scallops from 18 to 8°C significantly reduced the clapping rates and maximum number of claps in a series at every sampling time (12 to 156 h) following thermal transfer. After 15 min of recuperation from exhaustive escapes, the percent initial claps was lower than that of control scallops (~40–50% vs. 60–70%). The time spent closed after exhaustive exercise was similar between the cold-stressed and control scallops, except at the first sampling time (6.5 and 2.7 min, respectively). Escape performance was not modified by 4 h air exposure. While decreased performance under cold stress could be ascribed to direct, kinetic effects of temperature, certain aspects of the swimming response improved during the 156 h at 8°C. However, the scallops did not completely acclimate their clapping rate to the thermal change within 6 d, suggesting that if a cold stress accompanied seeding, cultured scallops may remain vulnerable to starfish predation during a prolonged period. Seeding operations should therefore try to minimize thermal shock.

KEY WORDS: *Placopecten magellanicus*, escape responses, aquaculture, temperature, emersion, acclimation

INTRODUCTION

The sea scallop, *Placopecten magellanicus*, is a cold-water species that does well at temperatures ranging from 5°C–15°C, with optimum growth occurring at about 10°C (Naidu et al. 1989). Depending on previous thermal acclimation history, temperatures above 21–23.5°C can cause scallop mortality (Dickie 1958). Specific thermal regimes are known to influence growth, to provide stimuli for synchronous spawning (Bonardelli et al. 1996) and to condition predator-prey interactions (Hatcher et al. 1996). Low temperatures can delay larval growth and increase larval mortality as a consequence of longer exposure to predators (Dickie 1955, Young-Lai & Aiken 1986). High temperatures have frequently been held responsible for mass mortalities of scallops since the 1920s in the southwestern Gulf of St. Lawrence (Dickie & Medcof 1963). Since most of these mortalities occurred in the summer at depths of less than 12–20 m, oscillations in the thermocline were likely to have led to exposure of scallops to lethally high temperatures. Moreover, warm water debilitates sea scallops and increases their susceptibility to predation (Dickie & Medcof 1963). Thus, the sea scallop, which performs best at 10°C ± 5°C, can be exposed to thermal fluctuations that modify its performance in its natural habitat and during aquaculture operations.

Aerial exposure and handling prior to seeding may weaken scallops, rendering them more vulnerable to predation. In summer and autumn, scallops can take more than 3 days to recover from such stress (Fleury et al. 1996). While some bivalves are well adapted for air exposure, scallops such as *Pecten maximus* are unable to withstand a progressive respiratory acidosis, and some may die after approximately 72 h of emersion (Duncan et al. 1994). Further, adult saucer scallops *Amusium japonicum balloti* suffer appreciable mortality when exposed to air more than 2 h (Dredge 1997), while mortality of juvenile *P. maximus* increased significantly after 15 h of dry transport (Maguire et al. 1999a). Desiccation stress and air exposure reduce both the righting and recessing activities of juvenile scallops (Maguire et al. 1999b, Minchin et al. 2000). During air exposure of scallops, the adenylate energy charge (AEC) in the striated muscle decreases markedly, but recovers after a few hours in aerated seawater (Maguire et al. 1999a, Maguire et al. 1999b). When scallops, *Chlamys opercularis* (4–5 cm in diameter), were exhausted and then allowed to recover in the air, the adductor muscle AEC of the scallop increased to 92% of its original value within 30 min. However, final recovery of muscle energetic status only occurred in aerated seawater (Grieshaber 1978).

Since metabolic pathways and the contractile machinery are temperature-sensitive (Olson & Marsh 1993), escape responses may decrease during short-term exposure to cold. Subsequent acclimation to such cold temperatures is likely to compensate for this reduction in performance. For example, scallops living at greater depths compensate for the prevailing lower temperatures through an increase of membrane fluidity by adjustments of membrane fatty acid composition (Napolitano et al. 1992). Thus the escape responses of scallops may be temporarily reduced by changes in temperature.

During bottom seeding operations, juvenile scallops can be exposed to marked changes in temperature as well as periods of air exposure. For example, the scallops may be transferred from a warmer rearing temperature (i.e., during suspension in pearl nets) to a cooler temperature on the bottom. Both air exposure and thermal change during seeding operations may hinder the development of escape responses. In this study, we examined whether such stresses contribute to the loss of juvenile scallops after seeding, by reducing their escape response capacity or their recuperation from exhausting escape responses.

MATERIALS AND METHODS

Scallop Collection, Storage, and Tagging

Spat were collected east of the Îles-de-la-Madeleine in September 1997 (Fig. 1). Thirteen months later, juveniles (17–23 mm shell height) were transferred for intermediate culture in pearl nets (35-cm square base, with a 6 mm mesh netting) at a density of $100 \cdot \text{net}^{-1}$. From June to September 1999, the scallops were maintained at a density of 20 individuals per pearl net (35-cm square base, with a mesh size of 9 mm). For our experiments, we selected individuals between 35–45 mm of shell height (maximum dorsal-ventral distance). Hallprint™ labels (4 × 8 mm) were glued on the upper valve using cyanoacrylate adhesive to identify the scallops during sequential tests.

Cold Shock Experiment

On September 19, 1999, 64 scallops were brought in an icebox from their suspended culture site in the Havre-aux-Maisons lagoon to the laboratory (emersion time <10 min; see Fig. 1). Temperature in the lagoon was measured hourly to the nearest 0.1°C by a Sealog-T V 1.04 thermograph during this period. Water temperature in the lagoon was approximately 18°C the week before retrieving experimental scallops (Fig. 2A). Hence, we used 18°C as our control treatment and 8°C to simulate the cold stress experienced during transfer from suspension culture in the lagoon to the seeding ground (Fig. 1), since autumn seeding may expose scallops to such bottom temperatures. The scallops were equally divided between 2 well-aerated 200-L tanks, one at 18°C (control) and the other at 8°C (thermal stress). The photoperiod was maintained at natural day lengths (12 h light and 12 h dark). Salinity ranged from 29.0–30.5‰. No food was supplied and seawater was filtered (1 μm) and UV-sterilized.

Cold Shock with Air Exposure Experiment

A second group of scallops was brought to the laboratory on September 26th to compare the impact of air exposure coupled with cold stress (thermal stress + air (TSA) with that of air exposure alone [control + air (CA)]. The transfer from warm (15.5°C) (see Fig. 2) to low (8°C) temperature was preceded by a 4 h emersion (18°C) during which the scallops were sprayed with seawater every 30 min to keep them damp. As in the former experiment, 32 scallops were placed at 8°C and 32 others were kept at 18°C. Scallops were maintained in the same conditions as indicated earlier.

Evaluation of Escape Responses

Scallops were put in 33 × 28 × 12 cm-basins and tested separately after a minimum of 2 min without disturbance. An escape

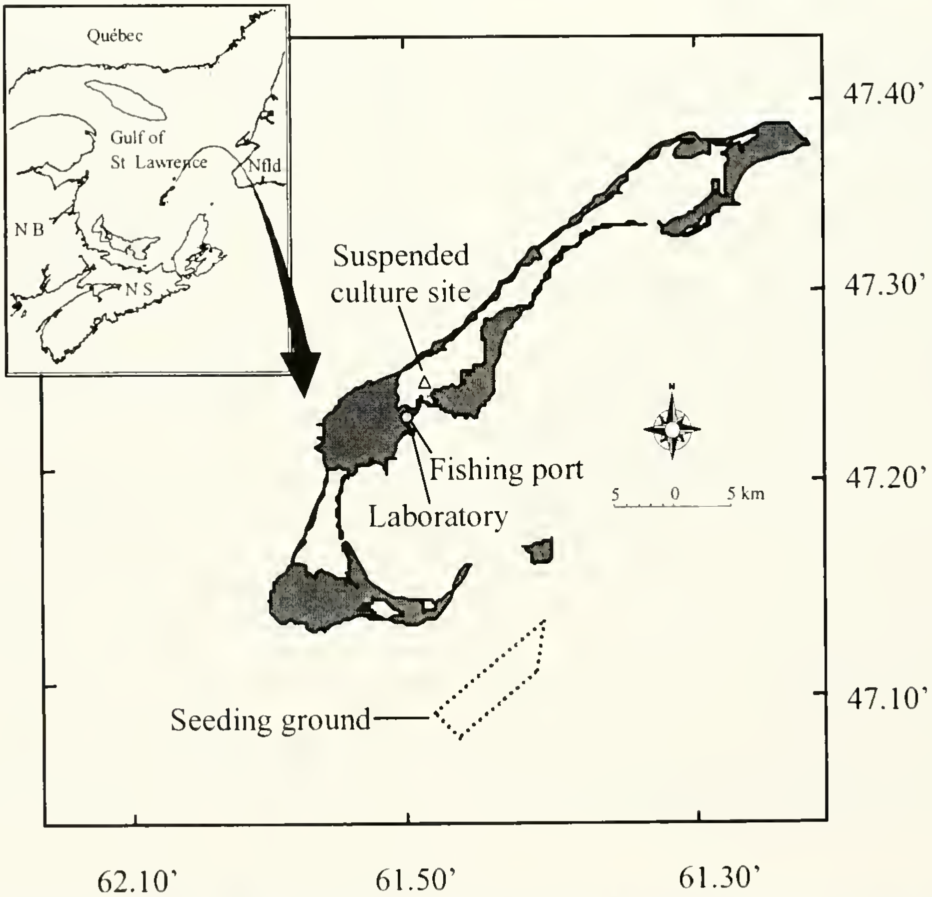

Figure 1. Location of sites for sea scallop suspension culture in pearl nets (Havre-aux-Maisons lagoon) and seeding on the sea bottom (Chaîne-de-la-Passe fishing ground) in the Îles-de-la-Madeleine. Inset shows location of the study site in the Gulf of St. Lawrence, eastern Canada.

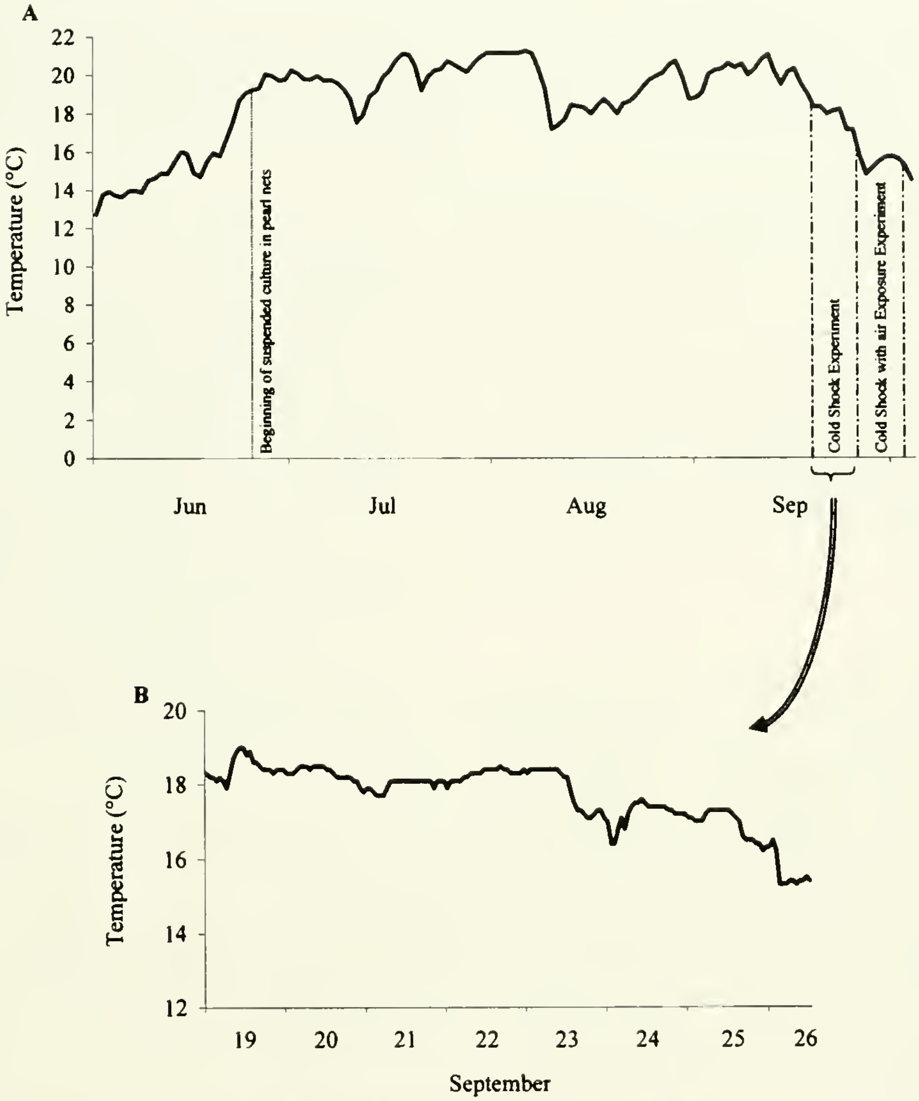

Figure 2. Temperature measured in the Havre-aux-Maisons lagoon (A) between early June and early October and (B) for the week (September 19–26) that scallops of the Cold Shock with Air Exposure Experiment spent in the lagoon, while scallops of the Cold Shock Experiment were being tested. Data were collected hourly with a precision of 0.1°C using a Sealog-T thermograph.

reaction consisted of a jumping or a swimming response following contact with the arm of a starfish. Time, number of valve claps (adductions) and the maximum number of claps in a series were counted until repeated stimulation did not elicit a clap within 1 min of the previous clap (exhaustion). Once the scallop was exhausted, it was left in its aerated basin for 15 min. Then the escape response was quantified a second time. Each escape parameter evaluated during this second test was called "response after 15 min of recuperation". Response time, defined as the time from initial contact of a starfish with the scallop mantle to first valve adduction, was measured in seconds. At the end of the escape response, the scallop was classified either as a "swimmer" or a "jumper". A "swimmer" performed several series of claps (3 claps or more) in response to predator stimulation, whereas a "jumper" did not clap more than twice in a row. The escape responses of twenty-four scallops from each treatment were measured 12, 24, 36, 48, 60, 84, 120, and 156 h after transfer. The remaining eight scallops from each treatment were left undisturbed in their respective tanks all week. These reference scallops (from the Cold Shock with Air Exposure Experiment) allowed us to examine the effect of repeated swimming behavior on the levels of macromolecular reserves in the muscle. The experiments on the impact of thermal transfer were carried out a week before those examining the combined impact of air exposure and thermal change. Whenever a percentage of recuperation is given for an escape parameter, it represents the ratio of the performance during the second stimulation (after 15 min of recuperation) relative to the initial response. These values are useful in that they show the extent to which a particular response returns to initial values after a short recuperation.

The *Asterias vulgaris* (radius of 5.5–7.5 ± 0.25 cm) used to provoke the escape responses were collected in the lagoon Le Bassin (southern end of the Îles-de-la-Madeleine) and kept in tanks containing filtered, continuously aerated seawater either at 18°C or 8°C (holding capacity of ~80 and 180 L, respectively) 30 h before the first stimulation. The starfish used in a particular escape response test were haphazardly chosen among 12 individuals at the experimental temperature. The same starfish was used for the two tests carried out on a given scallop at a given sampling time.

Biometric Measurements and Macromolecular Reserves in Adductor Muscle

Dissections of the scallops used for the Cold Shock with Air Exposure Experiment were carried out the day after the last escape response tests. The adductor muscles were immediately frozen on dry ice and maintained on dry ice for approximately 1 mo before transfer to a −80°C freezer at Université Laval. Other soft tissues were dried to constant mass at 60°C to determine their water content. We calculated a "muscle index" (muscle mass/mass of total soft tissues minus muscle mass) to examine the relative contribution of the adductor muscle. Muscle protein concentrations were measured using the bicinchoninic acid method with bovine serum albumin (BSA) as a standard (Smith et al. 1985). Muscle carbohydrate levels were determined using the phenol-sulfuric-acid method of Dubois et al. (1956), as modified by Martinez (1991).

Statistical Analyses

Clapping behaviors were compared using repeated measures ANCOVAs following the MIXED procedure (SAS 1999). The two main factors, Treatment (control vs. stress) and Time (12, 24, 36,..., 156 h after start of experiment) were considered as fixed effects. Individuals ($n = 24$) nested within Treatment were considered as a random effect. Time was better defined with a spatial power covariance structure (SP(POW) command) since it followed an exponential distribution. The Interaction term, Treatment × Time, was always included in models. Comparisons were only made between 2 treatments at a given sampling time using the difference of least squares means (LSMEANS TIME × TREATMENT / DIFF command). *P*-values associated with comparisons between treatment means at a given time came from these least squares means contrasts. The stability of escape performance over time for specific treatments (ex: Time × Treatment CA) was assessed by tests of effect slices (see Table 2). To meet requirements of normality and homoscedasticity of residuals, parameters may have been transformed using logarithms, square root or inversion although untransformed values are shown in the figures. If a behavioral response after 15 min recuperation exceeded 200% of the initial response, it was removed from the analysis (see notes in Tables 1, 2, and 3).

Multiple pairwise comparisons (Scheffe) were used to test for specific differences when ANOVAs showed significant effects (Table 4). Normality was assessed using the Shapiro–Wilk's test and homogeneity of variances by a Brown–Forsythe's test (SAS 1999). A probability level (α) of 0.05 was used.

RESULTS

Our first experiment compared the escape behaviors of scallops transferred from warm (18°C) to colder water (8°C) with those of scallops maintained in 18°C. The second examined the impact of such a thermal transfer when it followed 4 h of air exposure. Most of the escape response parameters (except clapping time and time spent closed) for control (control and control + air) scallops showed higher values than for cold stressed (cold and cold + air) scallops (Figs. 3, 4, 5, 6). The difference between control (control + air) and cold (cold + air) treatments was also apparent when considering the scallops' capacity for recuperation 15 min after the initial response (Figs. 4B, 4C, 4D; 6B, 6C, 6D; Tables 1, 2, 3).

Cold Shock Experiment (Control vs. Cold-Stressed)

Scallops responded to the first contact with the starfish by clapping their valves for a mean of 1.6 and 3.5 min before exhaustion (no clap within 1 min of the previous clap), during which an average of 51 and 45 claps was observed for control and cold-stressed scallops, respectively (Fig. 3A, 3C). Although the number of claps only differed between treatments at a few sampling times, control scallops had a significantly higher clapping rate and a greater number of maximum claps in a series at every test (Fig. 3E, 3G; Table 1). Control scallops kept a relatively constant clapping time throughout their successive encounters with starfish, whereas cold-stressed scallops showed a gradual reduction of their initial clapping time (Fig. 3C; Table 2). Initial clapping time differed between the two treatments throughout the 168 h. Clapping time after 15 min of recuperation did not vary throughout time for either group (Table 2). Cold-stressed scallops only showed longer clapping times than control scallops at 12, 60, and 156 h (Fig. 3D). In contrast, the gap between control and cold-stressed scallops for total number of claps, clapping rate and maximum number of claps in a series was similar or increased after 15 min recuperation (Fig. 3B, 3D, 3H).

The changes in escape behaviors during the experimental period provided indications of thermal acclimation (cold-stressed) and habituation (control and cold-stressed). Cold-stressed scallops improved some aspects of their responses while control scallops remained constant or worsened. Control scallops decreased the total number of claps and maximum claps in a series during successive sampling events while cold-stressed scallops maintained their values (Fig. 3B, 3G; Table 2). Control scallops showed steady clapping time and rate and time spent closed while cold-stressed scallops shortened their clapping time, increased their clapping rate and decreased the time closed (Fig. 3C, 3E; 4A; Table 2). The other parameters shared downward (Fig. 3A) or steady trends (Fig. 3D, 3F, 3H) in both groups (Table 2).

The time during which scallops kept their valves closed after exhaustion was similar in the treatments ($P \geq 0.058$; Fig. 4A; Table 1), except at the first observation period when cold-stressed scallops stayed shut more than twice as long as the control scallops ($P < 0.0001$). At virtually all observation periods, control scallops recuperated more of their initial response (i.e., in term of percentage) than cold-stressed scallops (Fig. 4B, 4C, 4D). This was particularly clear for the total number of claps (Fig. 4B).

Cold Shock with Air Exposure Experiment (Control + Air vs. Cold-Stressed + Air)

In this experiment, all scallops were initially exposed to air (18°C) for 4 h to simulate conditions during transfer from cultivation sites to seeding grounds. Control scallops were then returned to warm water (18°C) whereas cold-stressed scallops were transferred to 8°C. Scallops from these treatments made an average of 50 claps in the first escape test (Fig. 5A). At this time, the 1.5 min clapping time of control scallops was significantly shorter than the 2.5 min time for cold-stressed scallops ($P = 0.0002$) (Fig.

TABLE 1.

Statistical analysis of the effects of treatment and time on escape performance of juvenile sea scallops from Cold Shock Experiment. The scallops were transferred from pearl nets in the lagoon (18°C) to seawater at either 18°C (control) or 8°C (cold-stressed) in the laboratory to simulate the cold stress accompanying seeding operations. Each scallop (n = 24 per treatment) was measured during each sampling time (12, 24, 36, 48, 60, 84, 120 and 156 h).

5C). Thus, initial clapping rate was higher for control scallops (38.7 vs. 23.6 claps · min^{-1}). Control and cold-stressed scallops had, respectively, average maxima of 10 and 7 claps in a row (Fig. 5E, 5G).

One day (24 h) after re-immersion, the escape performance of cold-stressed scallops resembled that of control scallops. The initial number of claps of cold-stressed scallops remained constant throughout the experimental period while it gradually decreased for control scallops (Fig. 5A; Table 2).). The initial clapping time was only greater for cold-stressed scallops at the 84th (P = 0.032) and the 120th h (P = 0.0002) (Fig. 5C). Initial clapping rates remained similar between 24 and 156 h (Fig. 5E; Table 3). In spite of the slightly greater mean values for control scallops, the 2 treatments did not differ in the initial maximum number of claps in a series, except at the 48th h (P = 0.038) (Fig. 5G; Table 3).

After the15 min recuperation, control and cold-stressed scallops differed in terms of total number of claps for the first six sampling periods ($P \leq 0.046$) (Fig. 5B). This difference was alleviated at 120 and 156 h after transfer, when both groups made 22–24 claps. After recuperation, the clapping time of the two groups never differed (Fig. 5D; Table 3), even though the clapping time of cold-stressed scallops remained steady, whereas that of control scallops decreased slightly (Table 2). After recuperation, clapping rate and maximum claps remained stable for control and cold-stressed scallops (Table 2). Clapping rate tended to be higher for control scallops (Fig. 5F). Control scallops consistently made a maximum of 7–8 claps in a series in contrast to 4–5 claps for cold-stressed scallops (Fig. 5H; Table 3). Overall, cold-stressed scallops improved their performance relative to that of control scallops with time after transfer, either sustaining their performance as control scallops decreased (Fig. 5A, 5B; Table 2) or improving their performance while control scallops remained stable (Fig. 5E, 5G; Table 2).

During the first test 12 h after re-immersion, the time spent closed after exhaustion differed between control and cold-stressed scallops (3.8 vs. 6.7 min, respectively P = 0.0019). Subsequently,

TABLE 2.

Temporal stability of escape performance by juvenile sea scallops either maintained at 18°C (control: C), transferred from 18°C to 8°C (thermally-stressed: TS), air-exposed for 4 h (control + air: CA) or air-exposed for 4 h during a transfer from 15.5°C to 8°C (thermally-stressed + air: TSA). Tests of effect slices analogous to the ANCOVAs shown in Tables 1 and 3. Each scallop (n = 24 per treatment) was measured at each sampling time (12, 24, 36, 48, 60, 84, 120, and 156 h).

n.a. = not applicable.

both control and cold-stressed scallops maintained their valves closed 4–7 min (Fig. 6A; Table 3). Towards the end of the observations, control scallops stayed closed longer than cold-stressed scallops with this trend becoming significant at 156 h (P = 0.044).

As noted during the first experiment, control scallops recovered more of their initial responses than cold-stressed scallops (Fig. 6B, 6C, 6D; Table 3). This difference was again particularly marked for the percent initial number of claps (Fig. 6B). The overall recovery of control scallops was between 65–75% compared with 42–52% for cold-stressed scallops.

Evaluation of the Impact of Air Exposure

Statistical comparison of the escape performance (number of claps, clapping time, clapping rate, etc.) of the control groups from the two experiments did not reveal any differences. As the values for each escape parameter were similar, with P-values ranging from 0.12 to 0.94, 4 h of air exposure did not seem to affect the escape response capacity of the scallops.

Sixty to ninety percent of the air exposed scallops responded to the starfish within 5 sec of the initial contact whether they were

TABLE 3.

Statistical analysis of the effects of treatment and time on escape performance of juvenile sea scallops from Cold Shock with Air Exposure Experiment. A 4 h air exposure during the transfer of scallops from pearl nets in the lagoon (15.5°C) to seawater at either 18°C (control) or 8°C (cold-stressed) in the laboratory was used to simulate the cold stress with air exposure accompanying seeding operations. Each scallop (*n* = 24 per treatment) was measured during each sampling time (12, 24, 36, 48, 60, 84, 120, and 156 h).

cold-stressed or not (Fig. 7C, 7D). Interestingly, scallops from the Cold Shock Experiment (without air exposure) took more time (5–15 sec) than those given 4 h air exposure before initiating an escape response (Fig. 7A, 7B). Very few individuals (1 to 3 out of 24) required more than 15 sec following the initial contact with the starfish.

In both experiments, control scallops swam in virtually all tests (Fig. 8), while a greater proportion of cold-stressed scallops re-

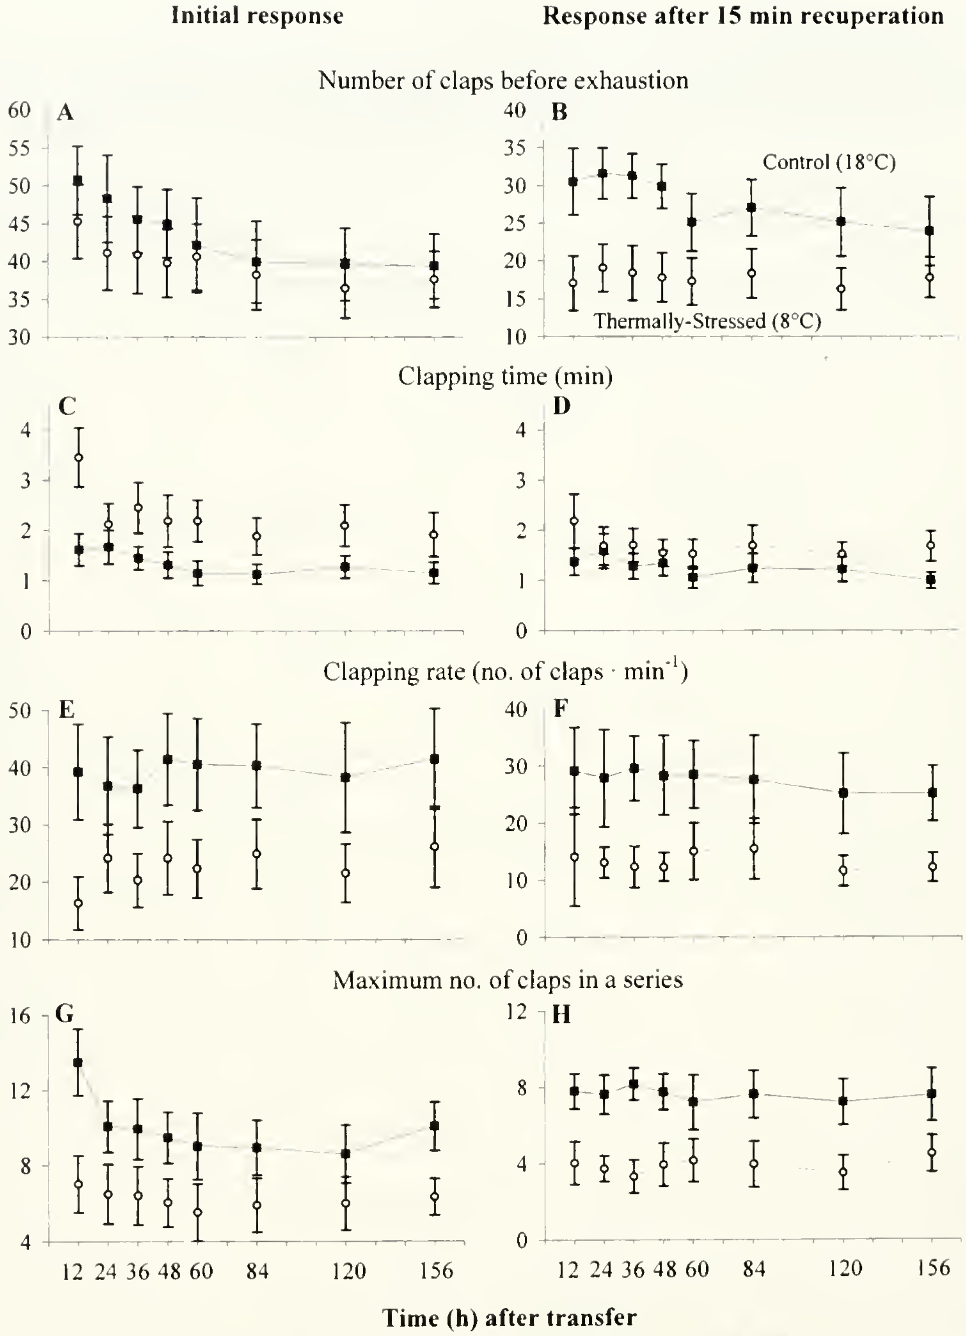

Figure 3. Effect of a transfer from 18°C to 8°C (thermal stress) vs. maintenance at 18°C (control) in seawater on the escape behaviors of juvenile sea scallops, *Placopecten magellanicus*, measured before and after 15 min of recuperation from exhaustive exercise. Means are shown for all parameters. Vertical bars indicate 95% confidence limits and $n = 24$ for each treatment.

sponded with jumps. In the experiment with air exposure, jumps were again more frequent for cold-stressed individuals, particularly within the first 60 h.

Biometrics and Muscle Energetics

At the end of the Cold Shock with Air Exposure Experiment, we compared shell characteristics and soft tissues of cold-stressed and control scallops. Furthermore, we compared resting scallops with those that had taken part in escape tests to assess the impact of the repeated escape measurements on tissue masses and muscle reserve levels. Shell mass was marginally smaller in resting scallops ($P = 0.040$). However, we found no differences between the adductor muscle mass ($P = 0.67$), digestive gland ($P = 0.13$) and the mass of other soft tissues (wet and dry; $P \geq 0.26$) of scallops that were induced to swim and those left undisturbed. Nonetheless, the muscle index of resting scallops exposed to air prior to the cold stress was slightly lower than that of control scallops ($P = 0.051$) (Table 4).

Muscle carbohydrates were decreased in scallops used for escape tests (Table 4). The phasic muscle of resting scallops contained about 18 mg of carbohydrates · g^{-1} wet tissue in comparison

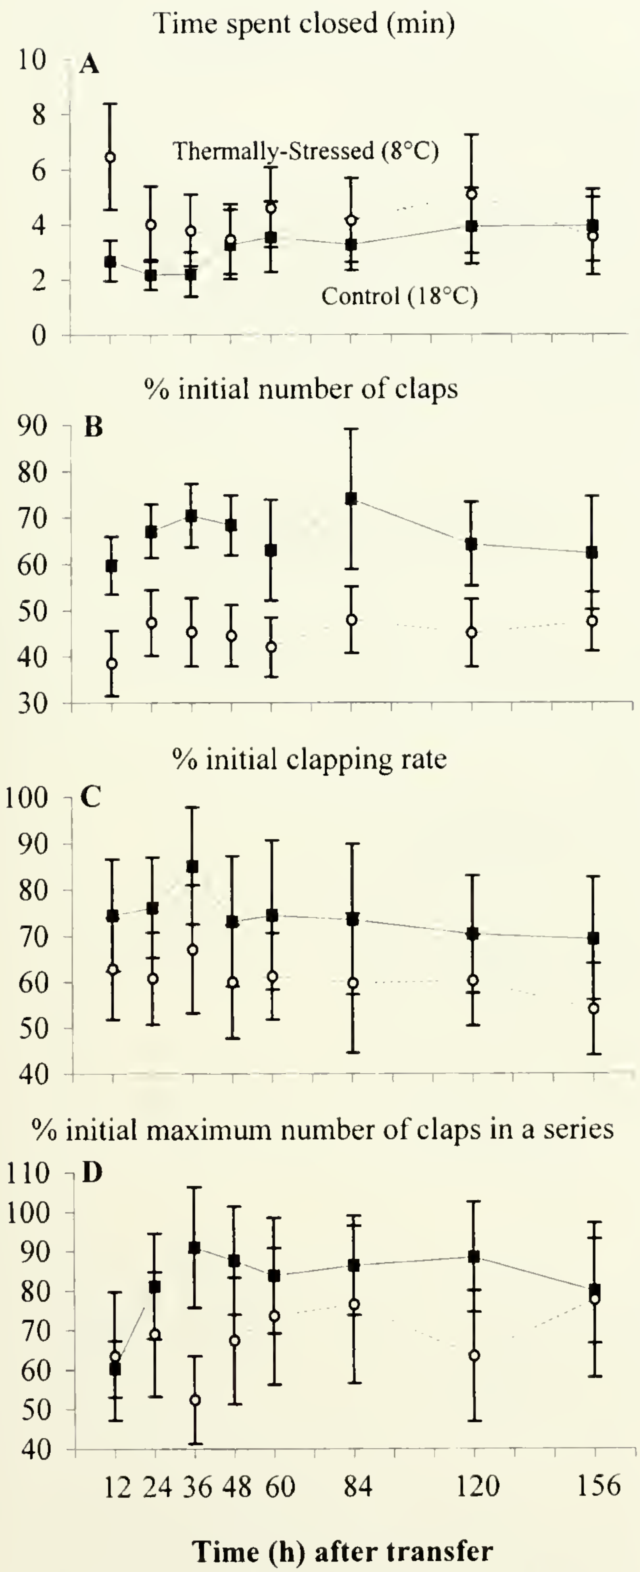

Figure 4. Effect of a transfer from 18°C to 8°C (thermal stress) vs. maintenance at 18°C (control) in seawater on (A) the time spent closed after initial exhaustive stimulation and (B, C, D) performance after 15 min of recuperation relative to initial response for the main escape behaviors of juvenile sea scallops, *Placopecten magellanicus*. Means are shown for all parameters. Vertical bars indicate 95% confidence limits and n = 24 for each treatment.

to 11 mg · g^{-1} wet tissue for exercised scallops. Muscle carbohydrate concentrations did not vary with cold stress. The mean muscle protein content was about 140 mg · g^{-1} wet tissue (Table 4); it did not differ between control and cold-stressed scallops or between the scallops that were forced to swim and those left undisturbed.

DISCUSSION

During seeding operations, juvenile scallops are often subjected to a cold stress. Although sea scallops can live at low temperatures, a rapid decrease in temperature will reduce the capacity to escape predators or colonize suitable habitats. Our results indicate that scallops cannot acclimate their clapping rate to such a cold stress within 6 days and thus may be more vulnerable to starfish predation. Indeed, the transfer of juvenile scallops from 18°C to 8°C markedly slowed their rate of clapping and the maximum number of claps in a series, but did not significantly alter the total number of claps carried out during an escape response. Nonetheless, after 6 days at 8°C, scallops reduced the time spent closed after exhausting escape responses and became similar to control scallops. Over the 6 days of study, cold-stressed scallops reduced their clapping time during an initial stimulation and increased their initial clapping rate whereas control scallops remained quite constant. Nevertheless, as the cold-stressed scallops did not attain the rates typical of control scallops, only partial thermal compensation occurred. Effectively, rate processes usually take considerable time to acclimate when an organism is moved into a colder environment (Bennett 1990). Dickie (1958) stated that the loss of the acclimation to warm temperatures may require up to 3 mo in nature and that sea scallops are extremely slow to recover their normal behavior when exposed to a sudden decrease in temperature.

A marked impact of cold stress was apparent in the recuperation from escape responses. Cold-stressed scallops were less able to recover their total claps and clapping rate than control scallops. Fifteen minutes after exhaustion, scallops transferred to cold water only recuperated 40–50% of their total claps relative to 60–70% for the control scallops. In the Îles-de-la-Madeleine, predators aggregate within three days after seeding of juvenile scallops (Cliche et al. 1994). Since seed scallops are unlikely to have recuperated from cold stress in such a short time, this may place them at a disadvantage when faced with predators that elicit active escape responses.

Temperature is likely to be a major determinant of predation rate since it involves many behaviors (location, attack, capture, and ingestion of prey) that are sensitive to temperature. Up to a certain point, predator activity is known to increase with temperature. For example, predation by starfish on 5–9 mm juvenile scallops shows a Q_{10} of 6.9 (between 4–15 °C) (Barbeau & Scheibling 1994). On the other hand, scallop escape reactions also benefit from higher temperatures (Barbeau & Scheibling 1994). Valve contraction rate increases with temperature (Dadswell & Weihs 1990, Manuel & Dadswell 1991, Olson & Marsh 1993). Sea scallops (5–35 mm in shell height) increase their clapping rate between 9 and 14.5°C (Q_{10} of 1.9) (Manuel & Dadswell 1991). The clapping rates of our 35–45 mm sea scallops gave Q_{10} values of 2.4 (8–18°C) and 1.6 (8–15.5°C) in our first and second experiments, respectively.

The thermal sensitivity of clapping rate may reside in any of its components: latency period, time to peak force and time to relaxation (Olson & Marsh 1993). Thus, a greater clapping rate may come from more rapid adductions, more rapid opening of the

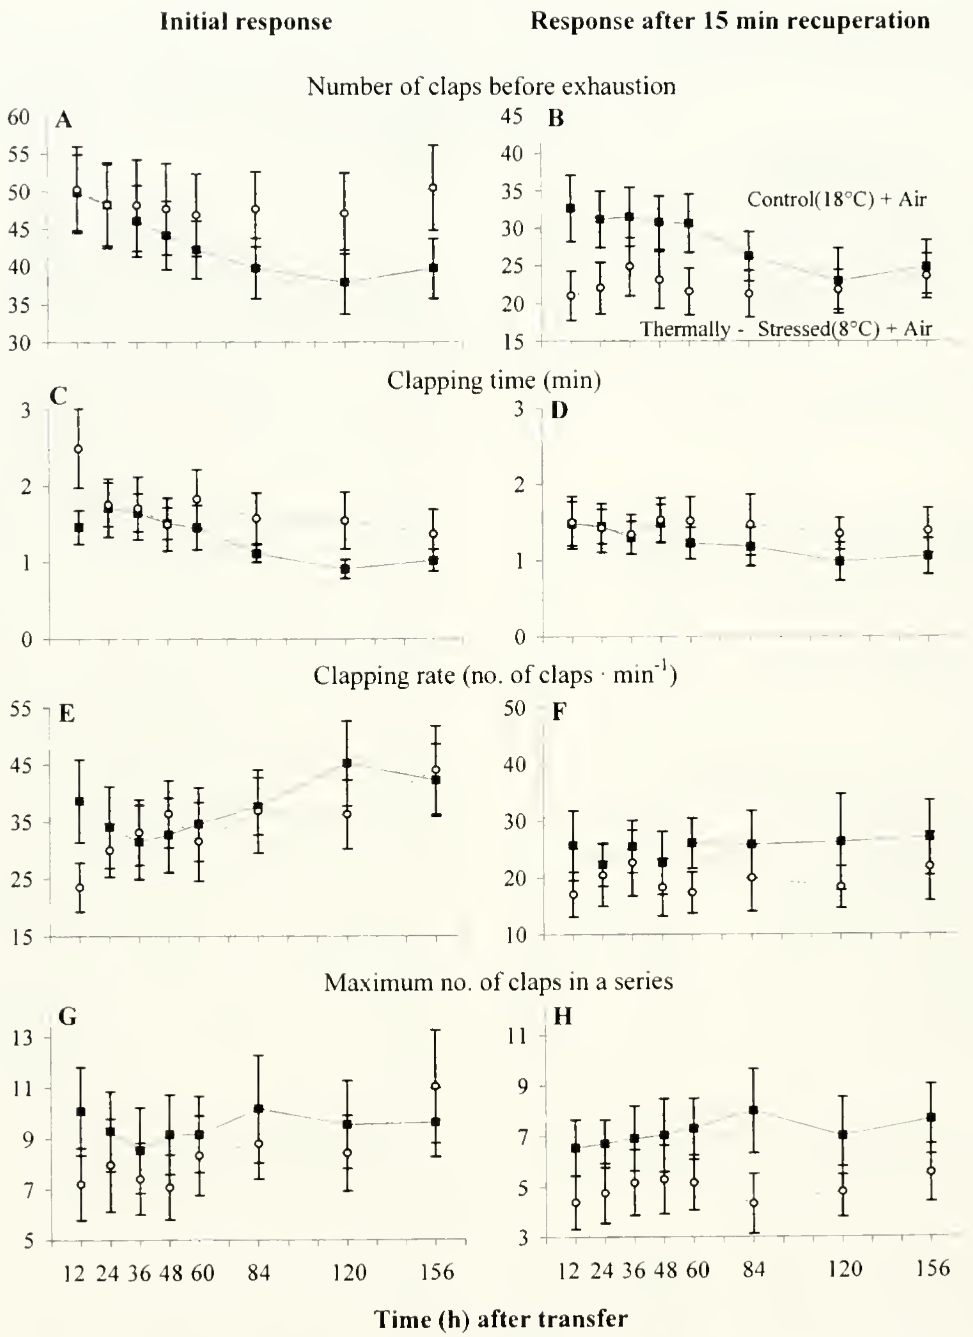

Figure 5. Escape response behaviors of juvenile sea scallops, *Placopecten magellanicus*, after 4 h air exposure and transfer to seawater at 8°C (thermal stress + air) or at 18°C (control + air) measured before and after 15 min of recuperation from exhaustive stimulation. Means are shown for all parameters. Vertical bars indicate 95% confidence limits and *n* = 24 for each treatment.

valves (due to an increase of the hinge elasticity or to greater power in the adduction), or a combination of these factors (reviewed by Manuel & Dadswell 1993). In some interactions between scallops and gastropod or starfish predators, the scallop's response time was greater at a low temperature (Ordzie & Garofalo 1980). Since the liberation of active substances (e.g., saponins (Mackie et al. 1968)) by predators and chemical sensitivity of the scallop's tentacles may decrease with temperature, delayed predator detection may account for this longer latency period. Although the sudden cooling reduced the scallops' escape responses, it did not completely inhibit them. Hence, we did not observe the debility described by Dickie and Medcof (1963). In Dickie's work (1958) with larger *Placopecten magellanicus* (80–100 mm), a drop of 4°C to 7°C was enough to cause virtual immobility for prolonged periods, with scallops keeping their valves almost closed with the tentacles only slightly extended for periods as long as 40 d. The smaller sea scallops we worked with were probably more active. Effectively, swimming is more frequent among younger and medium-sized scallops and rarely seen in >70 mm scallops (Dadswell & Weihs 1990). Further research should assess the resistance of different size classes to fluctuating temperatures (Dickie & Medcof 1963).

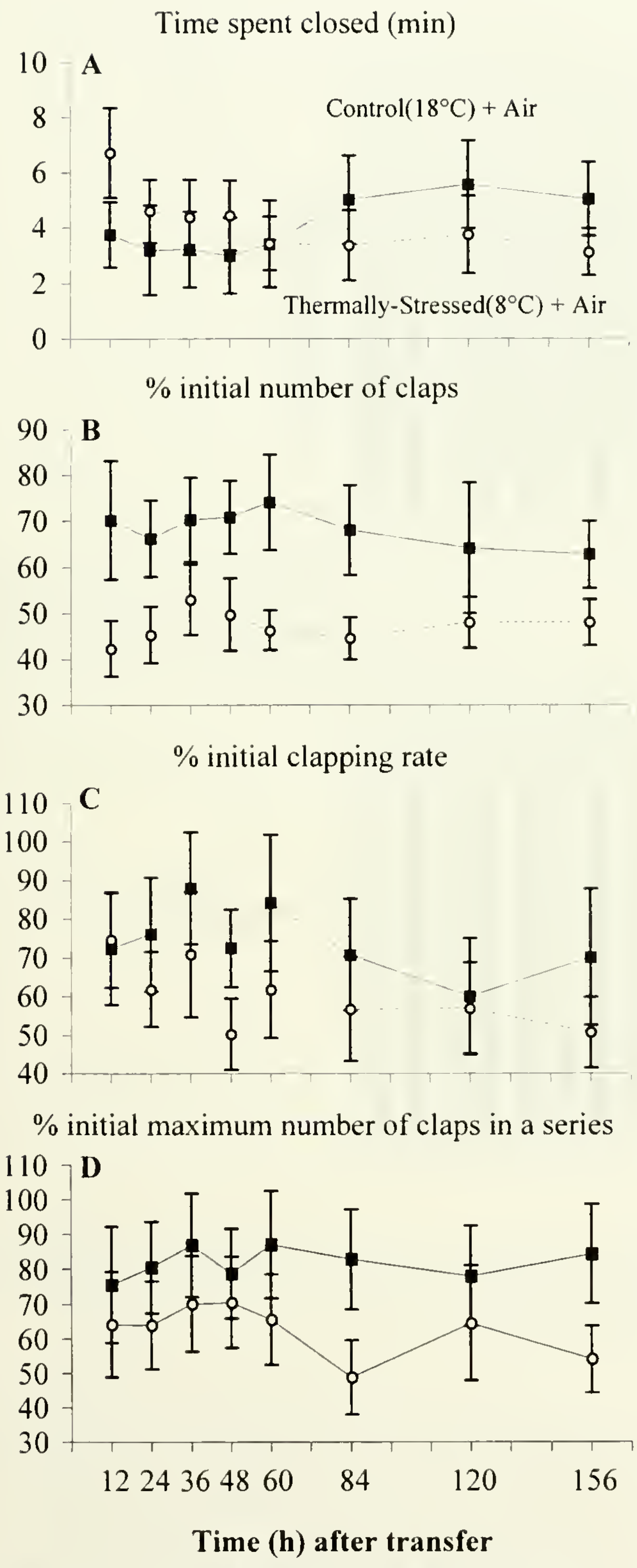

Figure 6. Escape response behaviors of juvenile sea scallops, *Placopecten magellanicus*, after 4 h air exposure and transfer to seawater at 8°C (thermal stress + air) or 18°C (control + air). (A) Time spent closed after initial exhaustive stimulation and (B, C, D) performance after 15 min of recuperation relative to initial response for the main escape behaviors. Means are shown for all parameters. Vertical bars indicate 95% confidence limits and $n = 24$ for each treatment.

Starfish from two thermal regimes were used to provoke escape responses. They were put in tanks at 8°C or 18°C the day before the first escape test. Although we manipulated the predator arms to stimulate the scallops, the amount of chemical cues emitted by cold-stressed and control starfish may have modified escape responses. However, no differences were detected in the response times of scallops at 8°C and 18°C.

In the Cold Shock with Air Exposure Experiment, the differences between control and cold-stressed scallops were smaller than those in the Cold Shock Experiment. The drop of water temperature in the lagoon from 18°C to 15.5°C (September 23–26; see Fig. 2) may have initiated acclimatization to cold water in the scallops remaining in pearl nets. Thus, a transfer to 8°C would have been less of a stress during the second than the first experiment. This suggests that seeding juvenile scallops later in fall when thermal shock is reduced could reduce losses from predation.

The 4 h air exposure seemingly had no effects on the escape parameters of the two groups of control scallops. This is consistent with previous studies of *Pecten maximus* showing no significant differences between 0 and 3–4 h of air emersion on various assessments of scallop's quality (Maguire et al. 1999b, Christophersen 2000, Minchin et al. 2000). Also, our preliminary investigations showed that the righting time of juvenile sea scallops was not significantly prolonged by 4 h emersion (unpublished data). The 4 h emersion period of juvenile scallops during their transfer from the lagoon to open sea seems not to be an issue in terms of vulnerability to predation.

Air exposure for 4 h led the scallops to react more quickly to contact with the starfish. The occurrence of a stress such as air exposure, even if it may not be injurious, may increase the general excitability (Wilkens 1981). Scallops held in laboratory conditions react more rapidly to any perturbation during the first days of their captivity (unpublished data). As contact of a starfish near the region of the dorsal ears often triggers a swimming response (Wilkens 1981), we consistently stimulated in this region, making it unlikely that, the greater occurrence of jumps in cold-stressed scallops was due to differences in our method of stimulation.

Total tissue mass of the control scallops was similar to that of cold-stressed scallops in the air exposure experiment. This variable was not affected by thermal regimen when juvenile sea scallops were subjected to constant (10°C) or fluctuating temperatures (6–15°C, 8 d temperature cycle) during 48 d (Pilditch & Grant 1999). The muscle carbohydrate content of resting scallops from the Cold Shock with Air Exposure Experiment did not differ from that obtained for cultured scallops of the same size, same origin and under similar grow-out conditions (Lafrance et al., submitted). Thus, a 4-h air exposure did not influence muscle carbohydrate levels. The muscle of scallops that performed escape responses contained carbohydrate levels 40% lower than that of resting scallops. Thus, repeated exhausting escapes markedly reduce the scallop's energy reserves in an environment with no food. Extrapolating results from laboratory to field is risky since laboratory conditions can lead to abnormally high levels of stress (Pilditch & Grant 1999). Nonetheless, repeated attacks by predators on the sea bottom, even if not successful, could make scallops more vulnerable to other stresses (sustained food shortage, diseases, etc.). Hence, predator elimination (Ventilla 1982) on seeding grounds should be considered to increase their chance of survival.

The metabolism of *Placopecten magellanicus* is tightly coupled to thermal fluctuations, as shown by Pilditch and Grant (1999) who observed that metabolic rates did not acclimate to thermal oscil-

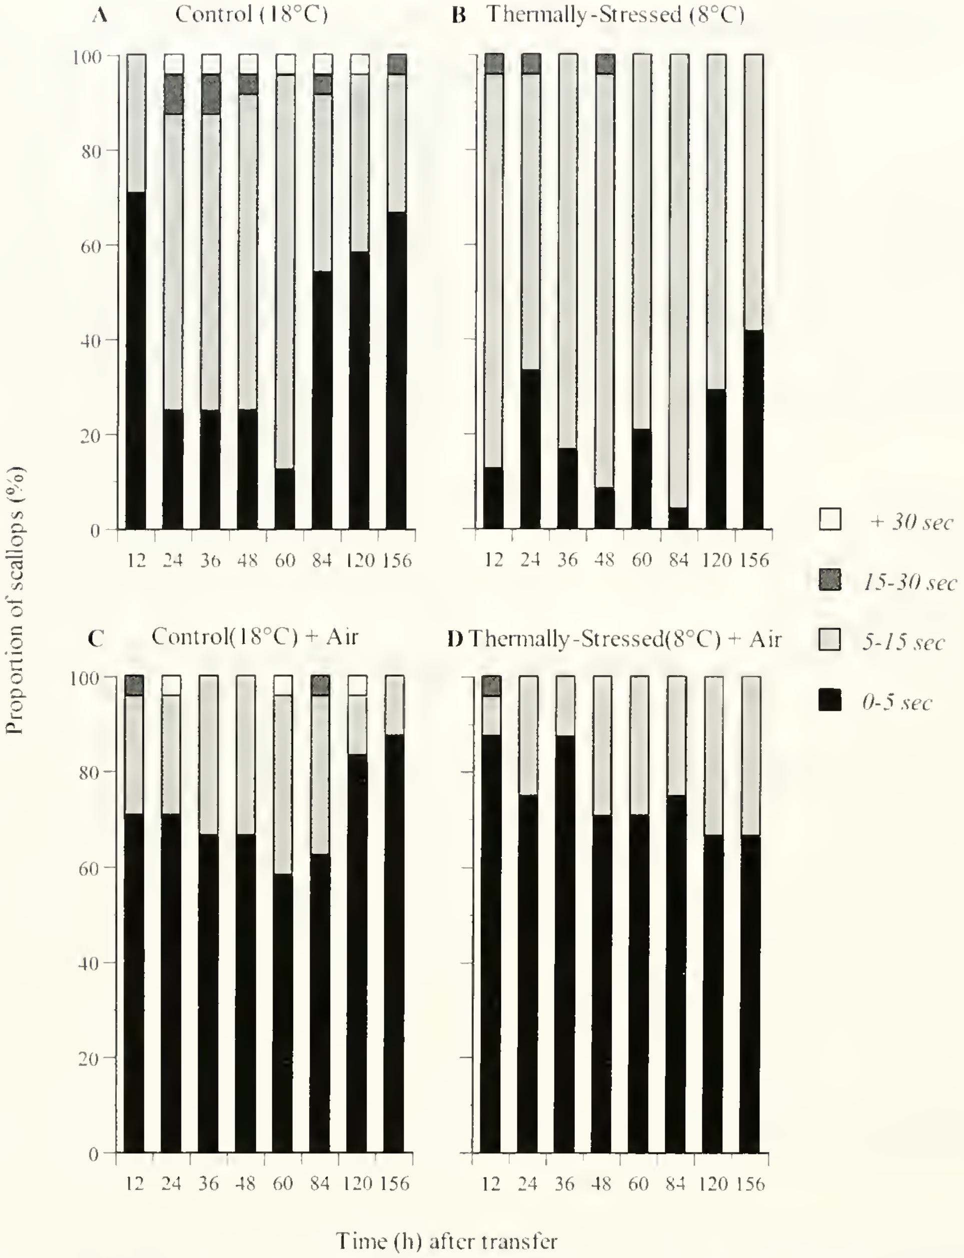

Figure 7. Effect of a thermal stress (transfer from 18°C to 8°C) and a 4 h air exposure on the delay before initiation of escape reaction of juvenile sea scallops stimulated by contact with a starfish. One-hundred percent of scallops corresponds to $n = 24$ for each treatment from (A, B) Cold Shock Experiment and (C,D) Cold Shock with Air Exposure Experiment.

lations between 6°C and 15°C during 6 × 8 d cycles. On the other hand in our study, temperature only decreased at the start of our observations. During long term exposure to low temperatures, scallops are likely to acclimate and at least partially compensate for the decrease in temperature, as shown by the changes in membrane fluidity during thermal acclimation of *P. magellanicus* (Napolitano et al. 1992). In a study of the time course of changes in membrane fluidity during transfer of *P. magellanicus* from 15°C to 5°C, compensation of membrane fluidity through increases in the proportion of polyunsaturated fatty acids required 15 to 21 days (Hall 1999).

This study provides information that should help planning of a crucial step in bottom culture of sea scallops. A 4-h air exposure does not enhance the impact of cold shock on escape responses of *Placopecten magellanicus*. While it has been argued that seeding of juvenile scallops should be performed at cold temperatures to decrease predation (Barbeau & Scheibling 1994), cold temperatures also reduce the scallop's viability in terms of escape behavior. As the scallop's escape capacities require more than 6 days before complete thermal acclimation, seeded juveniles may benefit from operations minimizing thermal shock or from the use of an acclimation period with no predators at intermediate seawater temperatures prior to seeding operations. This need for an acclimation period agrees with the recommendation of Barbeau et al. (1994). However, since crab attacks overwhelm the anti-predator defenses of juvenile scallops at virtually all temperatures (Barbeau &

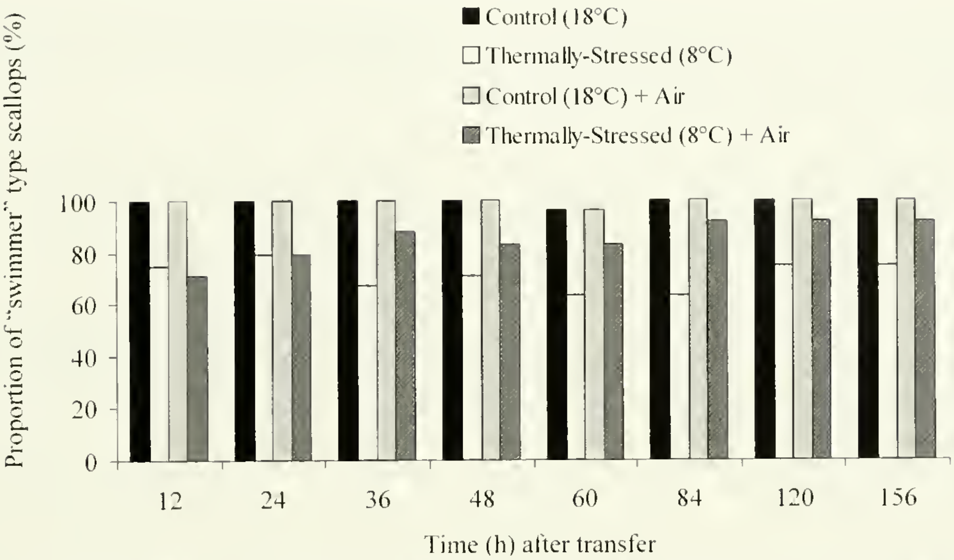

Figure 8. Influence of a thermal stress (transfer from ~18°C to 8°C) and a 4 h air exposure on the proportion (%) of juvenile sea scallops using swimming behavior as a means of escape from a starfish. A "swimmer" was defined as a scallop that made at least 3 claps during most series of claps during the stimulation (evaluated on the response after 15 min recuperation). n = 24 for each treatment from Cold Shock Experiment and Cold Shock with Air Exposure Experiment.

Scheibling 1994, Barbeau et al. 1996), such considerations would not be relevant in an environment dominated by crabs.

ACKNOWLEDGMENTS

This study was supported by funds from MAPAQ (Ministère de l'Agriculture des Pêcheries et de l'Alimentation du Québec) to M. Lafrance and H. Guderley and by an operating grant from the NSERC to H. Guderley. The authors thank the staff of the Station Technologique Maricole des Îles-de-la-Madeleine of MAPAQ for assistance. Special thanks are extended to C. Cyr for technical help, to H. Paradis and G. Daigle for their statistical support, and to J. H. Himmelman and B. Myrand for their insightful comments on the manuscript.

SELECTIVE INGESTION OF PELAGIC VERSUS BENTHIC ALGAE BY THE COCKLE *CERASTODERMA EDULE* (LINNÉ, 1758)

JOSE L. RUEDA[1]* AND AAD C. SMAAL[2]
[1]*Marine and Estuarine Ecology Unit, Department of Zoology and Entomology, The University of Queensland, Brisbane Qld 4072, Australia;* [2]*Netherlands Institute for Fisheries Research (RIVO), P. O. Box 77, 4400 AB Yerseke, The Netherlands*

ABSTRACT The pre-ingestive selection of microphytobenthic algae by the cockle *Cerastoderma edule* was studied in comparison with diets containing the pelagic diatom *Phaeodactylum tricornutum*. Treatments with the different diets covered a range of seston concentrations and organic content similar to field conditions. Rejection rates of *C. edule* exposed to the different treatments were significantly correlated with the concentration of total particulate matter. No significant differences in total rejection rates were found between pelagic and benthic diets. Organic rejection rate was significantly correlated with particulate organic matter of the treatments and no significant differences were found between both diets. Selection efficiency was significantly correlated with particulate organic matter concentration in both diets and no significant differences were found between the diets. Analysis of the pseudofeces composition by flow cytometry from cockles exposed to a mixed diet of microphytobenthic algae and *P. tricornutum*, showed a preferential ingestion of the pelagic diatom. Benthic species, such as small pennates and *Navicula* sp., were preferentially ingested in comparison to larger microphytobenthic species. The largest microphytobenthic species, *Cylindrotheca* sp., was significantly rejected. In general, *C. edule* is an opportunistic filter feeder that takes advantage of both pelagic and benthic algal cells.

KEY WORDS: Benthic diatoms, cockles, flow cytometry, rejection, selection efficiency, *Cerastoderma edule*

INTRODUCTION

Filter feeding bivalves are able to sort particles with their gills and labial palps (Kiørboe & Møhlenberg 1981, Newell & Jordan 1983, Newell et al. 1989, Ward et al. 1993) resulting in preferential ingestion of organic material and rejection of inorganic particles in pseudofeces. This preingestive selection has also been observed within phytoplankton with preferential ingestion of some groups of algal cells, both benthic and pelagic (Shumway et al. 1985, Bougrier et al. 1997, Baker et al. 1998). Preingestive selection of particles may be influenced by their chemical composition or by their size and shape.

Some studies about preingestive selection in bivalves have been carried out by using microscopic techniques to compare water and biodeposits or stomach contents in different species of deposit or filter feeder bivalves (Hummel 1985, Kamermans 1994, Shumway et al. 1987). Flow cytometry offers opportunities for the analysis of algal cells in experiments on the feeding behavior of bivalves (Shumway et al. 1985, Bougrier et al. 1997, Baker et al. 1998). Differential selection of various algal species has been demonstrated, using flow cytometric techniques by Peirson (1983) in the scallop *Argopecten irradians* (Lamarck 1819) and by Shumway et al. (1985) in *Ensis directus* (Conrad 1843), *Ostrea edulis* Linné, 1758, *Placopecten magellanicus* (Gmelin, 1791) and *Arctica islandica* (Linné, 1767). Shumway et al. (1985) showed that the flat oyster *Ostrea edulis* fed with a mixture of three algae of similar size (*Phaeodactylum tricornutum, Prorocentrum minimum,* and *Chroomonas salina*) preferentially ingested the dinoflagellate *Prorocentrum minimum*. In contrast, Cucci et al. (1985) have shown that individuals of *Mytilus edulis* Linné, 1758 fed with a mixed diet of the diatom *Phaeodactylum tricornutum*, the dinoflagellate *Prorocentrum*, and the cryptomonad flagellate *Chroomonas salina*, showed no differential ingestion of cells from suspension. Bougrier et al. (1997) found differences in the preingestive selection of different algal cells (mainly pelagic) by *Mytilus edulis* and *Crassostrea virginica* (Gmelin, 1791) and related to differences in the shape of the algal cells. Recently Loret et al. (2000) have shown preferential ingestion of nanoflagellates and cryptophytes by the bivalve *Pinctada margaritifera* (Linné, 1758), by applying *in situ* HPLC techniques.

There is some controversy about the feeding behavior of bivalves, especially *C. edule*, exposed to benthic algae compared with pelagic algae, or the importance of microphytobenthos as a food source. Kamermans (1994) found microphytobenthic algae in the stomachs of the filter feeding bivalves *Mya arenaria* (Linné, 1758), *C. edule* and *M. edulis*, although the percentage of their abundance compared with pelagic algae, was higher in the deposit feeders *Scrobicularia plana* (Da Costa, 1778) and *Macoma balthica* (Linné, 1758). Recently two studies have been done measuring ratios of C and N isotopes in different primary producers and benthic invertebrates (Kang et al. 1999, Riera et al. 1999). These studies concluded that *C. edule* may prefer to ingest microphytobenthos and phytoplankton compared with detritus from fragments of benthic macro-algae and seagrasses or detritus from other origins. However, Herman et al. (2000), using also stable isotopes ratios, suggested that suspension feeders, such as *C. edule* and *M. arenaria*, depend almost exclusively on pelagic rather than microphytobenthic algae.

The aim of this study is to quantify the pre-ingestive selection of microphytobenthic algae in comparison with a pelagic species by the cockle *Cerastoderma edule*. A mixture of benthic and pelagic micro-algae occurs in the tidal flat environment of this filter feeder bivalve. The response of cockles exposed to the different diets was studied separately and also when both diets were mixed in the water column. In the latter case analysis were done by flow cytometry to analyze differential algal cell acceptance or rejection.

MATERIALS AND METHODS

Animals

In total 187 cockles (*Cerastoderma edule*) were used in the different experiments. Cockles had a shell length of 29.78 mm ±

---

1.27 (mean ± standard error) in experiments with microphytobenthos and 29.75 mm ± 0.46 in experiments with *Phaeodactylum tricornutum*); ash free dry weight was 255.75 mg ± 30.15 in experiments with microphytobenthos and 259.87 mg ± 20.55 in experiments with *P. tricornutum*. No significant differences were found in shell length or ash free dry weight of the animals used in both experimental treatments. All individuals were collected from an intertidal mudflat situated in the Oosterschelde estuary (SW Netherlands). Experiments were performed in spring 1997 and summer 1999, in a field laboratory at Jacobahaven (Oosterschelde estuary—SW Netherlands).

Shell length, dry tissue weight (DW) and ash-free dry tissue weight for each animal were determined. After measuring the shell length, animals were immersed in boiling water until the shell was opened. Soft tissues were excised, dried at 70°C for minimum 48 h in a drying oven and weighed (= dry weight). Ash-free dry weight is determined as the weight loss after ignition in a furnace at 520°C for 3 h.

Diets and Treatments

Two different diets were used in the different experiments: microphytobenthic algae (Benthic) and cells of *Phaeodactylum tricornutum* (Pelagic). Microphytobenthic algae were collected in the Oosterschelde estuary. The top layer of sediment (2–3 mm) was sampled and after sampling, coarse sediment and microphytobenthos were separated by mixing them in filtered seawater. After sedimentation of the large particles the water containing mainly benthic algae (based on observations with microscopy) was used for the experimental treatment. The microphytobenthic species were benthic diatoms, including species from the genus *Nitzschia* (length 61 ± 11 μm; width 7 ± 1 μm), *Navicula* (length 46 ± 11 μm; width 22 ± 3 μm), *Cylindrotheca* (length 81 ± 5 μm; width 23 ± 2 μm), and small pennate cells (length 30 ± 2 μm; width 6 ± 1 μm). The pelagic diatom *P. tricornutum* was cultured outdoors in 100-l reservoir tanks.

Pelagic and Benthic algae were added separately to filtered seawater in different concentrations (treatments) for both diets (Table 1). Each treatment was completed by adding silt particles collected in the same location as cockles and microphytobenthos. This silt was dried and burned at 520°C during 4 h for removing the organic content. A coulter counter was used to determine particle concentration, which was monitored during the experiment for differences of the particle concentration from the experimental treatments. Total particulate matter in the different experiments ranged from 40.2 mg.l^{-1} to 161.2 mg.l^{-1} and the organic content ranged from 9.08%–58.91% (see Table 1).

Analysis of Particulate Matter

Water samples of the different treatments were collected from the control chamber (without animal) at the start of the experiment and before collection of the biodeposits. Total particulate matter (TPM: mg.l^{-1}) was determined by filtering one liter sample onto pre-weighed and pre-ashed Whatman GF/C filters, rinsing with ammonium formate and drying at 70°C (minimum 24 h). Particulate inorganic matter (PIM: mg.l^{-1}) was estimated from the same filters as the weight after ignition during 3 h at 450°C. Particulate organic matter (POM) resulted from the difference of TPM and PIM. In all weight measurements an electronic balance was used which determined the nearest 0.01 mg. Dietary composition was characterized in terms of organic content by weight (%OM = POM × 100/TPM), POM and TPM.

TABLE 1.

Characteristics of the different experiments for each diet and treatment. Concentrations of total particulate matter (TPM: mg · l^{-1}), particulate organic matter (POM: mg · l^{-1}), particulate inorganic matter (PIM: mg · l^{-1}) and percentage of organic matter from the seston (% OM).

Experiments with Separate Diets

A flow-through system was used in all experiments. The water containing the different treatments was pumped to the experimental chambers from a diet-reservoir (300 L) in which a mixer and an air pump promoted the resuspension of particles. Peristaltic pumps (Watson Marlow) were used for pumping the water to the individual experimental chambers. The animals were placed individually in chambers of 300-ml volume and one chamber was used as a control for sedimentation of particles. The flow in all chambers during the experiments was between 3 and 4 l/h, and the concentration of particles in the outflow of the chambers containing animals was always more than 70% compared with the control chamber (without animals).

Collection of pseudofeces started after an acclimation period of 3 h to each treatment. Pseudofeces rejected during 3-h periods were collected 2 to 3 times separately for each individual. Pseudofeces samples were filtered on preweighed Whatman GF/C filters and measured according to the same procedure as described for samples of the diets. Rejection rates (mg.h^{-1}) of total (RR), organic (ORR) and inorganic (IRR) particulate matter were calculated. Rates were standardized to an equivalent 500 mg ash free dry tissue cockle by calculating the expression $Ys = Ye\ (0.5/We)^b$, where Ys: rate of standard-sized cockle; Ye: uncorrected physiologic rate; We: measured ash free dry weight of experimental animal; b: allometric coefficient for clearance rate of cockles (b = 0.57; Urrutia 1997, Smaal et al. 1997).

Selection efficiency (SE) was calculated using the values for organic fraction of seston (f = POM/TPM) and pseudofeces (p = ORR/RR) from the different experiments. Values were calculated as: SE = $(1-(p/f)) \times 100$.

Experiments with a Mixed Diet

In these series of experiments, cockles were exposed to a mixed diet and the same flow through system described in the previous paragraph was used. The diet contained a mixture of microphytobenthic algae and the diatom *P. tricornutum* (size 17 ± 2 μm). The different size of this pelagic species, and its fluorescence characteristics make it clearly distinguishable from the microphytobenthic species used (sizes between 30 ± 2 μm and 81 ± 11 μm). Individuals were acclimated 3 h to the mixed diet and pseudofeces produced by each animal were collected during periods of 1 h. Sample analysis by flow cytometry was done directly after the experiment. Another series of samples of pseudofeces was collected in the experiment for selection efficiency measurements.

Algal composition of diet and pseudofeces was analyzed using a flow cytometer (EurOPA: European Optical Plankton Analyser). Standard beads (1.07 μm, Duke Scientific, USA) were used for calibration and optical adjustments of the EurOPA instrument. A 529 nm and 633 nm laser were used for excitation. Laser light is scattered when a particle traverses the laser beam and is measured in forward and perpendicular (PLS) direction. Laser light irradiating autotrophic phytoplankton is partly emitted as fluorescence. Fluorescence emission excited by the green laser is measured in the red (FGR) and orange (FGO) bandwidth. The number of particles processed in the flow cytometric analysis was 5,000 and 20,000. Only data derived by FGR-triggering (i.e., fluorescent particles) were used to distinguish between groups of particles with different optical characteristics. The grouping or clustering of data was calculated by using the software program Matlab version 1.0.

The algal species studied are easy to distinguish in the scatter plots of the graph representing FGR and PLS data. The star-shaped form of *Phaeodactylum tricornutum* occupied a large area with values of PLS, between 1,500 and 2,200, and values of fluorescence FGR in general below 2,200 and above 1,900. Microphytobenthos were composed with mainly four subgroups (related to the most abundant species). The benthic diatom species with lower FGR and lower PLS was *Navicula* sp., together with a group of small pennate cells, which could not be identified with values of PLS (1,800–2,300) and FGR (1,900–2,200). *Nitzchia* species had a higher PLS value (2,400–2,500) and higher FGR (2,500–2,700). *Cylindrotheca* species displayed the highest PLS (almost 2,500) and the highest FGR (almost 3,000).

To examine the degree of acceptance or rejection of particle types (pelagic or benthic algae), we calculated an electivity index (EI) (Jacobs et al. 1974), modified by Baker et al. (1998), as follows:

$$EI = -[(P - S) / ((P + S) - (2 * P * S))]$$

where P is the particle ratio in the pseudofeces and S is the particle ratio in the suspension. Electivity index can range from −1.0 to 1.0. A positive EI for a given particle type indicates preferential ingestion (depletion of the particle type in the pseudofeces compared with the suspension), and a negative EI indicates rejection (enrichment of a particle type in the pseudofeces compared with the suspension).

Subsamples of the diet and pseudofeces were also fixed in Lugol's and the algal composition was determined using microscopic techniques for determination in addition to the flow cytometer results.

Statistics

All statistical tests were performed using the program SYSTAT for PC version 9.0. Multiple stepwise regression analyses were used to test for significant relationships between physiologic rates and parameters of the treatments. Analysis of covariance was used for comparing the rejection rates and selection efficiencies of cockles with the different diets. Electivity indices were compared with zero using a one-sample, two-tailed, nonparametric Wilcoxon signed-rank test. These analyses test the null hypothesis that selectivity of a particular type is equal to zero (no sorting). A t-student test was used to compare concentrations of the different algal species in samples of the diet and pseudofeces.

RESULTS

Response to Diets

Data about quality and quantity of the experimental treatments are shown in Table 1. All treatments were above pseudofeces threshold and the obtained physiologic values with the different diets and treatments have been listed in Table 2. Multiple stepwise regression analyses indicated a significant positive relationship between rejection rate (RR) and total particulate matter (TPM) from the treatments of both diets (Fig. 1; Table 3). The model rejected parameters POM and %OM. Analysis of covariance in-

dicated that there were no significant differences between the diets ($/t/ = 0.256$; $P > 0.05$).

Organic rejection rates (ORR) were only significantly correlated to the particulate organic matter (POM) (Fig. 2, see Table 3), with TPM and %OM as nonsignificant parameters related to ORR. According to the regressions obtained in each case no significant differences were found between both diets ($/t/ = 1.136$; $P > 0.05$).

Multiple stepwise regression analysis indicated a significant positive relationship between selection efficiency (SE) and particulate organic matter (POM) (after log transformation) in both diets (Fig. 3 see Table 3). Although lower values of SE were obtained with the benthic diet, analysis of covariance indicated that there were no significant differences between diets ($/t/ = 0.791$; $P > 0.05$).

Response to a Mixed Diet

Selection efficiency values as a function of POM concentration (see Fig. 3) were generally lower for the mixed diet of pelagic and benthic cells. Higher values of SE were registered at higher values of particulate organic matter.

Flow cytometer results showed significantly lower cell concentrations (expressed as %-age) in pseudofeces in comparison to the diet composition (Fig. 4), and therefore significant positive electivity indices (EI) (acceptance). For both diets, differences of algal concentration in pseudofeces and diet were significant using a t-student test (Pelagic: DF = 12, t = 14.09, $P < 0.001$; Benthic: DF = 12, t = 4.86, $P < 0.01$). However, the EI of cockles was significantly higher for pelagic ($EI_{Pelagic} = 0.31 \pm 0.01$, mean ± standard error) than for benthic cells ($EI_{Benthic} = 0.20 \pm 0.03$, mean ± standard error), indicating a preferential acceptance of the Pelagic rather than the Benthic component of the mixed diet. A lower EI for the benthic species was due to differences in the acceptance or rejection of the different benthic species within the Benthic group (Fig. 5). The smallest benthic species, such as *Navicula* sp. and the group of small pennates, were significantly ingested, displaying higher EI values than larger species such as *Nitzchia* sp. However, *Cylindrotheca* sp., the largest species, was significantly rejected, resulting in a negative EI value.

DISCUSSION

Production of pseudofeces of cockles was significantly related to the seston concentration in both diets. This relationship between

RR and the seston concentration has been observed in several studies and rates were comparable with our outcomes (Iglesias et al. 1992, Navarro & Widdows 1997, Urrutia 1997). Similarly, the rejection rate of organic matter increased with organic content of seston. At a constant clearance rate, filtration rate increases at increasing seston concentrations and the digestive system reaches maximum capacity, hence pseudofeces production increases.

Together with the production of pseudofeces, selection of organic material occurs prior to ingestion. Selection efficiency (SE) values found in our experiments were very similar to values documented for *C. edule* under comparable conditions of food quality (Iglesias et al. 1992, Urrutia 1997). The response by the cockle to the pelagic diet did not differ significantly from the benthic diet. The SE maximizes in *C. edule* as a response of an increment in the organic content in the diet (Iglesias et al. 1992, Urrutia 1997) reaching a maximum value in our study of 40%. This maximum value of gross SE (measurements based on the organic content of pseudofeces) for the cockle is similar to those obtained in previous studies using pelagic algae as a food source (Iglesias et al. 1992, Urrutia 1997). The percentage of organic matter in the different treatments covered a range between 10%–60%. Several authors (Iglesias et al. 1992, Urrutia 1997) have described a decrease of the SE in *C. edule* exposed to treatments above 50% organic content. The decrease of SE values obtained in treatments containing Benthic algae could be related to a lower acceptance or the preferential rejection of some benthic species as it has been found with *Nitzchia* sp. and *Cylindrotheca* sp.

In this study, we have documented the selection and acceptance of microphytobenthos as a benthic food source by the cockle. However, pelagic algae were accepted preferentially when mixed with microphytobenthic species. Moreover, only some microphytobenthic species were preferentially accepted by *C. edule*. Micro-

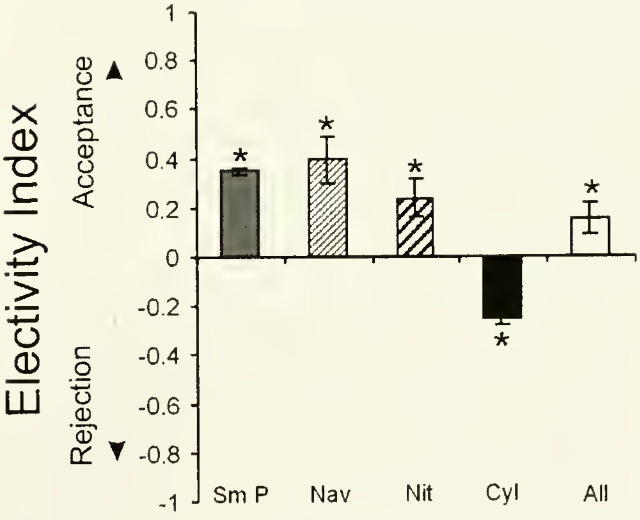

Figure 5. Electivity indices (EI) for the different microphytobenthic species, as separate species or as a group, relative to the total concentration of particles. The studied species are small pennate cells (SmP), *Navicula* sp. (Nav), *Nitzchia* sp. (Nit), *Cylindrotheca* sp. (Cyl) and the benthic group (All), which includes all microphytobenthic species. Vertical bars indicate standard error. * Indices significantly different than zero ($P < 0.05$). In all measurements $n = 14$.

phytobenthos seems to represent a food source in several species of bivalves and its importance for filter feeding bivalves has been addressed previously. Kamermans (1994) found relations between algal composition of the water column (30% were resuspended benthic diatoms) and the stomach contents of the bivalves *C. edule*, *Mya arenaria* and *Mytilus edulis* in the western Wadden Sea. She concluded that selection of algae by the bivalves was absent based on comparison of water and stomach samples. Recently two studies measured ratios of C and N isotopes in different primary producers and benthic invertebrates (Kang et al. 1999, Riera et al. 1999). These studies concluded that *C. edule* preferentially ingested microphytobenthos and phytoplankton compared with detritus from benthic macro-algae or sea grasses fragments. However, Herman et al. (2000) indicated that *C. edule* depends basically on pelagic algae as a food source and benthic algae hardly contribute to the metabolism. Our experiment showed a differential pre-ingestive selection by *C. edule* of the different benthic species. This may explain the actual controversy about microphytobenthos as a food source for suspension feeders. More detailed information about acceptance and/or rejection of single microphytobenthic algal species is needed to clarify the actual controversy.

Results obtained in this study, using flow cytometry techniques, showed a preferential ingestion of Pelagic over Benthic species and a differential selection of the benthic species. Within the Benthic group, some species such as *Cylindrotheca* sp. was rejected in significantly higher concentrations than small pennates or *Navicula* sp. The mixed composition of the benthic diet is a feature that resembles the natural conditions where *C. edule* lives and a preferential selection of some species may occur also in the field. Studies on sorting of food in bivalves using flow cytometry to determine the preferences within mixed samples are scarce (Cucci et al. 1985, Shumway et al. 1985, Chrétiennot–Dinet et al. 1991, Bougrier et al. 1997, Baker et al. 1998). Cucci et al. (1985) did not observe preingestive selection in mussels fed with a diet of a diatom, a dinoflagellate and a cryptomonad. However, Bougrier et al. (1997) observed in the oyster *Crassostrea gigas* (Thunberg, 1793) that a preferential ingestion of flagellates species occurred compared with diatom species. Moreover, Baker et al. (1998) examined the ability of zebra mussels *Dreissena polymorpha* (Pallas, 1771) to preferentially ingest or reject various phytoplankton species in the Hudson River (New York). In their study, zebra mussels selected more efficiently small algal cells, such as cyanobacteria, explaining the changes in the Hudson River phytoplankton community in the last decade.

Accepted benthic species by *C. edule* had smaller and similar sizes (*Navicula* sp.: measured size 46 ± 11 μm; small pennates: measured size 30 ± 2 μm) than the significantly rejected species such as *Cylindrotheca* sp. (measured size 81 ± 5 μm). Therefore, a possible relation may be found with a preferential ingestion or rejection of those algae and their size. Nevertheless, preingestive selection of algae in bivalves could also be related to chemical characteristics (e.g., taste of the particles) or to morphologic characteristics (e.g., shape of the particles). In this context, Shumway et al. (1990) discussed that not only size is an important factor in the preingestive selection of particles but also mucoid trapping and chemoreceptors. Chrétiennot–Dinet et al. (1991) reported that the relative ingestion or rejection was not dependent on the size of the algae in *C. gigas* and *M. edulis*. Bougrier et al. (1997) reported similar results on those bivalves and no relation was found between preingestive selections of algal species with their size. MacDonald and Ward (1994) showed that rejection is not dependent on particle size in the scallop *Placopecten magellanicus*.

The cockle, *C. edule*, preferentially accepted small benthic diatoms such as small pennates and *Navicula* sp., both also with an elliptical smooth shape, and rejected others such as *Cylindrotheca* sp., which has a larger size and large lateral spicules. The actual mechanisms whereby particles are selected on the gills and the labial palps have been studied using endoscopy (Ward et al. 1991, Ward et al. 1993) but not much information is known about their relation with morphologic characteristics of the particles. Bougrier et al. (1997) indicated that a differential rejection or ingestion of diatom and flagellate species might depend on their shape and flexibility, with a preferential rejection of species with inflexible spicules or the presence of a non-flexible membrane (i.e., silicate frustule), which may hamper the pass through the gill filter. Some authors (Shumway et al. 1985, Bougrier et al. 1997) have also detected a preferential ingestion of flagellates in comparison to diatoms and have speculated that the presence of the silicate frustules from the diatoms may appear as mineral particles to sensory receptors of the labial palps. According to this hypothesis the preferential selection of the pelagic diatom *P. tricornutum* could be influenced because benthic species are, generally, attached to silt particles and it may be possible that some species will have more chance to be rejected as inorganic particles by *C. edule*.

In this study, similar values of selection efficiency were registered when *C. edule* was exposed to Pelagic and Benthic treatments, and lower values obtained in mixed treatments. Riera and Richard (1995) have reported in *C. gigas* a preferential ingestion of benthic diatoms and detritus compared with phytoplankton in shallow estuarine waters. But they also reported that *C. gigas* had a preferential ingestion of phytoplankton, when compared with benthic diatoms and detritus, in deeper waters from the same bay. Shumway et al. (1987) found a preferential ingestion of benthic algae by *P. magellanicus* collected from deep-water populations, however individuals from shallow water populations seemed to ingest more pelagic than benthic algae. Gut contents of *P. magellanicus* generally reflected available organisms in the immediate habitat. The preingestive selection of algae in some filter feeding bivalves, such as *C. edule*, could be adapted to the composition and the percentages of the different species available in the water column. The preferential ingestion of benthic species in comparison with pelagic species has been observed in the mussel *M. edulis* in conditions with low concentrations of pelagic algae in the water column (Prou et al. 1994). In our experiments, microphytobenthos is selected at the same efficiency as *P. tricornutum* in nonmixed treatments. In a mixture of pelagic and benthic species, the rejection of microphytobenthos is higher and this could be related to the dominance of the pelagic algae in the diet. Preingestive selection of benthic compared with pelagic species has been studied previously in the oyster *C. gigas* by using the flow cytometry technique (Bougrier et al. 1997). In those experiments oysters preferentially ingested pelagic species than benthic species, in a dominant pelagic species treatment. Baker et al. (1998) observed that the selectivity of different phytoplankton species by the zebra mussel *Dreissena polymorpha* differed depending on the complexity of the offered suspension.

Summarizing, the pre-ingestive selection of benthic algae by *C. edule* is similar and nonsignificantly lower than the pre-ingestive selection of pelagic species, when benthic and pelagic species are not mixed. This situation of maximum presence of benthic diatoms in the seston could be similar to environmental characteristics of tidal flat areas with high resuspension rates of benthic diatoms, or seasons with low pelagic productivity (e.g., autumn and winter). However, acceptance of benthic algae is lower, compared with pelagic, and not equal for the different components of the benthic group when mixed in a pelagic dominant treatment. These conditions may be present during warm periods of the year (e.g., spring and summer) when phytoplankton blooms occur in their natural environment. *C. edule* may be considered as an opportunistic filter feeder that may take advantage of certain algal species, both pelagic and benthic, in relation to their availability in the field.

ACKNOWLEDGMENTS

This work is a contribution to the ECOFLAT (Eco-Metabolism of a Tidal Flat) project carried out under contract ENV4-ct96-0216, jointly sponsored by the ENVIRONMENT and MAST programs of the EU. The first author has also been supported by a Marie-Curie Training Research Grant from the European Commission within the SIMCERE project (Fair GT 97-4525). The National Institute for Coastal and Marine Management (RIKZ), Middelburg (The Netherlands) offered us the possibility to use part of their equipment and technology. Many thanks go to researchers from RIKZ such as Thomas Rutten and Ben Sandee for their help in the analysis of the samples with the flow cytometer, Louis Peperzak for his help in the identification of the algal species and Fred Twisk and Richard Eertman for considerable support at different stages of this research. We also thank Dr. Pauline Kamermans and Dr. Sandra E. Shumway for their comments in earlier versions of the manuscript.

ABSTRACT Commercial clam landings reached an average of almost 91,000 tons annually in Chile over the last decade. In spite of the high value of this resource, few efforts have been made to understand the basic biology of the exploited species, data that might in the future be needed to aid in their protection or even artificial culture. This study is a contribution to the knowledge of the reproductive cycles of two valuable species, *Semele solida* (Gray) and *Gari solida* (Gray). Representative samples of these species were collected at two widely separated localities in Chile and examined histologically to determine their seasonal reproductive cycles. It was found that the species were of separate sexes, and had annual gonadal cycles. In *S. solida* from northern Chile, the reproductive period extended from June 1991 to February 1992. In *G. solida* from southern-central Chile, the reproductive period was relatively short, from October 1991 to February 1992. In both species, most specimens have empty gonads by March. The data obtained are useful in developing management plans related to their reproductive periods. Relevant to culture strategies, *S. solida* has the comparative advantage of a lengthy reproductive period, wherein mature individuals may be frequently encountered in nature for spawning inductions. *G. solida*, with its shorter annual reproductive cycle may have the advantage of being induced to mature in artificial conditioning systems over relatively short periods of time.

KEY WORDS: clam reproduction, reproductive cycle, bivalves, *Semele solida*, *Gari solida*, Chile

INTRODUCTION

Chilean coastal waters host very productive and diverse clam fisheries due to the rich coastal upwelling and favorable water temperatures. The largest clam populations occur in the protected bays and fjords of southern Chile. Over a number of years official fisheries records in Chile (SERNAPESCA 1990–1999) considered all clam species as one generic group ("clams") among which were included the venerids *Protothaca thaca* (Molina), *Venus antiqua* (King and Broderip), *Eurhomalea exalbida* (Chemnitz), *E. lenticularis* (Sowerby), *E. rufa* (Lamarck), and the mactrid *Mulinia edulis*. *Semele solida* (Gray) and *Gari solida* (Gray) belonging to the Semelidae and the Psammobiidae respectively, and objects of this study are also included in this group. They are primarily exploited in artisanal fisheries, and commercialized mostly in canned form. *G. solida* is highly valued from the culinary standpoint. In 1994, the first year of its listing as an individual species, 4613 tons of *S. solida* were harvested, declining to 2071 tons by 1999; *G. solida*, recorded separately beginning in 1990, was registered at 31,373 tons, which declined to 9931 tons by 1999 (SERNAPESCA 1990–1999). The only regulation for the fishery of these clams is a minimum size limit of 55 mm for *S. solida* and 60 mm for *G. solida* (Subsecretaría de Pesca 1996).

Despite their great economic value, not much research has been done on reproduction in Chilean clams, particularly in *S. solida* and *G. solida*. One recent report (Jeréz et al. 1999) suggested that *G. solida* in southern Chile had a continuous reproductive cycle throughout the year, a pattern apparently common among the heavily commercialized clams such as *V. antiqua* (Lozada & Bustos 1984) and *P. thaca* (Henríquez et al. 1981). This also was true for *E. lenticularis* (Campos & Brown 1997, Campos et al. 1999) and *M. edulis* (Jaramillo et al. 1998).

Semele solida (Fig. 1A), locally termed "tumbao", occurs partially buried in sand and gravel bottoms from the intertidal (Osorio et al. 1979) to the subtidal zone (Urban 1994). Its geographic distribution ranges from 12°S to 47°S. (Viviani 1979). *Gari solida* (Fig. 1B), locally termed "culengue", occurs completely buried in bottom sands and gravels, usually at greater depths than *S. solida* from the intertidal to 15-m depth (Urban 1994). Its range of distribution along the Pacific Coast, as given by Viviani (1979) and later by Guzmán et al. (1998), was between 12°S and 47°S.

Biologic data for species of economic importance is fundamental for proposing regulatory recommendations for sustainable harvest of these resources over time. The obvious declines in harvest over the years enhances the need for more information on the reproduction and survival of these species to support efforts directed towards their artificial culture, repopulation, or management as a renewable resource in over-exploited beds.

In this study, we describe the reproductive cycles of *G. solida* and *S. solida* by means of histologic observations of gametogenesis during different seasons of the year. Patterns in reproductive cycles, including gametogenesis and resting gonadal periods were studied in a population of *S. solida* from northern Chile and in a *G. solida* population from central-southern Chile, representing the first study of this nature for these two clam species in their respective regions.

MATERIALS AND METHODS

Adults of each species were obtained by diving at monthly intervals from June 1991 to July 1992. *S. solida* was collected in La Herradura Bay (29°58′S) and *G. solida* from Coliumo Bay (36°32′S) (Fig. 2). Maximum anterior-posterior length of the shell was measured on each specimen, to the nearest 0.1 mm. Maturational status of the gonad was determined monthly on around 30 animals of each species. Tissue samples 5 mm in thick-

ness were obtained and fixed 24 h in Bouin's fluid and prepared by routine histologic procedures as follows: dehydration with graded series of ethanol, clearing in xylol and embedding in Paraplast. Five micrometers histologic sections obtained from three levels of each gonad separated 500 μm, were stained with hematoxylin and yellowish eosin, dehydrated in graded series of ethanol, cleared in xylol and permanently mounted with Canadian balsam (Gabe 1968).

The gametogenic cycles of the two clams were followed by describing the histologic appearance of the gonadal sections and classifying them into different stages of maturity using a modification of the scale proposed by Lucas (1965). Each individual was assigned to one of the following stages based on the degree of morphologic development of its germ cells: (d1) = initial development or maturation; (d2) = advanced development or maturation; (d3) = complete development or maturation; (r1) = initial regression or evacuation; and (r2) = total regression or evacuation. The results were expressed as percentage frequency histograms of: (1) males in each gonadal stage; (2) females in each gonadal stage; and (3) males plus females in each stage, separately for *S. solida* and *G. solida* during the sampling period from June 1991 through July 1992.

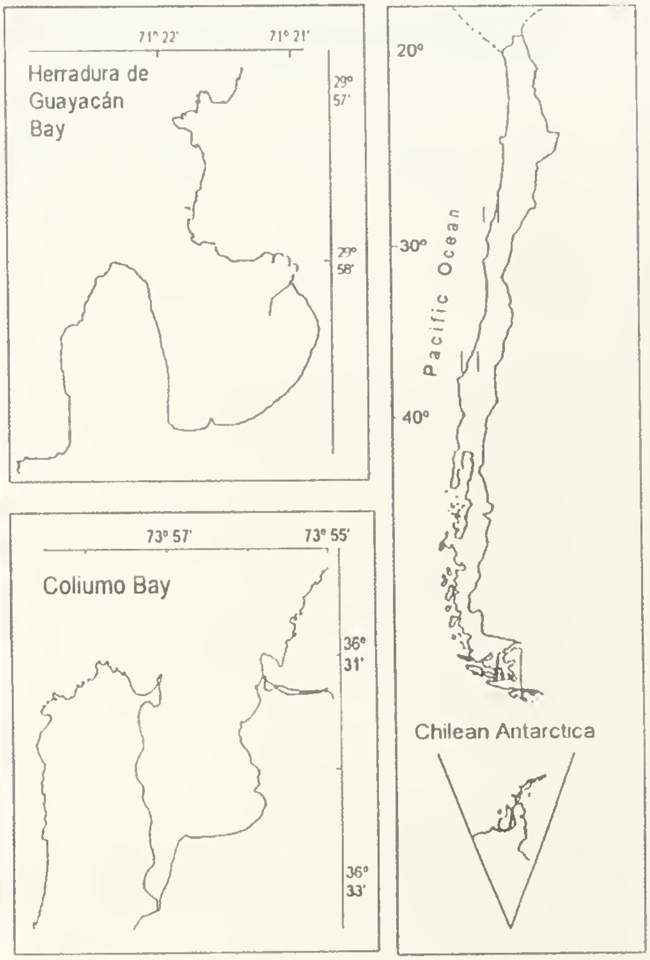

Figure 2. Location of collection sites for A: *S. solida* and B: *G. Solida* on the Chilean coast.

RESULTS

Semele solida specimens measured from 38.9 to 86.0 mm and *Gari solida* from 41.4 to 88.0 mm. The two clam species were of separate sexes, with no hermaphroditism and no sexual dimorphism evident. Histologic analysis of the gonad in both species showed a multilobulate organization of the acini connected to evacuation tubes covered by simple ciliated epithelium similar to that observed in other bivalves (Sastry1979). The acini consisted of a basal lamina of variable thickness depending on the stage of gonadal maturity. Its relative thickness was greatest in specimens initiating gametogenesis, and in those that had spawned. In these specimens an intra-acinar reticulum consisting of vesicular somatic cells and an intra-acinar space containing groups of amebocytes may be found (Figs. 3A and 4F).

The cells of the male germinal line that characterize spermatogenesis may be restricted to two zones of the gonadal acinus: (1) a basal region representing the early germinal line that includes spermatogonia and spermatocytes that form a band of circular voluminous nuclei, and recently formed round spermatids that also form a band of small circular nuclei (Figs. 3A, 3B and 4A, 4B), that is evident in *G. solida*; and (2) a lumen region, representing an advanced germinal line with spermatids undergoing cytodifferentiation with heavy stained elongated nuclei, gathered by their heads in double columns, giving a "feathered" appearance (Figs. 3B, 3C and 4B, 4C).

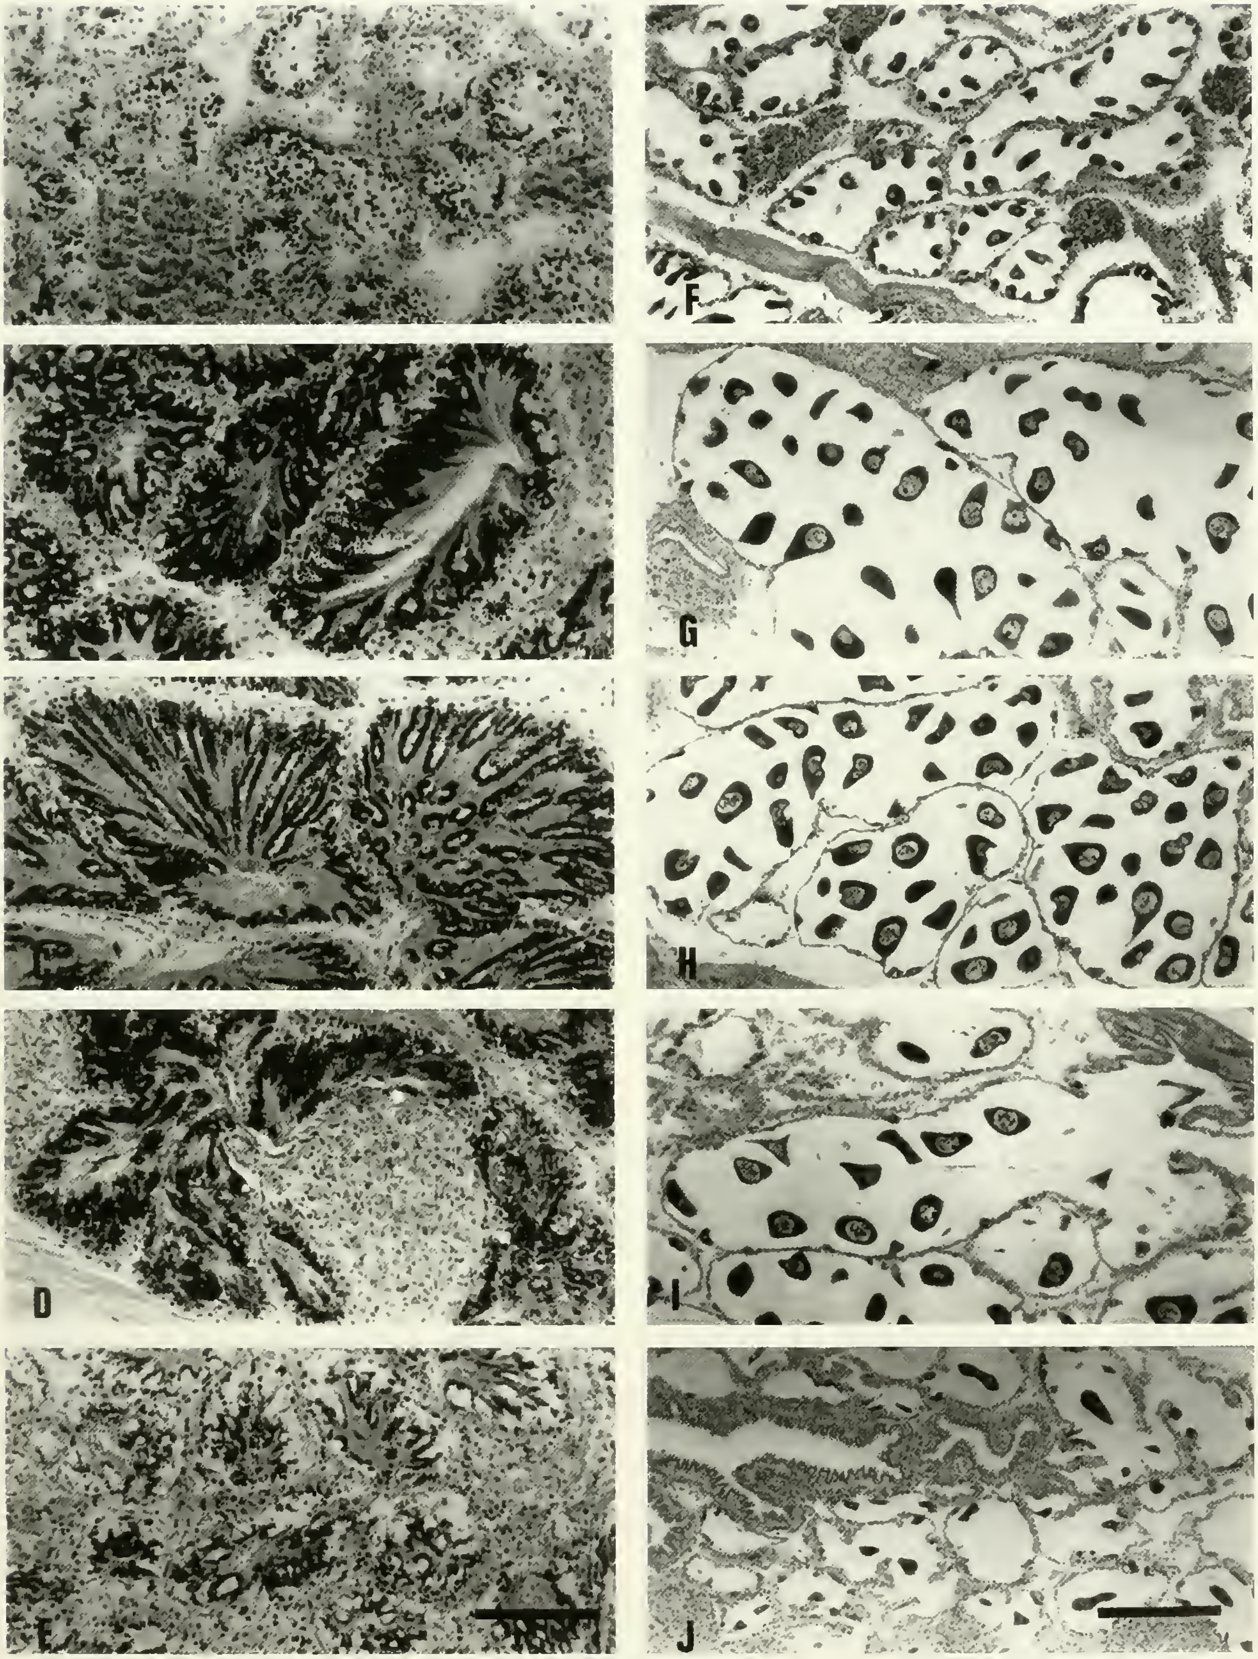

Figure 3. A–E: Light photomicrographs of different histological stages of male and F–J: female gonadal acini of *S. solida* collected in La Herradura Bay from June 1991 to July 1992. A–E bar = 100 µm; F–J bar = 200 µm; A and F = initial development of maturation (d1); B and G = advanced development of maturation (d2); C and H = total development or maturation (d3); D and I = initial regression or evacuation (r1); E and J = total regression or evacuation (r2).

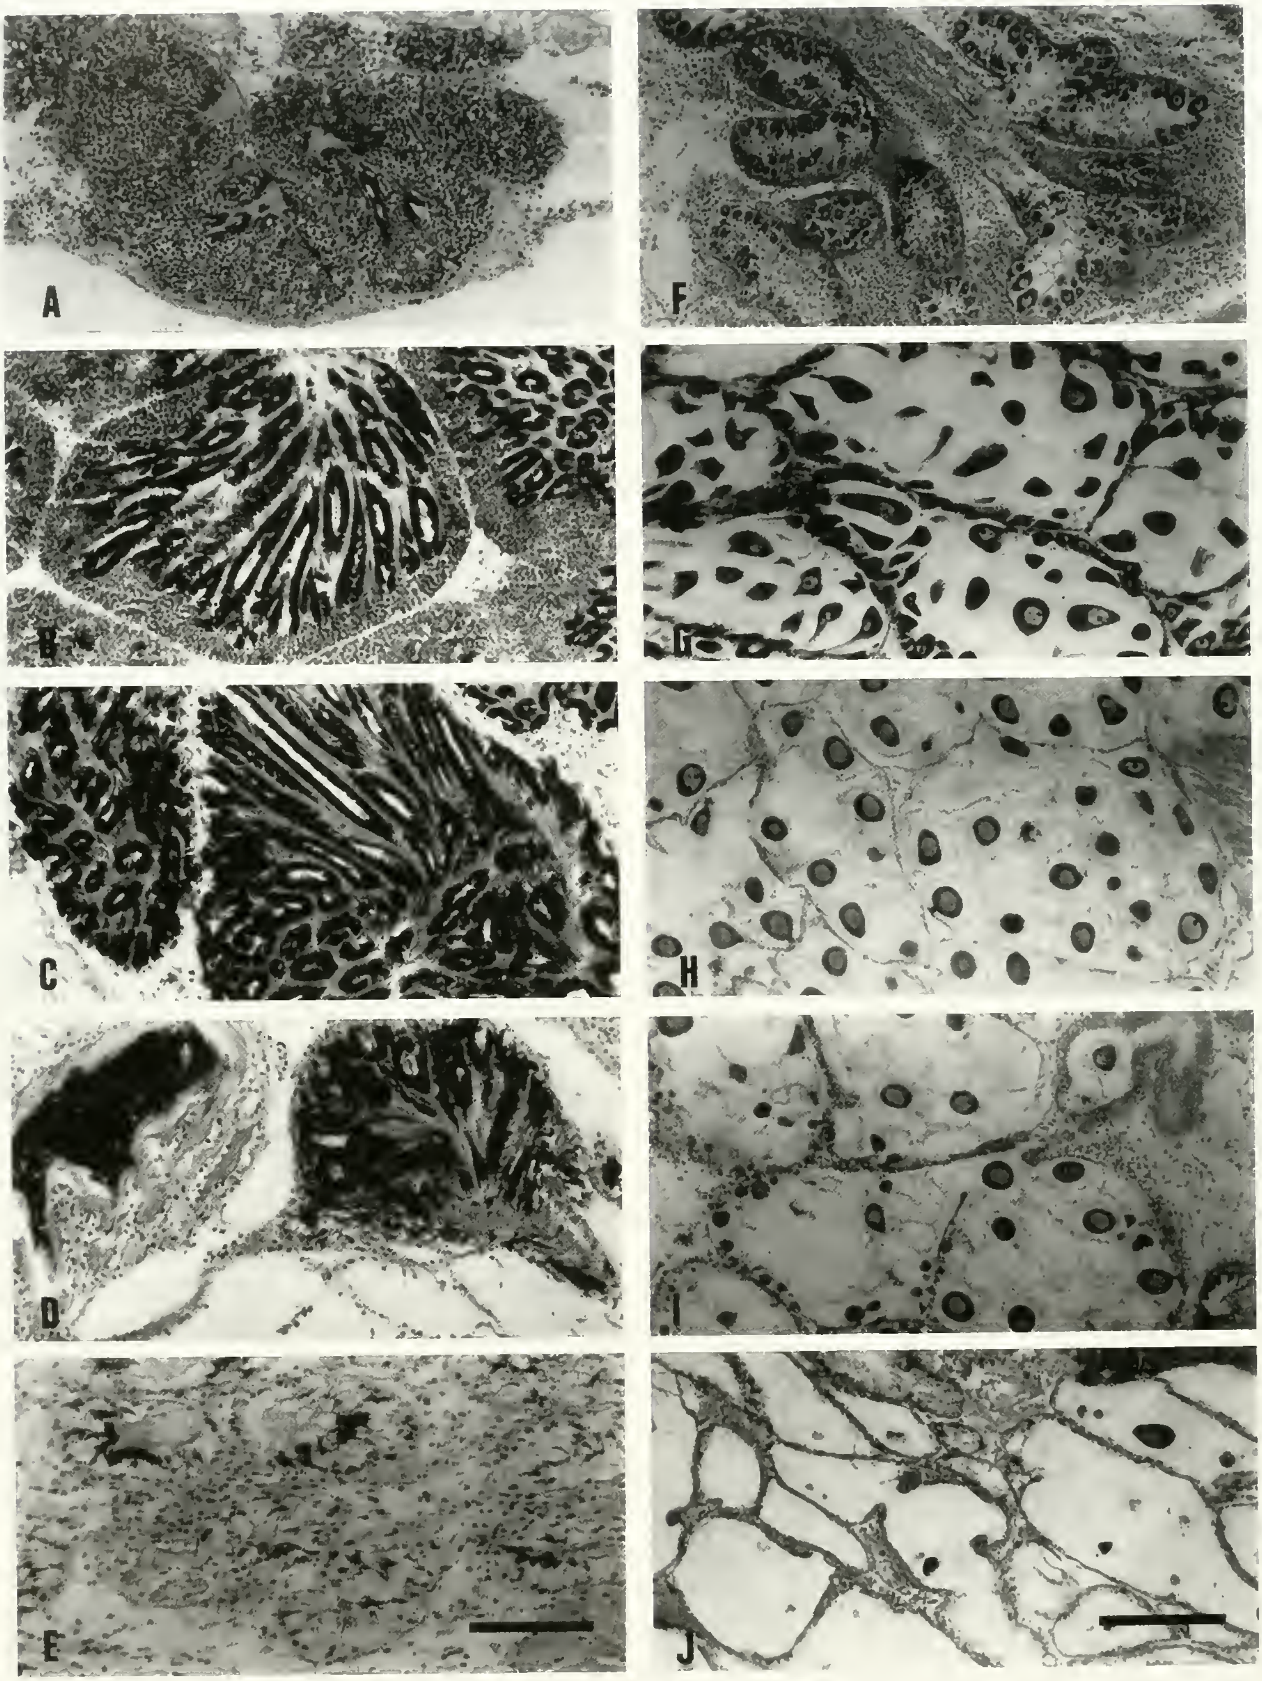

Figure 4. A–E: Light photomicrographs of different histological stages of male and F–J: female gonadal acini of *G. solida* collected in Coliumo Bay from June 1991 to July 1992. A–E bar = 100 μm; F–J bar = 200 μm; A and F = initial development or maturation (d1); B and G = advanced development or maturation (d2); C and H = total development or maturation (d3); D and I = initial regression or evacuation (r1); E and J = total regression or evacuation (r2).

The cells of the female germinal line in the basal region are represented by oogonia, previtellogenic and adhered vitellogenic oocytes. In the lumen region they are represented by pedunculate vitellogenic oocytes as well as free oocytes (Figs. 3G, 3H, and 4G, 4H). The histologic stages of the gonads of *S. solida* and *G. solida* females are shown in Figures 3F–3J and 4F–4J, respectively.

The three sampled areas of the gonad from both species all showed the same degree of gametogenic activity or development of the germinal line, indicating synchronic maturation throughout the gonad.

Semele solida

The distribution of percentage frequencies of the different histologic stages in male gonads, female gonads, and in the population as a whole for *S. solida* are given in Figures 5A, 5B and 5C, respectively. This species presented a seasonal pattern of gonadal development in both sexes. Males and females with developed or mature gonads (d3 stage) as well as in initial regression (r1) (Figs. 3D and 3I) were predominant from June 1991 to February 1992. In contrast, from March to June 1992, there was a greater frequency of individuals in total regression (r2) (Figs. 3E and 3J). Although in both sexes the frequency of samples with gonads in initial stages of development (d1) (Figs. 3A and 3F) was observed between April and July 1992, the number of females in this stage was greater, and predominated over those in total regression (Fig. 5A vs. Figure 5B). However, during the first period, there was a small percentage of males in total regression (r2) and in initial development (d1) (Fig. 5A), which was a condition more apparent in females (r2-d1; Figure 5B). Some observations not included in the figures suggested that individuals technically considered to be in regression could show a new wave of initial maturation beginning at the germinal line in the gonadal acini.

The second period was characterized by the total regression stage (r2), where all individuals had gonads with depleted acini in March 1992 (Figs. 5A, 5B). The percentage frequency distribution of the different gonadal stages for the population sample (Fig. 5C) shows this tendency in both males and females.

It is of interest to point out the difference in gonadal conditions between specimens sampled in June to July 1991 compared with those from the same period in 1992. In 1991 a high frequency of both sexes contained elevated numbers of specimens with gonads in advanced and total development (d2–d3), whereas in 1992 this condition was different, with specimens containing gonadal acini in total regression (r2) or without advanced germinal line (Fig. 5).

Gari solida

In this species the distribution of percentage frequencies of the different histologic stages in males, females, and the entire population are given in Figures 6A, 6B, and 6C, respectively. There is a periodicity in both sexes with the same general tendency.

There is a well-marked period in which advanced and totally developed gonads (d2-d3) are observed, as well as those in initial regression (r1) (Figs. 4D and 4I) from October 1991 to February 1992. In females this period is much shorter (November 1991 to January 1992). This condition persisted in some males until April 1992. Some observations not included in the figures showed individuals in regression during this period, which had a new wave of initial maturation beginning at the germinal line, as observed in *S. solida* (see earlier). In a second, more extensive period, the gonads were characterized by the occurrence of total regression and initial development (r2–d1) (Figs. 4E and 4A, respectively) in males from June to September 1991, and from March to July 1992 (Fig. 6A). In females the r2–d1 period (Figs. 4J and 4F, respectively) extended notably until October 1991, and from February to March 1992 (Fig. 6B).

Figure 6C shows the general frequency of the gonadal stages for the general population, with a similar pattern to that presented separately for males and females. From June to August 1991, February 1991, and April to July 1992 the number of specimens in each population sample exceeded the males and females together because included were specimens whose total regression stage was such that there were no cells on the germinal line differentiated enough to permit sex determination. In comparing the gonadal stages of specimens obtained in June to July 1991 with those of the same period in 1992, stages were observed that were near total regression and initial development showing an inverse fluctuation where regression predominated in 1991 and initial development in 1992.

Finally, it was apparent in both species that the stages of advanced or total maturity were observed in water having higher relative temperature, whereas initial stages of development were related to water of relatively low temperature, although our temperature measurements were not extensive (Figs. 5C and 6C).

DISCUSSION

The reproductive cycle is characterized by a series of events that in annual species comprises a reproductive period involving the gametogenic and spawning phases and a resting period in which there is not gametogenic activity.

Present results have shown similar values between the annual reproductive cycles of *S. solida* and *G. solida*, where both showed seasonal gametogenesis and spawning, followed by a resting period without production of gametes.

The reproductive period of *S. solida*, from June 1991 to February 1992 was longer than that of *G. solida*. Most of the specimens showed gametogenic activity and signs of having spawned. The majority of spawning occurred in February, and in March all specimens had empty gonads. This point marked the initiation of the resting period, indicated by a completely regressive condition in the gonad, which was more marked in *G. solida* than in *S. solida*.

We are cautious to consider the possibility of a second spawning phase during the reproductive period of *S. solida* because of the low number of animals (4) sampled and examined in October, notwithstanding that all of them were in advanced development (D2).

In *G. solida* the reproductive period was relatively short, from October 1991 to February 1992; the spawning phase mostly occurs in February. A majority of the specimens had empty gonads in March 1992; then the spawning phase mostly occurs in February. The presence of specimens with gonads in the initial state of development in this period may indicate possible activity in gonial multiplication and generation of cytes without gametogenic activity that leads to massive production of differentiated gametes. The results showed that low temperatures favored the proliferative activity of the early germinal line, while high temperatures aided cytodifferentiation of the advanced germinal line. This condition was most notable in the reproductive cycle of *G. solida* from Coliumo Bay, a more southerly location. These events occurred

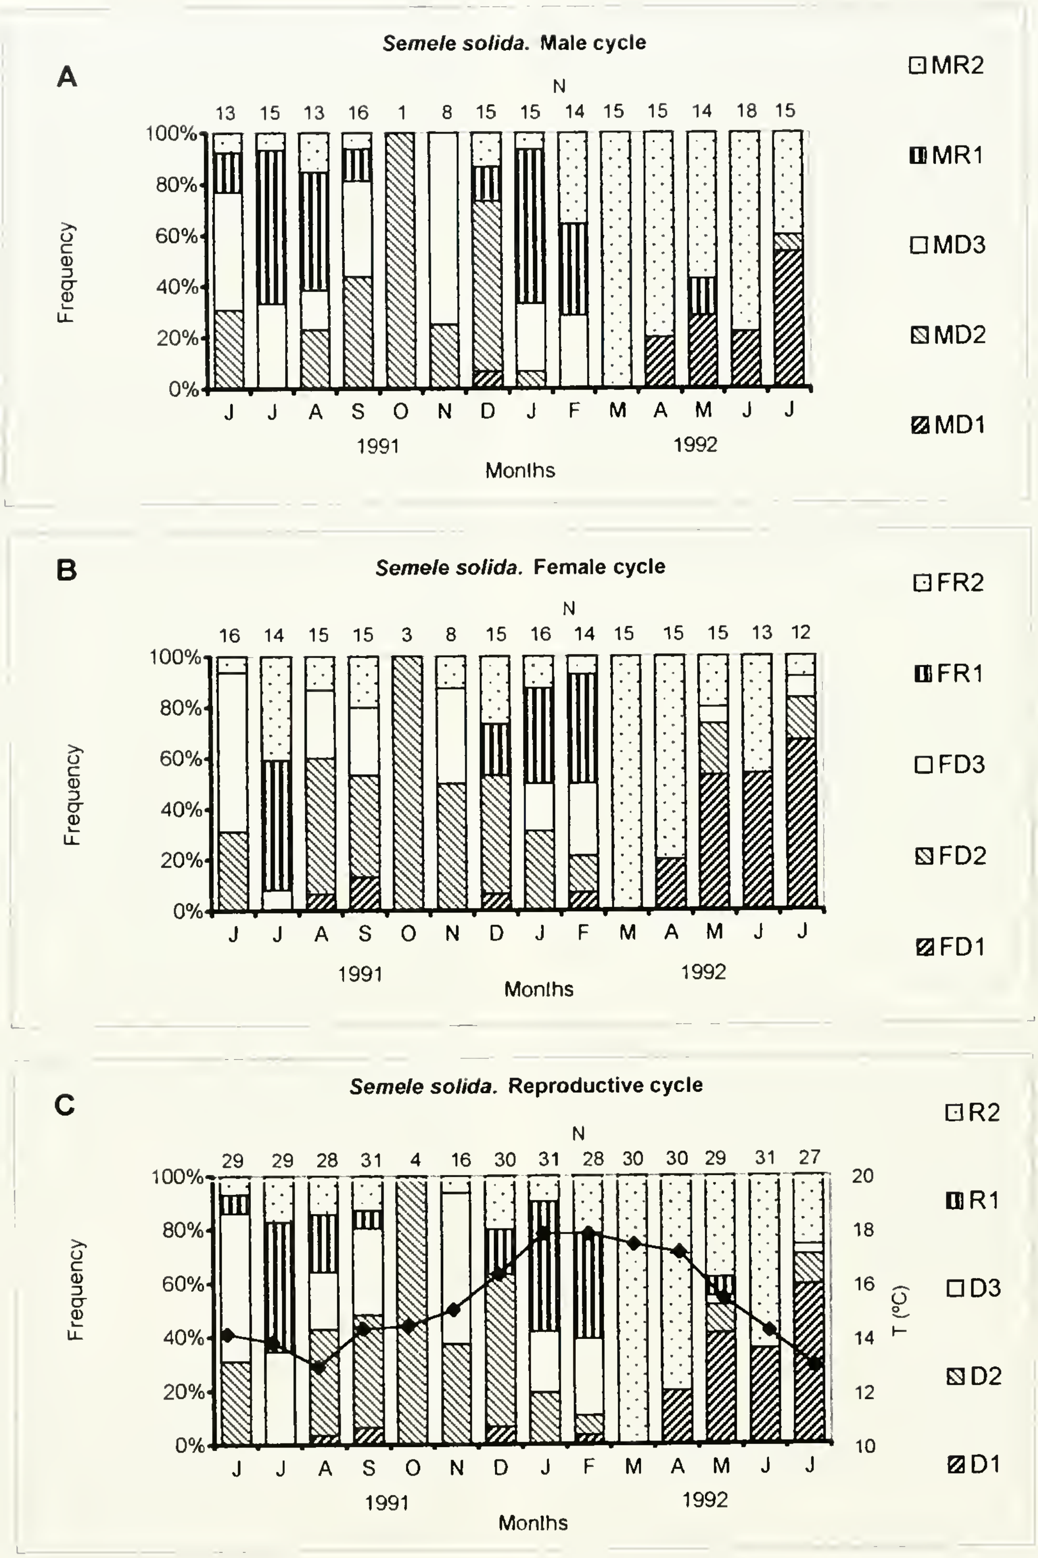

Figure 5. Distribution of different gonadal stages in A. males; B. females; and C. males + females of *S. solida* colleced in La Herradura Bay from June 1991 to July 1992, with sea surface temperature added. The length of each area represents the percentage frequency of specimens in each histologic stage of the gonadal acini. N = number of specimens examined.

simultaneously in both males and females showing (expected) synchrony of the reproductive cycles.

Every monthly sampling during the reproductive period showed a few individuals having gonadal conditions differing from the majority of the specimens, a phenomenon more pronounced in *S. solida*. There was a predominance of advanced stages of gonadal maturity, and also those with complete regression as an evidence that spawning had occurred. These observa-

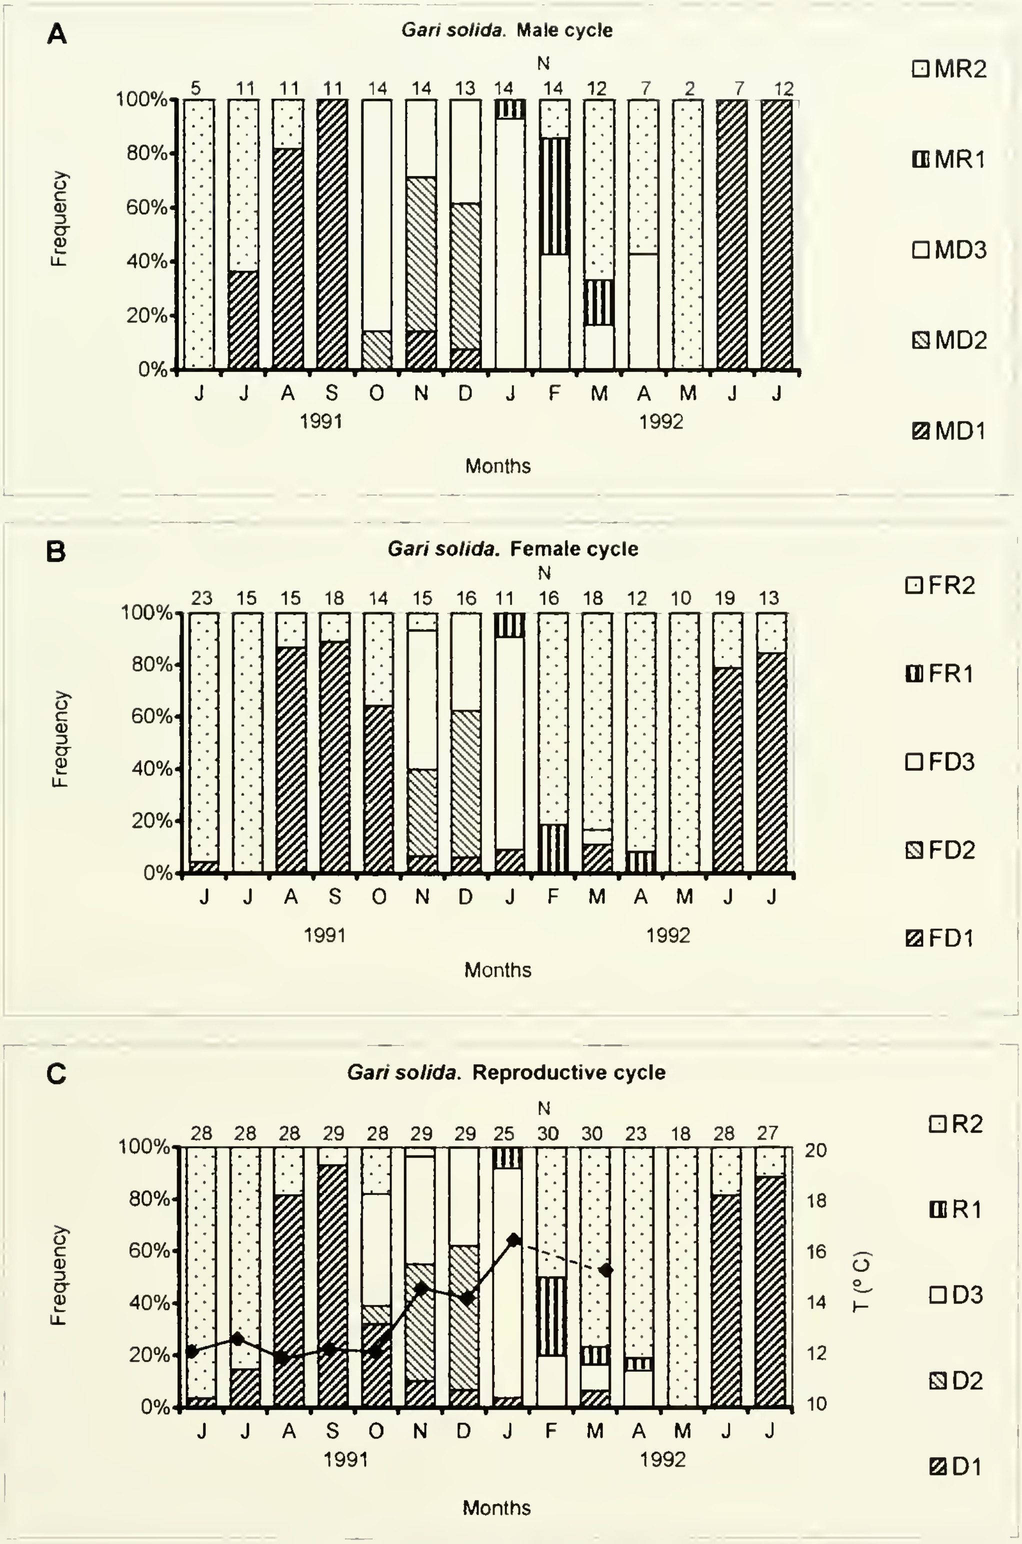

Figure 6. Distribution of different gonadal stages in A. males; B. Females and C. males + females of *G. solida* collected in Coliumo Bay from June 1991 to July 1992, with sea surface temperature added. The length of each area represents the percentage frequency of specimens in each histological stage of the gonadal acini. N = number of specimens examined.

tions suggest intrapopulation asynchrony of gametogenic activity, with partial evacuations of gametes over a longer period. The fact that the specimens showing signs of having spawned showed a new wave of maturation in the germinal layer of their acini, confirmed this asynchrony and strengthened the hypothesis of continuous gametogenesis with various cycles of gametogenic activity and spawning by each individual during the reproductive period.

A difference was observed in the degree of maturity of the population samples of *S. solida* between June and July 1991 where advanced and complete maturity were well represented; in the same period of 1992, on the contrary, maturity was just beginning. This difference may be explained by normal adaptation to environmental conditions such as temperature and food availability, which may vary within a limited range from year to year.

Although Urban and Campos (1994) suggested that the reproductive cycles of *S. solida* and *G. solida* were influenced by temperature, Jeréz et al. (1999) working on a *G. solida* population from the south of Chile found the annual reproductive cycle to be continuous without a marked resting period. Further studies are required to evaluate seasonal variations in gonadal cycles of these species with latitude, as they are distributed over a broad latitudinal range from Callao, Peru (12°S) to Chile's Chonos Archipelago (44°S). The hypothesis here is that the reproductive cycles of these clams become shorter in populations the farther south they occur on their distributional gradient. Some data available on other clam species with extensive distributions support this hypothesis. Populations of *Protothaca thaca* (Henríquez et al. 1981), *Tagelus dombeii* (Acuña et al. 1994) and *Eurhomalea lenticularis* (Campos & Brown 1997) from central and north-central Chile exhibit continuous gonadal activity with various important spawning peaks throughout the year. Nevertheless, *T. dombeii* from south-central Chile showed a period of gonadal regression in the fall (Jaramillo et al. 1998). This phenomenon is not clear across other clam species inhabiting the south-central zone of Chile, such as *Venus antiqua*, *Tawera gayi*, *Mulinia edulis* and *Ensis macha* that show continuous reproductive cycles without resting periods (Lozada & Bustos 1984, Jeréz et al. 1999).

From the practical point of view, regulation of harvesting these clams should be based on considerations of their reproductive cycles by limiting their harvest during the major spawning season. Consideration of the reproductive cycles is also important in obtaining broodstock for aquaculture. Experimental studies should prove this a feasible alternative for production or protection of the resource. In studying resource management of these clams, *S. solida* shows a comparative advantage in having a more extensive reproductive period, as mature individuals may be encountered over an extended period. This implies that mature broodstock would be available in nature for artificially induced spawning (e.g., in aquaculture experimentation) over comparatively long periods. Although *G. solida*, in contrast, has a more restricted reproductive period, it may be a species amenable to artificial conditioning in aquaculture systems, given that its gonads almost always contain high numbers of immature gametogenic cells.

ACKNOWLEDGMENTS

The authors thank Ms. T. Jerí for sampling *G. solida* at Coliumo Bay, and Ms. G. Bellolio (U. Católica del Norte at the time) for providing *S. solida* from Herradura Bay. We also thank Dr. R. Guerra for her supervision of the histologic processing at the U. de Valparaíso, and Mr. C. Olivares for assistance in histologic analyses. Corrections and comments by anonymous reviewers helped to improve the manuscript. The work was financed by FONDECYT Grant 91-502 to B. Campos.

O. Box 12559, Charleston, South Carolina 29422; and [4]Marine Science Program, Department of Biological Sciences, University of Alabama, Dauphin Island, Alabama 36528

ABSTRACT To better understand how seagrasses influence the growth of northern and southern quahogs (*Mercenaria mercenaria* and *Mercenaria campechiensis*), we collected and compared the growth rates of clams from seagrasses and adjacent unvegetated locations along the Atlantic (Massachusetts and New Jersey) and Gulf of Mexico coasts (Alabama and Florida) using identical methods. In particular, we sought to test hypotheses that clam growth is influenced not only by the presence or absence of seagrass (*Thalassia testudinum, Halodule wrightii*, and *Zostera marina*), but also by location within seagrass beds. Walford plots constructed using annual shell-growth band analyses showed that *Mercenaria* spp. growth was significantly affected by the presence of seagrass habitat, although the magnitude of this effect varied with clam age (size) and latitude. Specifically, first-year growth was significantly greater in unvegetated than in adjacent vegetated sites, whereas a measure of lifelong growth (Ford's growth coefficient) was not significantly different between adjacent vegetated and unvegetated sites. We hypothesize that these conflicting results may be due, in part, to differing patterns of energy resource allocation in *Mercenaria* at various life cycle stages. During the first 1.5 y or so, a clam's energy resources are allocated primarily to somatic growth, whereas in subsequent years energy is also allocated to reproduction. Therefore, factors affecting *Mercenaria* growth, such as the presence or absence of submerged vegetation, should be most easily detectable in analyses examining the first year's growth. Even though our data showed greater first-year growth at lower latitudes (Gulf of Mexico sites versus New Jersey and Massachusetts), overall lifelong growth rates were greatest at the Massachusetts sites. We attribute this pattern to the fact that higher first-year growth rates quickly become asymptotic in the warm waters of the Gulf of Mexico, whereas slower but more constant growth rates are typical of clams from colder water sites. We found little evidence for the effects of location (as measured as distance from bed edge) on growth of individuals collected from grassbeds, except where patterns of water movement showed consistent directionality (e.g., Gulf of Mexico sites). Given the multitude of variables that can interact to influence clam growth rates and the unresolved variability in results from single-site studies performed in different locations, some complex, carefully controlled experiments are still needed to elucidate the dominant factors that regulate both short and long-term clam growth.

KEY WORDS: hardclams, *Mercenaria*, seagrass, latitude, growth, quahog

INTRODUCTION

Growth and survival[1] of suspension-feeding animals may be strongly influenced by the presence of submerged aquatic vegetation (SAV), presumably because macrophytes reduce flow and enhance the deposition of suspended materials (e.g., Scoffin 1970, Orth 1977, Tegner & Dayton 1981, Fonseca et al. 1982, Harlin et al. 1982, Eckman 1983, Peterson, et al. 1984, Dayton 1985, Wildish & Kristmanson 1997), thereby altering available food supply (Peterson & Beal 1989, Irlandi & Peterson 1991, Irlandi 1996, but see Judge et al. 1992, Nakaoka 2000). However, studies of the suspension-feeding bivalve *Mercenaria mercenaria* (The Northern Quahog), have continued to produce conflicting results (e.g., Belding 1912, Kerswill 1941, 1949, Haskin 1952; Pratt & Campbell 1956; Ansell 1968, Greene 1979, Hadley & Manzi 1984, Peterson et al. 1984, Arnold et al. 1991, Coen & Heck 1991, Irlandi & Peterson 1991, Judge et al. 1992, Coen et al. in prep.) with regard to the effect of seagrasses. For example, early studies by Kerswill (1941, 1949) found decreasing *M. mercenaria* growth rates as eelgrass (*Zostera marina*) density increased, whereas a later study by Peterson et al. (1984) found just the opposite.

More recent studies (Peterson & Beal 1989; Coen & Heck 1991; Slattery et al. 1991, Nakaoka 2000, Coen et al. in prep.) found that *M. mercenaria* in seagrass beds sometimes grew faster, slower, or at the same rate as *M. mercenaria* in unvegetated habitats. Peterson and Beal (1989) cited two possible explanations for the variability in their results. First, as water velocities decrease, the flux of suspended food particles passing by the clam's siphons will decrease. Alternatively, reductions in velocity could enhance the settlement of suspended materials and increase food concentrations near the bottom. The net effect of decreasing suspended horizontal food flux while increasing the number of food particles settling from the water column will determine whether the impact of vegetation on *Mercenaria* growth is positive or negative (Peterson & Beal 1989). Subsequently, Irlandi and Peterson (1991) have argued that measured variations in food concentration between vegetated and nearby unvegetated areas are insufficient to explain the observed between-habitat differences in clam growth.

There must also be an upper limit to current velocity beyond which bottom instability inhibits feeding, either directly by smothering or indirectly by requiring the clam to expend energy reburrowing to maintain a desired burial depth (Myers 1977, Orth 1977, Turner & Miller 1991, Irlandi & Mehlich 1996, Irlandi 1996) or by decreasing assimilation efficiency (Bricelj & Malouf 1984). Greater bottom stability in vegetated habitats produced by the baffling effect of seagrasses could also lead to greater growth of *Mercenaria* located within seagrass beds (cf. Peterson et al. 1984; Irlandi & Peterson 1991; Irlandi 1996, Coen, unpublished, 2000).

Location within a landscape of habitats and the associated system states (i.e., food, flow, competitors, predators, see Micheli 1996) can also significantly affect bivalve populations. This can result from local food depletion from upstream-feeding individuals (e.g., Okamura 1986, Peterson & Black 1987, Fréchette et al. 1989), within or among habitat conditions (e.g., Irlandi & Peterson

---

1991, Kamermans 1993) or the physical activity of neighboring animals interfering with feeding or space acquisition (Virnstein 1977, Peterson 1979, Okamura 1986, Nakaoka 2000). These can manifest themselves under certain situations as density-dependent effects (Grizzle & Morin 1989, Grizzle & Lutz 1989, Grizzle et al. 1992, Kamermans et al. 1992).

The growth of suspension-feeding bivalves may also be influenced by lethal or nonlethal (siphon nipping, reduced foraging) predation by numerous species, such as fishes, gastropods, and crabs (e.g., Coen & Heck 1991, Irlandi & Peterson 1991, Kamermans & Huitema 1994, Peterson & Skilleter 1994, Skilleter & Peterson 1994, Bonsdorff et al. 1995, Nakaoka 2000). Although the siphon tip is easily regenerated, this requires an expenditure of energy (see Peterson and Fegley 1986) that could otherwise be used for shell and soft-tissue growth/repair and reproduction (e.g., Trevallion et al. 1970, Hodgson 1982, Peterson & Quammen 1982, Festa 1975, De Vlas 1985, Zwarts 1986, Coen & Heck 1991, Skilleter & Peterson 1994, but see Irlandi 1994, 1996, and Irlandi & Mehlich 1996 for counter examples). In addition, the mere presence of potential disturbers or predators in the vicinity of *Mercenaria* may cause individuals to cease feeding and thereby lead to reduced growth rates where predators are abundant (e.g., Blundon & Kennedy 1982, Irlandi & Peterson 1991, Nakaoka 2000).

This study was designed to investigate how the presence of vegetation and location within a bed can influence the growth of selected Atlantic and Gulf of Mexico (U.S.) populations of the northern and southern quahogs, *M. mercenaria* and *M. campechiensis*. We were especially interested in determining whether 1) generalizations could be made that would apply to populations of both the northern and southern quahog species regarding the effect of seagrasses on growth; and 2) whether the distance of individual clams from the bed's edge could be an indirect measure of habitat quality as a result of potential differences in food supply, and therefore help explain some of the conflicting evidence regarding the effects of seagrasses on quahog growth rates.

MATERIALS AND METHODS

Study Locations

M. mercenaria and *M. campechiensis* populations were sampled at six different locations in four states (Massachusetts, New Jersey, Florida, Alabama) along a latitudinal gradient from about 42° to 30°N. The Massachusetts sampling area was located on Cape Cod in the Nauset Marsh system (Nauset Harbor and Salt Pond Bay; 42°N, 70°W), whereas *M. mercenaria* were collected from both vegetated ($n = 51$ clams) and unvegetated (sand) substrates ($n = 52$ clams) in May 1987. Vegetation consisted of pure stands of *Z. marina*, and water depth at low tide was less than 1.0 m.

The New Jersey sampling site was in southern Barnegat Bay, near Marshelder Island (39°N, 72°W), and *M. mercenaria* were also collected from both vegetated ($n = 51$ clams) and adjacent unvegetated (sand) substrates ($n = 84$ clams) in May 1987. Vegetation was dominated by eelgrass (*Z. marina*), with lesser amounts of widgeon grass (*Ruppia maritima*). Water depth (at low tide) was less than 1.0 m.

Collections were also made in the Perdido Bay system (30°N, 87°W), with one site at the western end (see Fig. 1 in Coen & Heck 1991; Perdido Pass, Alabama), and one site at the eastern end of the Bay (in the Gulf Islands National Seashore, Big Lagoon, Florida, see Fig. 2 in Spitzer et al. 2000). Native *M. campechiensis* were collected at the Perdido Pass site in April, May, and June 1987 ($n = 32$ clams) and at the Gulf Islands National Seashore site (30°N, 87°W), in June 1987 ($n = 21$ clams). All clams collected from these two sites were taken from vegetated habitats because there were no hard clams found in the unvegetated sand adjacent to the seagrass beds. Submerged vegetation at the two sites consisted of shoal grass, *Halodule wrightii* (Alabama) and mixed stands of *H. wrightii* and turtle grass, *Thalassia testudinum* (Florida). Water depth (at low tide) at both sites was less than 1.5 m.

Additional details on vegetation composition and physiochemical conditions at these study sites can be found in Heck et al. (1989, Massachusetts); Wilson et al. (1990, New Jersey); and Coen and Heck (1991), Judge et al. (1992, 1993), and Wilson (1991) for the Gulf of Mexico sites.

Clams were collected by hand after being located by treading at each sampling location. Clam location within grassbeds relative to the edge of the bed was estimated as the minimum distance from collection point to the nearest grass bed edge along one of the four compass directions. All *Mercenaria* were frozen after collection and later were thawed to allow removal of the soft tissue without damaging the shell. Shells were then washed and allowed to air dry. Valves of each clam were separated, with one valve used for age and growth estimates and the other archived (see also Wilson 1991). We assumed that all specimens collected from Atlantic locations are *Mercenaria mercenaria* (L.), and all individuals collected from Gulf sites are *Mercenaria campechiensis* (Gmelin).

Analysis of Growth Increments

For age and growth determinations, one valve from each clam was embedded in epoxy resin before sectioning with a Buehler Isomet™ low-speed saw. Sections were made through the umbo to the ventral margin, along the axis of maximum growth (Kennish et al. 1980). A second cut was made approximately 10 µm from the first to produce a thin section. To facilitate examination of annual growth increments, each thin section was ground and polished on a Buehler Ecomet III™ grinder/polisher with appropriate polishing compounds. During the polishing procedure, visual inspection of the thin section under a microscope determined when the thin section was readable (see Wilson 1991 for more detail).

When thin sections were viewed under the microscope, growth increments appeared as alternating translucent narrow dark and wide white (opaque) regions corresponding to periods of slow (narrow microgrowth increments) and rapid (wide microgrowth increments) growth, respectively (Barker 1964, Rhoads & Pannella 1970, Kennish 1980, Fritz & Haven 1983, Peterson et al. 1983, 1985, Grizzle & Lutz 1988, Arnold et al. 1991, 1996, Bert & Arnold 1995). One annual growth cycle, therefore, consists of two opaque regions (spring and fall) and two translucent regions (summer and winter). In older *Mercenaria*, there is often only one opaque region, with the fall band being faint or absent. Annual growth was marked at the end of each successive winter band for Atlantic sites (Pannella & MacClintock 1968, Rhoads & Pannella 1970, Kennish & Olsson 1975, Fritz & Haven 1983), and at the end of each successive summer band for the Gulf of Mexico sites (Clark 1979, Fritz & Haven 1983). Thus, one year's growth was measured as the linear distance between consecutively marked annual growth bands.

To obtain a quantitative measurement of annual growth, the distance between consecutive bands was traced on paper at 60×

with a camera lucida. Tracing followed the boundary between the outer, prismatic and middle, homogeneous shell layers with the end points located at the point where each successive annual band crossed this boundary (rather than the point where each successive annual band reached the outer edge of the shell), serving to delineate each year's growth. Distances were measured with a calibrated ocular micrometer.

Visual examination of the thin sections indicated that annual growth increments corresponding to ages >12 y could not be resolved with certainty (Wilson 1991, Lowell Fritz, Rutgers University, personal communication). In older *Mercenaria*, annual growth increments become narrower and more difficult to distinguish owing to decreased lateral shell growth (Hopkins 1941, Fritz & Haven 1983). This slowing of lateral growth may be accompanied by an increase in shell thickness, especially along the shell's margin. This pattern of shell growth was evident in most of the larger (i.e., older) *Mercenaria* specimens in this study. Visual examination of the thin sections identified clear annual growth increments corresponding to ages <11 y. Therefore, only the first 10 annual growth increments from each individual specimen were used for growth rate determinations.

Walford plots (see Ricker 1975) of yearly clam growth in length were constructed for individual *M. mercenaria* and *M. campechiensis* (see above assumption) for each site by plotting total length in a given year (designated G_{t+1}) versus total length in the previous year (designated G_t). Total length was calculated directly from the summation of annual measured growth increments measured from thin sections. In all cases, the first data point represents length at year two versus length at year one. "Population" Walford plots for each site, constructed by plotting G_{t+1} versus G_t values across all ages and clams from a given site, contained a minimum of 63 and a maximum of 756 data points (Wilson 1991).

A linear regression of G_{t+1} versus G_t yielded two values of interest: the slope of the regression line and its y-intercept. The y-intercept is the growth for the first year (McCuaig & Green 1983, hereafter referred to as the first year growth). The slope (also called Ford's growth coefficient or simply growth coefficient) is the fraction of total growth still to be attained after the first year (Walford 1946, McCuaig & Green 1983). The slope represents the decrease in growth increments over age classes (Ricker 1975) and has been used to characterize clam growth rates after the first year. The point at which the regression line for the Walford plot intersects the line of slope = 1, indicates the point at which growth stops and maximum size is reached.

Walford plots were constructed for each site to determine the site-specific population growth coefficient and first year growth. SAS (Version 5) regression procedure (Proc Reg) and its "Test" option (Freund & Littell 1986) were used then to simultaneously test for differences in growth coefficient (slope), first year growth (intercept), and coincidence of the regression lines among pairs of sites. Pairwise comparisons of *M. mercenaria* between vegetated and unvegetated habitats were only analyzed for sites in Massachusetts and New Jersey. Between-habitat (within site) comparisons were not made at the two Gulf sites because no *M. campechiensis* were found in any of the surrounding unvegetated habitats in either Alabama or Florida.

Walford plots were also constructed for individual *M. mercenaria* and *M. campechiensis* to determine growth coefficients and first year growth for each clam. Ford's growth coefficient and first year growth for each clam were then tested for the significance of correlations between these parameters and the linear distance to the grassbed edge (see above). Because proper construction of the Walford plots requires a minimum of three sets of data points (i.e., three G_{t+1}, G_t pairs), only those individuals having four or more annual growth bands were used to calculate the growth coefficient and first year growth for individual *Mercenaria* and sites (see Wilson 1991 for more details).

RESULTS

Year 1 and Overall Growth

First year growth, calculated for each site (Fig. 1; Table 1) ranged from a high of 2.11 cm for the Gulf Islands National Seashore vegetated site in Florida (mixed *H. wrightii* and *T. testudinum*) to a low of 1.10 cm for the vegetated site in Massachusetts (*Z. marina*). First-year growth was significantly greater in sand (=unvegetated) than in seagrass at both the Massachusetts and New Jersey sites (see Table 2).

There was also significantly greater first year growth at the vegetated sites in New Jersey, Alabama, and Florida than at the

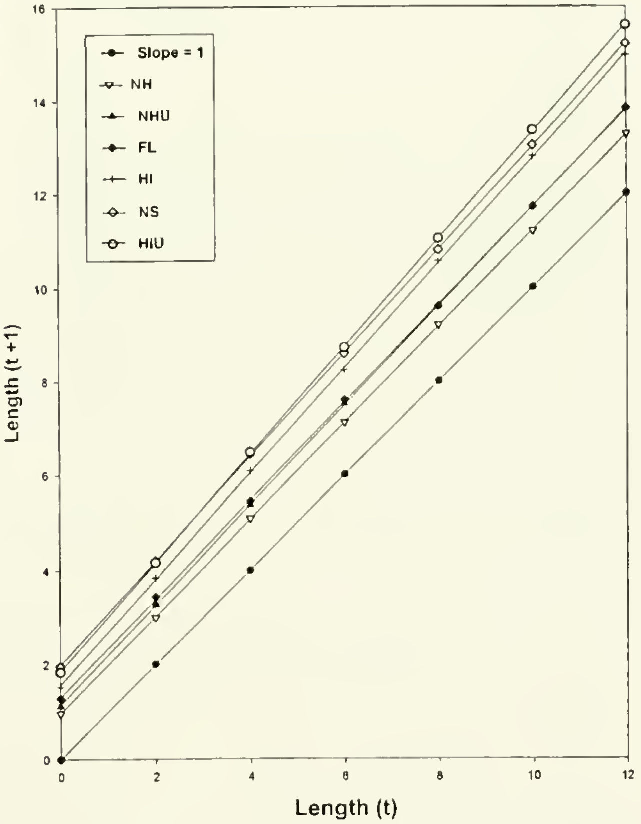

Figure 1. Walford plots for all six sites constructed by plotting length at year t_{+1} versus length at year t for all ages of all clams combined. Only the regression lines fitted to each site sampled and a line of slope = 1 (solid circle) are displayed. The six lines displayed correspond to the following sites: (1) unshaded diamond ◇ line = vegetated Gulf Islands National Seashore, Florida site (mixed *Thalassia testudinum* and some *Halodule wrightii*), (2) open circle line ○ = unvegetated New Jersey site (sand), (3) solid diamond line ◆ = vegetated Perdido Pass, Alabama site (*Halodule*), (4) large ✚ line = vegetated New Jersey site (*Zostera marina* and some *Ruppia maritima*), (5) large shaded triangle line ▲ = unvegetated Massachusetts site (mud/sand), and (6) large unshaded triangle line ▽ = vegetated Massachusetts site (*Z. marina*).

TABLE 1.

Growth parameters for Walford plots calculated from clams collected at each study site.

Study Sites	n	Intercept (First-Year Growth) cm	Slope (Ford's Growth Coefficient)	r^2
Massachusetts, vegetated (*Zostera*)	51	1.10	0.91	0.96
Massachusetts, unvegetated	84	1.28	0.88	0.96
New Jersey, vegetated (*Zostera*)	51	1.64	0.82	0.95
New Jersey, unvegetated	52	1.88	0.80	0.94
Gulf Islands National Seashore, vegetated (*Thalassia*)	21	2.11	0.82	0.94
Perdido Pass, vegetated (*Halodule*)	32	1.73	0.81	0.87

Intercept represents the first year's growth and the slope represents Ford's growth coefficient.

Massachusetts site (Table 2), and first-year growth was significantly greater in Florida (*Thalassia/Hadodule*) than New Jersey (*Zostera*) grassbeds. However, no significant difference in growth was observed between clams from New Jersey and Alabama (Perdido Pass, *Halodule*) grassbeds.

Growth rates of the 291 clams measured, while not presented individually here, varied over about an order of magnitude. For example, first-year growth ranged from a low of 0.67 cm for a clam at the vegetated site in Massachusetts (in *Z. marina*) to a high of 6.31 cm for an individual at the Perdido Pass vegetated site (taken from *H. wrightii*).

Ford's growth coefficients for individual clams ranged from a low of 0.14 for a clam at the vegetated site in Perdido Pass (*H. wrightii*) to a high of 0.97 for an individual at the vegetated site in Massachusetts (*Z. marina*). Overall, site-specific Ford's growth coefficients ranged from a high of 0.91 for the vegetated site Massachusetts (*Z. marina*) to a low of 0.80 for the unvegetated site in New Jersey (Table 1; Fig. 1). The only significant differences in the growth coefficients were between both the Massachusetts sites and all other sites in New Jersey, Alabama, and Florida. These significantly higher growth coefficients at the Massachusetts sites were unexpected because first-year growth was lowest at these sites.

Growth and Location in the Grassbed

There were two significant positive relationships between first-year growth and distance to the edge of the grassbed, which were found at the vegetated sites in Massachusetts (*Z. marina*) and Perdido Pass, Alabama (*H. wrightii*; r = 0.315 and 0.432; $P < 0.05$ and 0.01, respectively), indicating greater growth in year 1 with increasing distance from the edge of the bed at these two sites (Table 3). The only significant correlation between Ford's growth coefficient for individual clams and distance from the grassbed edge was found at the vegetated site at Perdido Pass (*H. wrightii*; Table 3, $r = -0.435$; $P < 0.05$), a result that indicates greater lifelong growth near the edge of the bed.

DISCUSSION

The effects of habitat (seagrass versus unvegetated substrate) on clam growth did not vary consistently when examined by either clam age or geographical location. With respect to age, we found significantly greater growth during year one in clams collected from the unvegetated habitats at both Massachusetts and New Jersey (Table 2). We attribute this to the fact that *M. mercenaria* growth is greatest during the first 1.5 y of life, with decreasing growth thereafter as sexual maturity is reached (Haskin 1952, Gustafson 1955, Walker 1985, Eversole et al. 1986). This suggests to us that habitat effects would be most evident in analyses of the rapid growth attained in the first year. However, this finding conflicts with that of Irlandi and Peterson (1991), who found faster growth of juvenile clams (mean size of 2.6–2.87 cm in length) planted for up to 6 months in seagrass (vs. sand), and who concluded that ". . . results should dispel any remaining doubts about

TABLE 2.

Pairwise comparisons of first-year growth and Ford's growth coefficient among study locations.

Pair-Wise Comparisons	N Site 1/Site 2	First-Year Growth F Value	First-Year Growth Significance Level ($P <$)	Ford's Growth Coefficient F Value	Ford's Growth Coefficient Significance Level ($P <$)
Massachusetts, vegetated vs. unvegetated	51/84	7.90	0.01	3.10	Not significant
New Jersey, vegetated vs. unvegetated	51/52	9.61	0.01	3.72	Not significant
Massachusetts, unvegetated vs. New Jersey, unvegetated	84/52	78.80	0.01	50.71	0.01
Massachusetts, vegetated vs. New Jersey, vegetated	51/51	55.47	0.01	37.28	0.01
Gulf Islands National Seashore vs. Perdido Pass	21/32	5.92	0.05	0.29	Not significant
Massachusetts, vegetated vs. Gulf Islands National Seashore	51/21	89.21	0.01	22.66	0.01
Massachusetts, vegetated vs. Perdido Pass	51/32	38.03	0.01	21.10	0.01

the potential for seagrass in relatively high-energy environments to promote faster growth of suspension feeder living buried in the sediments." Perhaps the key to resolving the differences in our results and those of Irlandi and Peterson (1991) is differences in flow regimes among sites examined. These differences could also reflect some inherent latitudinal differences between conditions in North Carolina and those conditions further north (see results of Ansell 1968, or life-long growth reported by Slattery et al. 1991). For example, at our two more northern sites, the winter dieback of seagrasses may impact clam growth seasonally to a greater extent, than that which more typically occurs in lower latitudes.

Pair-wise comparisons of first year growth between Massachusetts, New Jersey, and Gulf of Mexico (Florida and Alabama) sites revealed significant differences in all but the vegetated New Jersey versus Perdido Pass comparison. The observed pattern of generally increasing first-year growth with decreasing latitude was expected, and is consistent with patterns reported more than 30 years ago by Ansell (1968).

Significantly higher values of Ford's growth coefficient were found for all comparisons of the vegetated site in Massachusetts with the other vegetated sites (Table 2) and in the comparison of the Massachusetts versus the unvegetated New Jersey sites. We attribute these differences to slower, but steady lifelong growth in Massachusetts, with clams eventually attaining a larger final size, in contrast to the more rapid year 1 growth that quickly becomes asymptotic in New Jersey, Alabama, and Florida. This is consistent with a previous study of both *Mercenaria* species (Jones et al. 1990), which found rapid, but variable growth in Gulf of Mexico *M. campechiensis* populations that was often, but not always, greater than rates measured for Atlantic coast populations of *M. mercenaria*. Jones et al. (1990) also found life spans to be typically shorter in Florida than elsewhere. Based on our finding of rapid early growth, and the results of Jones et al. (1990), it appears that Gulf of Mexico *M. campechiensis* typically have high but variable growth rates and often shorter life spans than their Atlantic coast congener.

We found no significant differences in life-long growth at either the Massachusetts or New Jersey sites (Table 2) when comparing clams in seagrass with those in adjacent unvegetated areas, although as noted above, we could only consider growth in the first 10 years of life. This result agrees with those of Slattery et al. (1991), who found no significant differences in lifelong growth between vegetated and unvegetated habitats at the same study sites in Massachusetts and New Jersey. However, Slattery et al. (1991) found that life-long clam growth in North Carolina was greater in vegetation than adjacent sand, just as Peterson and colleagues had previously reported (Peterson et al. 1984, Peterson & Beal 1989, Irlandi & Peterson 1991, but see Nakaoka 2000 for short duration results).

It is unfortunate that we could not find clams in unvegetated areas at our Gulf of Mexico sites to better determine whether there are generally observable latitudinal trends in the effects of vegetation on clam growth, or whether North Carolina conditions are unique for *Mercenaria* (e.g., Peterson & Beal 1989, Nakaoka 2000). Later studies at the same sites (Coen et al., unpublished data) also did not find clams in sand and recorded similar low densities within grassbeds. Some studies involving experimental planting of juvenile clams in the northern Gulf of Mexico, which controlled for location in the grassbed, genetic differences, filter feeder abundance, and sublethal predation, have reported shifts in growth rates between vegetated and unvegetated substrates depending on season and year. For example, Coen and Heck (1991) found greatest growth at the same Alabama site in sand than at the grass edge or bed center, whereas Coen et al. (manuscript in preparation) found that growth effects varied with location within the bed, although the relative importance of different effects sometimes varied with season at the same two Alabama and Florida sites.

Correlations between the growth coefficient and first-year growth and the distance of clams relative to the grassbed edge were significant only at the Perdido Pass *Thalassia-Halodule* site and for first year growth only at the Massachusetts *Zostera* site (Table 3). As Irlandi and Peterson (1991) note, until recently these results would have been unexpected because the prevailing view has been that bivalve growth is positively correlated with flow rates or food flux (Belding 1912, Kerswill 1949, Haskin 1952, Pratt & Campbell 1956, Greene 1979, Hadley & Manzi 1984, Bricelj et al. 1984, Arnold et al. 1991, Bock & Miller 1994, Wildish & Kristmanson 1997, but see Irlandi & Peterson 1991, Judge et al. 1992, Lenihan et al. 1996), and slower current velocities with increasing distance into the seagrass bed should lead to reduced growth (e.g., Fonseca et al. 1982). However, Peterson et al. (1984), Irlandi and Peterson (1991), and Judge et al. (1993) have all indicated that food supply may actually be greater in vegetated areas primarily resulting from the availability of suspended benthic diatoms and epiphytes. The latter work, along with Coen and Heck (1991), and Coen et al. (manuscript in preparation), also evaluated position in the grass bed and its affect on growth. An additional explanation for variable growth between vegetated and adjacent unvegetated areas was suggested by Irlandi and Peterson (1991), who found differential growth on alternate edges of seagrass patches, possibly as a consequence of variation in sediment stability.

Because current velocity and direction were not measured, verification of whether distance to the grassbed edge as recorded corresponded to distance from the source of prevailing currents was not possible. However, it did not appear that currents flowed in a consistent pattern across the beds in Massachusetts, New Jersey, and Florida but rather varied greatly in their point of origin. The Perdido Pass site had the clearest directionality of currents and the "leading (flood tide) edge" of the bed was easily determined (Judge et al. 1992, 1993), perhaps helping to explain the significant relationship found there between growth and proximity to the grassbed edge (Table 3). In addition, any shifts in seagrass bed boundaries over a clam's lifetime, or over a significant portion of the growing season because of winter dieoffs, could also affect our one time distance estimates from the point of collection to the edge of the bed and weaken the calculated correlations. Given the numerous articles that discuss seagrass patch dynamics, this potential problem is likely (e.g., Irlandi 1997, Robbins & Bell 2000). Our previous work has also suggested that siphon nipping can significantly impact clam growth (e.g., Coen & Heck 1991, Coen et al., manuscript in preparation)

An additional factor whose importance is difficult to assess here or in previous studies is the impact that harvesting may have. Both the New Jersey and Massachusetts populations are subject to recreational harvesting, and commercial harvesting was observed at the New Jersey site. In contrast, there is no recreational or commercial harvesting at either of the Alabama or Florida sites, resulting in a large part from, very low natural densities. To the extent that harvesting is biased toward different-sized individuals or to the extent that desirable sized clams are found and collected in specific locations within the beds, results from harvested populations could bias our conclusions. For example, we typically observed, as have others, how aggregated hard clams often are, with similar age-classes within a high-density patch. In addition, harvesting changes the number of filter feeders and potential competitors, which is another variable of potential significance that could not be controlled.

CONCLUSIONS

Our results clearly showed significantly greater first-year, but not life-long, growth in sand than in seagrass in Massachusetts and New Jersey habitats. Therefore, whether one concludes that the presence of seagrass significantly affects clam growth at our study sites depended on clam age and the amount of time considered. As reported previously by others, we found strong evidence for greater first-year growth in *M. campechiensis*, but we also found higher life-long growth rates in our most northern *M. mercenaria* population, and we found little evidence that location (i.e., distance to nearest bed margin) within the seagrass bed was consistently related to either short or long-term growth rates.

Although we attempted to account for one potentially confounding factor, location within a seagrass bed, we were unable to control for siphon nipping, a factor that seems to produce significant effects on clam growth only some of the time (Coen & Heck 1991, Irlandi & Peterson 1991, and Coen et al., manuscript in preparation vs. Kamermans & Huitema 1994, Irlandi & Mehlich 1996, Irlandi 1996, and Nakaoka 2000), nor could we control for the effects of harvesting on filter feeder abundance. Given the complexity of factors that interact to affect clam growth rates over *Mercenaria*'s broad geographic range, and past conflicting results, it is clear that additional, extensive field experiments using the same design are still needed. At present, we are still unable to make accurate predictions about the effects of seagrasses on bivalve growth rates and related post-settlement survival.

ACKNOWLEDGMENTS

This work was supported in part by NSF (EPSCOR) Grant No. R11-8996152 to Kenneth L. Heck, Jr., and fellowship support for D. Marc Wilson was provided by the NOAA Office of Sea Grant, Department of Commerce, under Grant No. NA85AA-D-SGO05 (Project E/0-16), the Mississippi-Alabama Sea Grant Consortium, and the University of Alabama as well as the Mobil Foundation, Inc. and Shell Oil Company Foundation. The authors thank Drs. W. W. Schroeder, A. C. Benke, and M. Judge for their assistance with various drafts of this manuscript. Thanks are also extended to David Nadeau, Naomi Mitchell, and Rebecca Rolen for assistance in the field and in the laboratory, to Randy Schlude for her guidance and help with data processing and analysis, and to Lynn Bryant and Carolyn Wood for assistance with manuscript preparation. Special thanks are also extended to Lowell W. Fritz for his assistance in verifying annual growth bands on thin sections. This is Contribution #341 from the Dauphin Island Sea Lab and Contribution #492 from the Marine Resources Research Institute, SCDNR.

REPRODUCTION OF *CALLISTA CHIONE* L., 1758 (BIVALVIA: VENERIDAE) IN THE LITTORAL OF MÁLAGA (SOUTHERN SPAIN)

C. TIRADO,[1] C. SALAS,[1]* AND J. I. LÓPEZ[2]

[1]*Departamento Biología Animal, Facultad de Ciencias, Universidad de Málaga, E-29071- Málaga, Spain;* [2]*Delegación Provincial de Agricultura y Pesca, Avda, Aurora 47, E-29071- Málaga, Spain*

ABSTRACT The reproductive cycle of *Callista chione* Linnaeus, 1758 was studied using histology and changes in flesh dry weight, in the littoral of Málaga (southern Spain), from June 1999 to May 2000. Histologic study of the gonads showed a long reproductive period, with spawning throughout the year. Three peaks of spawning have been observed through histology as well as flesh dry weight variation. The first one lasts from February to March and is accompanied by the highest decrease of weight; the second one is in spring, with the highest percentage of population in spawning but with a lower decrease of weight, and the third one is in summer. The latter peak represents a new activation of the gonads from postactive stages, without passing through a resting period. The absence of a resting period in the reproductive cycle of the studied population could be influenced by the mild seawater temperatures and high levels of chlorophyll *a* (attributable to the occurrence of upwellings) in the littoral of Málaga. The decrease of the average size in the population of Málaga from 1981 (70 mm) to 1999–2000 (54 mm length), points out an overexploitation of this resource. The above data, together with the removal of the close of season since 1990 in Málaga province, make it necessary to regulate a close of season in this area. We propose a close of season from February to March, months during which there was the most intense release of gametes in the population.

KEY WORDS: *Callista chione*, histology, biomass, reproductive cycle, fishery

INTRODUCTION

Callista chione Linnaeus, 1758 is an Atlantic-Mediterranean species ranging in the Atlantic from the southwestern British Isles to Morocco, and also in the Canary, Madeira, and Azores islands (Tebble 1966, Poppe & Goto 1993), and in the Mediterranean. It lives in fine and clean sand, from low tide down to 180 m (Poppe & Goto 1993).

Most of the studies on this species regard growth (Hall et al. 1974, Cano 1981, Forster 1981, Valli et al. 1983–1984, Strada & Zocco 1985, Valli et al. 1994). Because *C. chione* is a commercial species, some studies in Mediterranean waters were conducted in relation with the monitoring of infections by protozoans (Bravo et al. 1990, Canestri-Trotti et al. 1998, Canestri-Trotti et al. 2000) and heavy metals (Belmonte & Grasso 1986, Valli et al. 1994). Others were related with the influence of the dredge design on the size of the individuals captured and on the damage caused to the associated macrofauna (Gaspar et al. 1999), and with the fishery of this species in the Gulf of Trieste (Italy) (Del Piero 1994). Some few studies have addressed physiologic aspects. Charles et al. (1999) analyzed the selective utilization of bacteria and microalgae by *C. chione*. Cano (1983) analyzed different indexes of condition over a year in Málaga.

Although *C. chione* is a target-species of local fisheries in the whole Mediterranean area, there are few studies on reproduction. Valli et al. (1983–1984) presented preliminary data on the reproduction of *C. chione* in the Gulf of Trieste (northern Adriatic) later completed in Valli et al. (1994). Nicotra and Zappata (1991) analyzed the ultrastructure of the mature sperm and spermatogenesis from an Italian population.

In southern Spain, *C. chione*, locally known as "concha fina," is a very popular shellfish with a considerable consumer market and an average of about 599 tons/year from 1985–1996, according to the data of regional authorities. Most of 90% of this amount was obtained and consumed in the littoral of Málaga. Moreover, there is an significant illegal market and a quantity of catches that could be of the same order of magnitude as the official catch, but is not taken into account by official statistics. The law in Andalucía (an autonomous region including eight southern provinces of Spain) rules that the fishing season for *C. chione* must be closed from 1 February to 30 September (order of Consejería de Agricultura y Pesca, November 12, 1984). However, the provincial delegations are authorized to change it within this interval; in the case of Málaga, the close of season has been removed since 1990. The latter decision has been justified by the absence of biologic studies on the reproductive cycle of the species in the area, together with the fact that Málaga is a tourist area, which implies greater demand for shellfish species during almost all year, particularly in summer.

The absence of previous studies on the reproductive cycle of *C. chione* in southern Spain together with the overexploitation of this resource because of the absence of close of season, led the regional authorities of fishery (Consejería de Agricultura y Pesca) to promote this research. This is part of a project on the reproductive cycles of the most important commercial bivalves of Andalucía supported by the Consejería de Agricultura y Pesca (Department of Fishery) and entrusted to D.A.P. enterprise (Tirado & de la Rúa 2000).

MATERIALS AND METHODS

A total of 3,882 specimens of *C. chione* were examined and measured for shell length, ranging from 23–89 mm. The samples were collected from June 1999 to May 2000, with monthly frequency from October to February and with fortnightly frequency in the other months. The specimens were captured using a dredge with a toothed aperture, teeth length of 26 cm, and 6.7 cm of mesh, usual among the fishermen of the area. The samples were taken in Fuengirola (36°28′N, 4°43′W) (Fig. 1), at 20 m depth, in a sandy bottom.

To evaluate the possible influence of environmental factors on the cycle, the temperature of the seawater at 20 m depth was measured. Samples of water (2 L) were taken from the bottom for

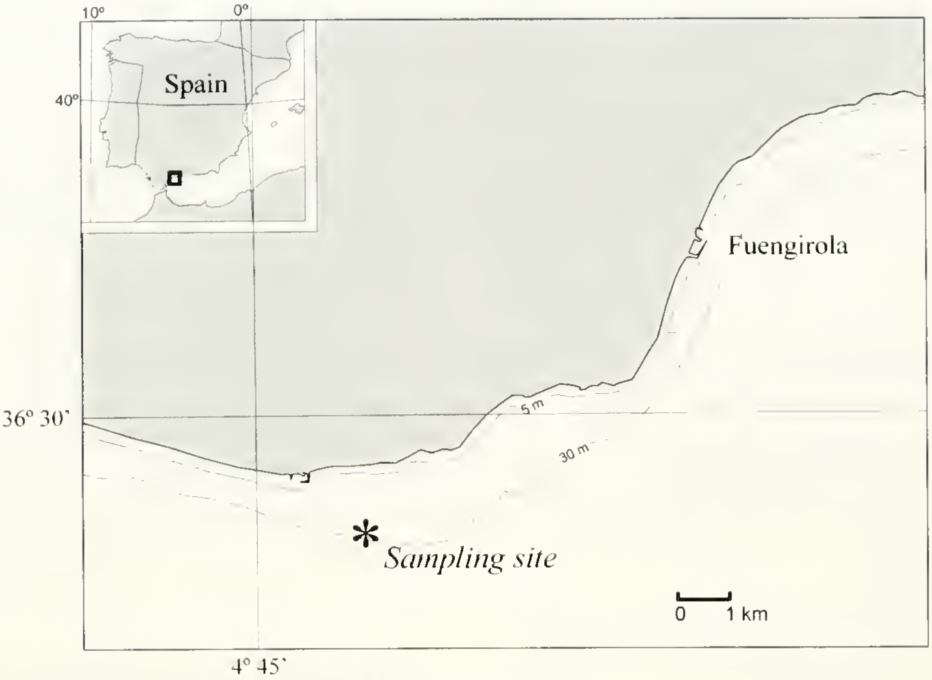

Figure 1. Sampling area.

determination of chlorophyll *a*. Pigment analyses were carried out by filtering the water through Whatman GF/C glass filters. The pigments of the retained cells were then extracted with acetone for twelve hours in cool, dark conditions, following the recommendations of Lorenzen and Jeffrey (1980). Concentrations of chlorophyll *a* were calculated using the trichromatic equations of Jeffrey and Humphrey (1975).

A total of 3,371 specimens were used for the analysis of flesh dry weight variation (about 200 specimens/sample). The length of every specimen was measured, and the soft parts were then pulled out of the shell, placed in the drying stove at 100°C for 24 h, and weighed to the nearest milligram. Two different indexes of condition were applied, the flesh dry weight/L^3 variation, and that proposed by Crosby and Gale (1990) Condition Index (CI) flesh dry weight × 1,000/volume of the internal cavity of the shell.

The regression of flesh dry weight on the length was calculated for each sample to estimate the variation in biomass of a standard individual, based on the logarithmic transformation of Ricker's function $W = aL^b$ (Ricker 1975), where W is the weight, L is the length, a is the ordinate at origin, and b is the slope.

The histologic study was performed on 511 specimens (usually 30 per sample), with shell length ranging between 23–85 mm. For the histologic processing, specimens were anesthetized with $MgCl_2$, fixed in 10% formaldehyde, embedded in paraffin, sectioned at 10 μm, and stained with hematoxylin of Carazzi and eosin, and a trichromic staining (V.O.F according to Gutiérrez 1967) of hematoxylin of Carazzi, light green, orange G, and acid fuchsine. The stages of gonad development were scored according to the scale proposed by De Villiers (1975) for *Donax serra* Röding 1798 in South Africa: cytolized, preactive, active, spawning, and postactive [the equivalent stages from Seed (1969) and Boyden (1971) are provided in Table 1].

The test of Kolmogorov–Smirnov and Kendal and Pearson's rank correlations included in the program SPSS 8.0, were used to check the distribution of the data. Cross correlation between both condition indexes and percentage of spawning with seawater temperature and chlorophyll *a* levels were calculated to assess the influence of the environmental factors on the reproductive cycle.

RESULTS

Sex Ratio

The sex of the specimens of *C. chione* cannot be distinguished macroscopically by the color of the gonads. Therefore, sex determination must be made microscopically. A total of 511 specimens were microscopically examined, but it was impossible to determine the sex of some individuals in several months. These samples were not considered for the sex ratio estimation. From the remain-

TABLE 1.

G = gonad.

ing 272 individuals, 125 (45.96%) were males and 147 (54.04%) females. The sex ratio for all them can be considered as 1:1 (χ^2 = 0.012, $P > 0.95$) (Fig. 2).

Sexual Cycle

Biomass Analysis

The variation of flesh dry weight/L^3 ratio during the annual cycle is shown in Figure 3. The mean values of both variables, flesh dry weight and size (L^3), were considered. The standard deviations were between 10.59–48.32%. A broad size range (Fig. 4) can be observed in the samples, which explains, in part, these differences. Also, a broad weight range can be observed in most of the samples (Fig. 5), which is related, in part, with the presence of different stages of development of the gonads.

From June to October, *C. chione* shows two decreases of the above ratio (Fig. 3), with a small increase in August. During the autumn months, there is another increase, followed by a decrease from January to March. During the spring, there is a continuous slight increase, before the first spring decrease.

The other index (CI) shows less pronounced increases and decreases (Fig. 6). Two decreases can be detected, one of them from late August to December and the other one from January to March.

To minimize the bias introduced by the somatic growth of individuals during the cycle and by the variation in the size of the specimens between successive samples, the variation of flesh dry weight was estimated for a standard individual of 54-mm length, taking into account the regression lines for every sample (Table 2). This size is close to the mean size of the population.

Figure 7 shows a major decrease in the flesh dry weight from January to March, although there are also drops from June to September. It is interesting to observe the difference in flesh dry weight between the first half of June 1999 and second half of May 2000, which could indicate that the sexual cycles are out of phase between contiguous years. In autumn, the values remain more or less stable. The two major increments of the flesh dry weight of the standard individual were registered between March and April and between the two samples of June.

Gametogenic Cycle

Data from the histologic study are presented in Table 3, which shows the total number of specimens analyzed and their development stages, according to the scale of De Villiers (1975). The studied population of *C. chione* shows continuous spawning throughout the year, with values higher than 30% of the population in 12 of the 17 samples examined. The whole population was spawning in May, while the lowest percentage of spawning (30% of the sample) was registered in the first half of September (Fig. 8).

If we considered the absence of any individual in cytolized or postactive stage, the main period of sexual activity lasts from February to June. In February, the presence of active individuals points to the beginning of the active period (Table 3). There is not, however, a true resting period because of the existence of spawning in the population at any time of the year. The regression of the gonads begins in June and July, with the occurrence of individuals in postactive stage, which were predominant from the second half of September to December, together with the presence of some individuals in cytolized stage.

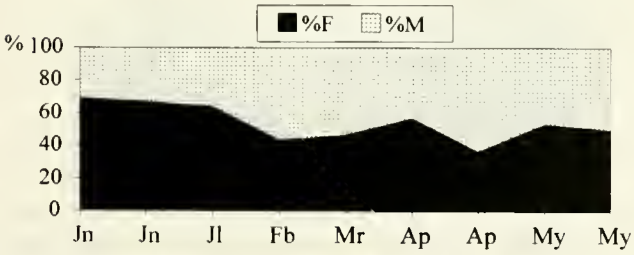

Figure 2. Relative frequency (%) of sexes during the year of study.

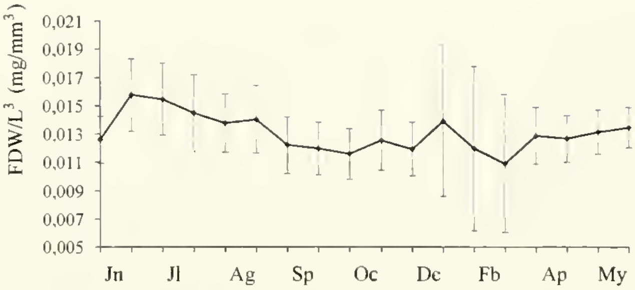

Figure 3. Flesh dry weight (FDW)/Length (L^3) ratio throughout the year of study. Bars show standard deviation.

The gametogenic cycle is asynchrononic in the population, which is evidenced by the presence of at least two developmental stages in nearly all the samples. An asynchrony is also detected in the individuals attributable to the coexistence of areas with different stages in the same gonad.

Several cohorts of ovocytes can be detected throughout the year, together with the direct step from postactive to active stage, without a previous cytolized and preactive phases.

Environmental Factors

The maximum temperature (Fig. 9) was registered in the second half of August (22°C) and the minimum (13.8°C) in January. The maximum of chlorophyll *a* (Fig. 9) levels occurs in the first half of August 2000 and the second peak in the first half of May 1999. Between these extremes, we observed several minor peaks, at the end of summer (first half of September), in autumn (October), and at the end of winter (March).

Coefficients of correlation of Pearson were estimated between temperature and FDW/L^3 and temperature and CI, because the variables showed a normal distribution (according to the test of Kolmogorov–Smirnov). However, between percentage of population in spawning and temperature, chlorophyll *a* levels, and the different condition indexes, the coefficients of correlation of Ken-

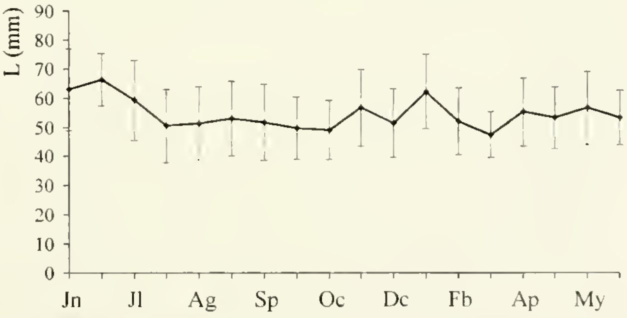

Figure 4. Monthly average length (L) throughout the year of study. Bars show standard deviation.

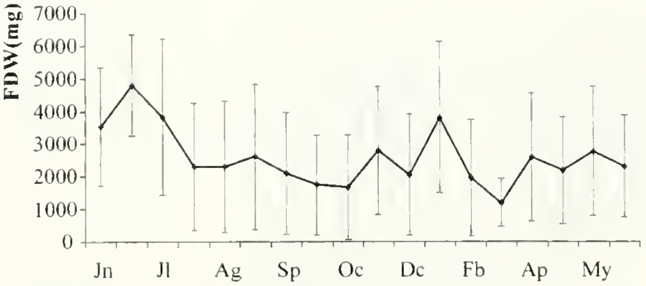

Figure 5. Monthly average flesh dry weight (FDW) throughout the year of study. Bars show standard deviation.

dal were estimated, because the percentage of spawning dataset showed a non-normal distribution.

These coefficients of correlation have been calculated simultaneously and with one and two months of delay. The temperature was directly correlated, with one month of delay, with CI ($r = 0.629$, $P < 0.05$). In the same way, the temperature was also directly correlated, with a delay of two months, with the FDW/L^3 of the population ($r = 0.573$, $P < 0.05$). A significant coefficient of Kendal's correlation has been obtained between the temperature and the flesh dry weight of the standard individual, with a month of delay ($\tau = 0.394$, $P < 0.05$). No other correlation was significant.

DISCUSSION

Sex Ratio

Callista chione is a species that does not show sexual dimorphism, and the sex ratio is 1:1. Our data regarding the sex ratio are similar to those of Valli et al. (1994) in the Gulf of Trieste, who obtained percentages of 46.25% males and 53.75% females. Also, we have not found any hermaphrodites in the studied population.

Reproductive Cycle

According to the histologic data, *C. chione* from the littoral of Málaga had individuals in spawning stage throughout the year (Fig. 8), while in the Gulf of Trieste (northern Adriactic) the spawning extends from February to September (Valli et al. 1983–1984), or from March to September (Valli et al. 1994). This difference is easily explained by the much lower winter seawater temperatures (in the order of 6°C) registered in the Northern Adriatic. However, the high amount of phytoplankton and zooplankton of the Gulf of Trieste resulted in the absence of a resting period, because the individuals remain in a preactive stage during autumn and winter months (Valli et al. 1994). In Málaga, most of the individuals remained in postactive and spawning stages during the autumn and winter months (Fig. 8). Cano (1983) studied different condition index in *C. chione* from the littoral of Málaga, detecting only one strong decrease of dry weight (between January and February of 1981). Other species from southern Spain, such as *D. trunculus*, *D. venustus*, and *D. semistriatus*, show very long spawning periods, but in these species, there was at least one month without spawning (Tirado & Salas 1998, Tirado & Salas 1999).

LM = average length; R^2 = coefficient of determination; R = coefficient of correlation; *n* = number of observations; W (L = 54 mm) = weight of a standard individual of 54-mm long.

The mild seawater temperature (between 13.8°C–23°C) and the high concentration of phytoplankton (because of the presence of upwellings) in the littoral of Málaga (Fig. 9) would favor, probably, a long reproductive cycle and the absence of a resting period. The temperature is the most influential factor, according to the coefficients of correlation. It is correlated with weight increments, a consequence of development of the gonads.

According to the hypotheses of most authors, the gamete release seems to be controlled by such physical environmental variables as changes in temperature, salinity, or photoperiod (Sastry 1979 and references therein). An alternative hypothesis is that phytoplankton induces spawning (Ruiz et al. 1992). Starr et al.

C = cytolized; Pr = preactive; EA = early active; A = active; S = spawning; Ps = postactive; *n* = number of observations.

(1990) showed that blooms of phytoplankton should be sufficient to induce spawning in mussels as well as in urchins. The spawning of *Crassostrea gigas* in El Grove (Galicia, northwestern Spain), with water temperature below 18°C, was correlated with phytoplankton bloom (Ruiz et al. 1992).

Although the chlorophyll *a* levels in the littoral of Málaga during this study did not show significant correlation with any analyzed index or variable, the coincidence of some decreases in weight (Figs. 3, 6) with peaks of chlorophyll *a* (Fig. 9), seem to indicate some influence.

The data of biomass showed three important decreases: between January–March, second half of August–September, and June and July (Figs. 3, 7). The latter was not reflected in CI (Fig. 6). The first drop is coincident with the start of activation of the gonad and with the increase of percentage of population in spawning (Fig. 8). At the first half of summer, there are high percentages of individuals in postactive stage, which begin a new gonadal activation in the second half of July. This direct step from postactive to active stages without a previous cytolized phase, has been found in *Donax trunculus* (L. 1758) from the littoral of Málaga (Tirado & Salas 1998) and seem to be related with the presence of peaks of chlorophyll *a* in this area (Fig. 9). Ansell (1961) reports that in the population of *Chamelea striatula* from Kame Bay (Millport), the ovary passes directly from the spawning condition to an early stage of development, because of the development of young ovocytes in the ovary before the end of spawning.

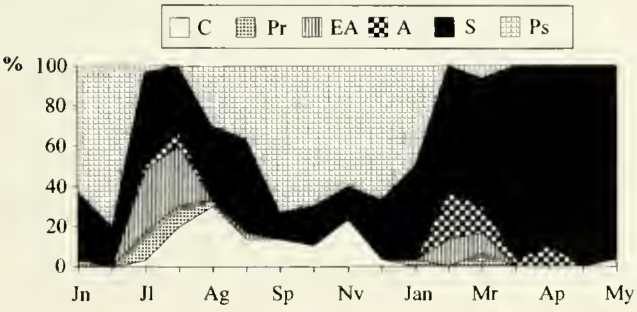

Figure 8. Relative frequency of different stages of development of the gonads in *C. chione*.

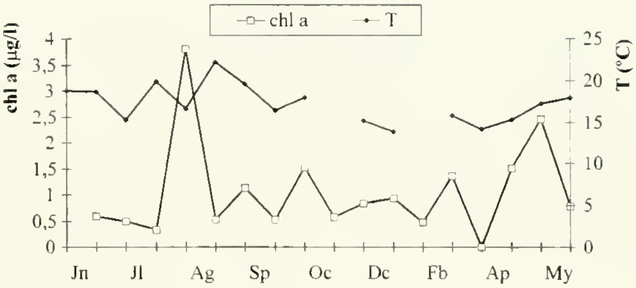

Figure 9. Seawater temperatures and changes in concentration of chlorophyll *a* in seawater throughout the year of study.

Also, according to the data for the standard individual (Fig. 7), the main decrease of flesh dry weight was registered in winter; whereas, those of summer seem to be less intense. Although the percentage of the population spawning in spring was the highest of the year (Fig. 8), the resulting decrease of biomass was less than in winter or summer (Fig. 3). This is consequence of the fact that the emissions from winter were more intense, with implication of the entire gonad; whereas, in spring and summer, there were only partial spawnings. The latter, together with the coexistence of different stages of development in the same gonad, could indicate that the spring/summer spawning is at least the second one for an individual during the cycle. In the field, it is difficult to know if a particular individual has more than two spawnings by reproductive cycle. In the laboratory, the venerid *Chamelea striatula* spawns repeatedly at intervals throughout the spawning season (Ansell 1961). In the littoral of Málaga, two spawning periods per individual were detected in *D. trunculus*; whereas, in other such species as *Donax venustus* and *Donax semistriatus*, only one spawning per individual and cycle was observed (Tirado & Salas 1998, Tirado & Salas 1999).

The asynchronic gametogenic cycle in the population is reflected by the high standard deviations of the flesh dry weights (Fig. 5), the existence of several cohorts of ovocytes, and the coexistence of several stages of development in the same gonad. The coexistence of different stages has been found in many bivalves from temperate areas, among them, *Chamelea striatula* (Ansell 1961), *Donax serra* (De Villiers 1975), *Tapes rhomboides* (Morvan & Ansell 1988), *D. trunculus* (Tirado & Salas 1998), *D. venustus* and *D. semistriatus* (Tirado & Salas 1999).

Although the total of captures of *C. chione* in the littoral of Andalucía is high (about an average of 599 tons/year from 1985–1996), in the last few years (from which statistical data have been published) this volume has decreased to values of about 188 tons in 1995, or about 259 tons in 1996. On the other hand, the average length of the Málaga population has decreased from about 70 mm in 1979–1981 (Cano 1981) to 54 mm in 2000 (present study). All these points indicate an overexploitation of this resource. Moreover, the recorded data on growth indicate a slow growth of *C. chione*. Hall et al. (1974) registered a growth of 2 mm by year in the Gulf of Trieste; Forster (1981) suggested that a specimen of Plymouth reaches 9 cm in 40 y. The above data make it an urgent necessity to provide a close of season that, according to the data of this study, must be February–March period during which there was the most intense release of gametes in the studied population.

ACKNOWLEDGMENTS

The authors thank David López, Daniel Gómez, and Mª José García-Patiño for helping in the laboratory process. This study is part of a project supported by the Junta de Andalucía, (Department of Fishery). Mª Dolores Atienza, general manager of the Department of Fishery is thanked for her trust in our work and the permission to publish. We are grateful to Manuel Castañon (Provincial Manager of Fishery) for his encouragement in this research. The project was entrusted to D.A.P. enterprise, which is thanked for the use of facilities given for realization of the work and publication of the results. We are grateful to Ildefonso Márquez and Manuel Aguilar for their management and the facilities given for the development of this research. Eva García is thanked for her help with the references.

ABSTRACT Olive oil gelatin-acacia microcapsules (GAMs) enriched with deuterium-labeled arachidonic acid (*AA) were prepared and fed to *Venerupis pullastra* larvae. In a first experiment, larvae were either starved or fed these microcapsules (*AA-GAM) for 12 h. The *AA-GAM–fed larvae incorporated *AA and oleic acid (OA) in their neutral and polar lipids. The incorporation yield was around 5% for *AA in neutral and polar lipids and 2% and 1% for OA in neutral and polar lipids, respectively. In a second experiment, larvae were fed for 7 days with a mixed algal diet supplemented with or without *AA-GAM. The microcapsules were ingested and digested without any harmful effect on larvae. OA was incorporated preferentially in neutral lipids whereas *AA was equally distributed in neutral and polar lipids. The incorporation yield was higher in the second experiment probably in relation to the presence of algae. However, the incorporation rate of both tracer fatty acids decreased with time in both lipid classes. *AA dropped form 16–2% in both neutral and polar lipids and OA decreased more rapidly in polar (16–3%) than in neutral lipids (33–15%). These changes in the incorporation yield could correspond to the growth slowing down at the approach of the metamorphosis or to a saturation in the levels of fatty acids because the percentage of natural arachidonic acid stayed stable in neutral lipids or tended to decrease in polar lipids. The easy fabrication and use of GAM associated to the direct measurement of a deuterated fatty acid by gas chromatography is a promising tool for studying lipid metabolism in mollusks.

KEY WORDS: clam, *Venerupis pullastra*, nutrition, microcapsules, larva, fatty acids

INTRODUCTION

The production of living microalgae (LMA) as food for the larvae and spat of bivalves in commercial hatcheries accounts for approximately 30% of operating costs (Coutteau & Sorgeloos 1992). Because of the high cost and unpredictability of the algal culture, the development of artificial diets for bivalve mollusks was attempted by several investigators (Jones et al. 1974). Microcapsules of the cross-linked protein-walled type were used to examine aspects of protein (Langdon & Siegfried 1984) and carbohydrate (Kreeger et al. 1996) metabolism of bivalves and gelatin-acacia microcapsules were investigated in lipid nutrition (Langdon & Waldock 1981, Chu et al. 1987, Numaguchi & Nell 1991, Knauer & Southgate 1997a, 1997b). Some potential alternatives, such as dried microalgae, microalgal pastes, lipid emulsions, and microcapsulated or yeast-based artificial diets (for revision, see Coutteau & Sorgeloos 1993; Robert & Trintignac 1997), have shown promising results. The total or partial substitution of microalgae by artificial particles has been proposed, where, ideally, nutritional requirements of bivalves should be satisfied using diets whose composition could be precisely controlled. The gelatin-acacia microcapsules (GAMs) are not a suitable vehicle to deliver complete artificial diets to the larvae of bivalves because only water-insoluble nutrients can be encapsulated using this method. However, they may be a useful tool in studies addressing aspects of the lipid nutrition in addition to being a supplement for mixed microalgal diets poor in some essential fatty acids. GAM could be a useful supplement if sufficient quantities of LMA were unavailable to feed spat (Numaguchi & Nell 1991). GAMs are simple to produce, relatively easy to use, and can be prepared rapidly on demand. However, the potential of GAM as a substitute for LMA under large-scale culture conditions must still be assessed (Knauer & Southgate 1997a). A number of studies have been undertaken to prove GAM ingestion, digestion, and assimilation and have shown that GAM were readily digested by bivalves (Chu et al. 1982, Southgate 1988) and that the lipids supplied were assimilated with high efficiency (Knauer & Southgate 1997c). The data generated in such studies will facilitate the further development of suitable artificial diets for the larvae of marine bivalves. The knowledge of the nutritional requirements of the larvae of cultured bivalves is necessary to improve the efficiency of algal diets used in hatcheries and to design convenient artificial diets. Previous studies pointed out the energetic role of lipids during the larval development of mollusks (Holland 1978), as well as the changes in the composition of the polyunsaturated fatty acids (PUFAs) occurring in neutral and polar lipids during embryogenesis. This nutritional transition suggests that a metabolic control takes place in developing larvae (Marty et al. 1992). It is probable that this control results from a selective incorporation of dietary fatty acids by acyltransferases, indicating a preferential incorporation of long-chain PUFA, especially the 22:6(n-3) in the case of the larval development of *Pecten maximus* (Marty et al. 1992). This study was proposed as an attempt to confirm the assimilation of the fatty acids incorporated in GAM and their bioconversion in endogenous fatty acids of neutral and polar lipids in the larvae of marine bivalves. The data generated could indicate whether GAM could serve as a tool in studies of lipid metabolism in marine bivalves as well as demonstrate their use as a nutritional supplement in mixed microalgal–microcapsulated diets.

MATERIALS AND METHODS

Chemicals

Lipid Standards and Reagents

Deuterium-labeled arachidonic acid (FA-503 arachidonic acid-5, 6, 8, 9, 11, 12, 14, 15-d_8) was obtained from BIOMOL Research Laboratory, Inc. (Plymouth Meeting, PA). Identification and quantification were based on standard fatty acid methyl ester mixture (Sigma-Aldrich, Chemical Spain). Internal standard, Tricosanoic acid (C23:0), was purchased from Nu-Chek-Prep. Butylated hydroxytoluene (BHT) and fluorescein isothiocyanate (FITC) were supplied by Sigma Chemical Co. (St. Louis, MO) and sodium hydrogen bicarbonate was from Merck (Darmstadt, Germany).

Solvents

Hexane, chloroform, and methanol were high-performance liquid chromatography (HPLC) grade from Merck (Darmstadt, Germany). Boron trifluoride (10%, w/w) in methanol (BF_3) was obtained from Supelco (Bellefonte, PA).

Fabrication of GAMs

Two different sets of GAM were fabricated following a modified method described by Rodriguez et al. (1992).

FITC-GAM

GAMs were prepared with 500 μL of cod liver oil and by later addition of FITC. Briefly, 500 μL of cod liver oil was homogenized with antioxidant BHT (5%, w/v). Then, 500 mL of cod liver oil plus antioxidant was emulsified with a 1:1 mixture of a 2% (w/v) solution of gelatin and a 2% (w/v) solution of acacia, which had been made up separately in distilled water. The emulsion was stirred in a Virtis Tempest IQ^2 blade homogenator programmed at 30,000 rpm for 2 min The pH of the mixture was reduced until the coacervation pH (4.3), by the drop-by-drop addition of dilute HCl. The mixture was stirred for 40 min and pH was then raised to 9.3 by the addition of dilute NaOH. The resulting GAM suspension was poured into 500 mL of cold distilled water and kept in a refrigerator for 2 h. Previously a solution of FITC 0.25% (w/v) in 100 mM sodium hydrogen bicarbonate ($NaHCO_3$) was prepared. Two milliliters of stock microcapsules were incubated at 4°C for 12 h with 0.5 mL of FITC solution diluted with 2.5 mL of 100 mM $NaHCO_3$ solution. The mean diameter of FITC-GAM was 4.0 ± 1.0 μm (n = 100). Two milliliters of FITC-GAM was used to feed a batch of 23-day-old *Venerupis pullastra* larvae and subsequently were observed under fluorescent microscopy.

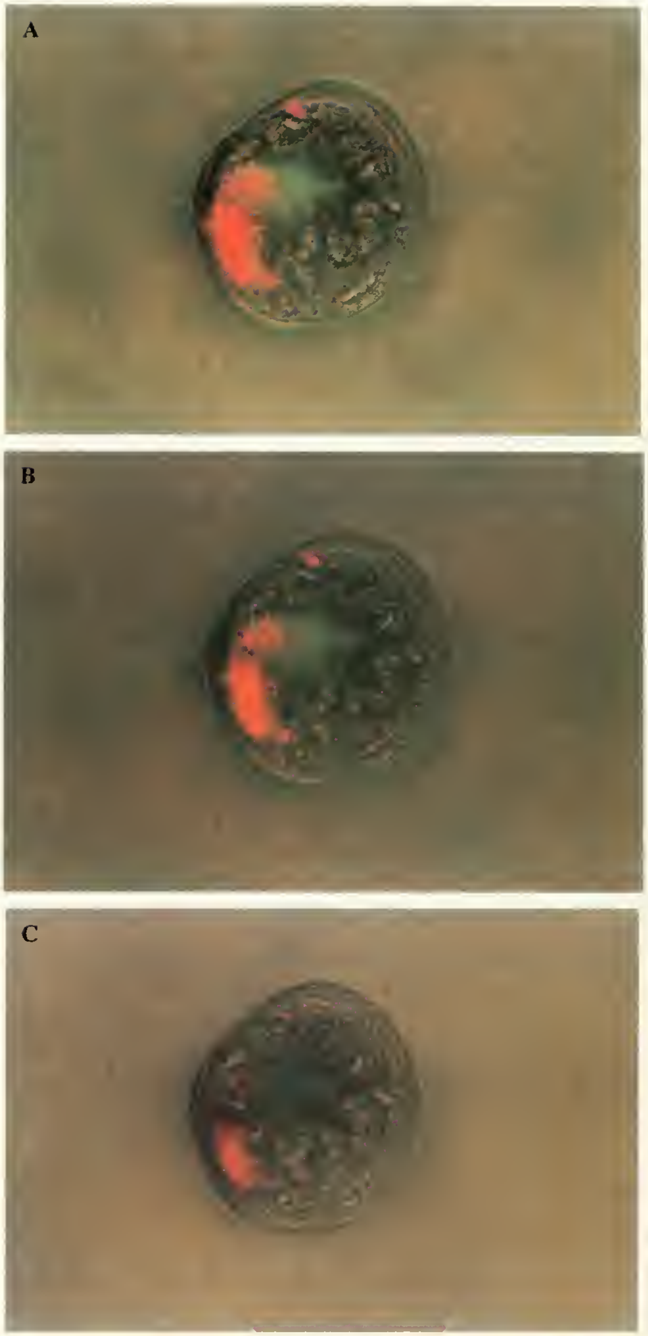

Figure 2. Digestion of microcapsules throughout a period of 20 min. Sequence A–C shows the disappearance of the yellow fluorescence inside a larva of *V. pullastra*. (Author: J.-L. Rodríguez)

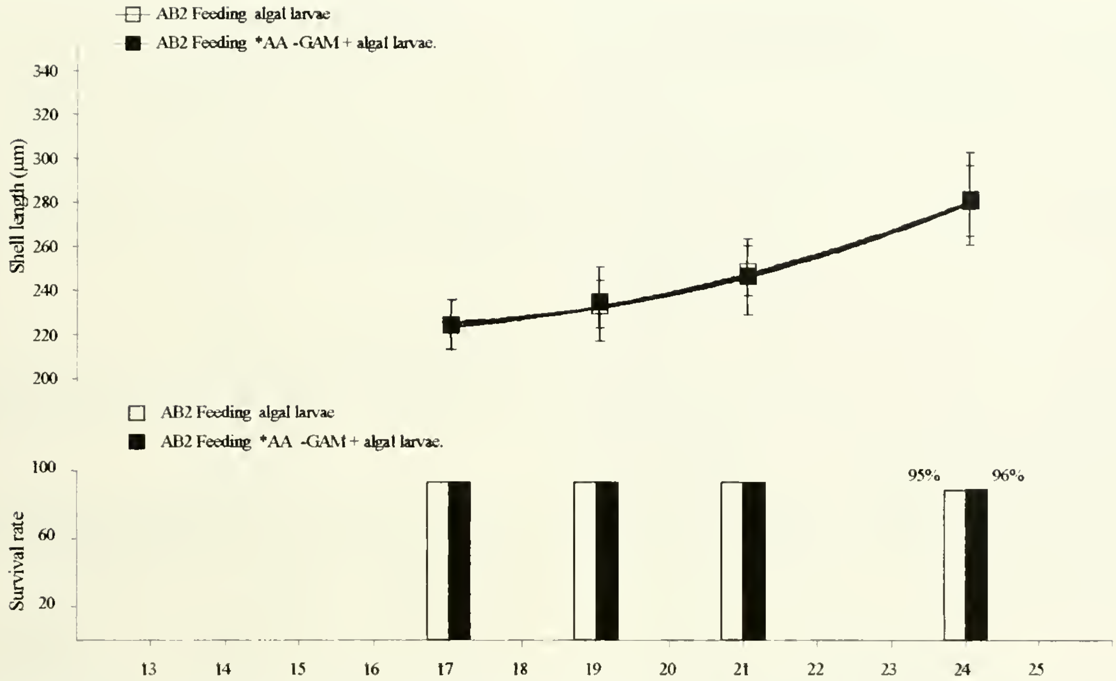

Figure 3. Shell length (µm) of the AB2 batch, fed with algal (open squares) and *AA-GAM + algal (solid squares). Survival rate (%) of the same batch fed with algal (open bars) and with *AA-GAM + algal (solid bars). Results are expressed in µm (%); Mean ±, SD, n = 100.

Deuterated Arachidonic Acid (*AA)-GAM

GAMs were prepared with olive oil supplemented with deuterium-labeled arachidonic acid. Briefly, 50 µL of olive oil was homogenized with 5 mg of deuterium-labeled arachidonic acid and antioxidant BHT (5%, w/v). Deuterated *AA-GAM was obtained following the method previously described. The resulting GAM suspension was poured into 250 mL of cold distilled water and held in a refrigerator for 2 h. The mean diameter of *AA-GAM was 3.5 ± 0.9 µm (n = 100) and the stock suspension of GAM was kept at 4°C and shaken daily.

Feeding Experiments

A population of *V. pullastra* D-larvae termed AB2 was selected by its good growth and survival rates and distributed in 500-L tanks at a density of 5 larvae·mL^{-1}. Larvae were fed daily with a microalgal mixture of *Pavlova lutheri* (Droop), *Isochrysis aff. galbana* Green (clone T-iso; Tahiti *Isochrysis*), *Skeletonema costatum* (Greville), and *Chaetoceros calcitrans* (Tanako) at a density of 15/15/15/15 cells·µL^{-1}.

Experiment 1

Larvae 14 days of age from the AB2 culture were collected and transferred at the same density into two 6-L flasks for a 24-h experiment. One batch was starved whereas the other was fed with 60 µcap·µl^{-1} *AA-GAM. *AA-GAM–fed larvae had seawater renewed 12 h after feeding, and no food was supplied then. Twelve hours later, both fed and starved larvae were collected on a 45-µm mesh.

Experiment 2

Larvae 17 days of age from the same AB2 culture were distributed in two 150-L tanks at a density of 4 larvae·mL^{-1} and fed daily with two different diets for 7 days, either a microalgal diet of *P. lutheri*, *I. aff. galbana*, *S. costatum*, *C. calcitrans*, and *Tetraselmis suecica* (Butcher) at a density of 20/20/15/15/10 cells·µL^{-1} or a diet consisting of the same microalgal mixture supplemented with 5 µcap·µL^{-1} *AA-GAM.

Samples for Fatty Acid Analyses

Larvae from the 24-h experience were collected as indicated above. Larvae from the 7-day experience that were 18, 19, 21, and 24 days of age were collected 4 h after feeding on a 45-µm mesh (n = 1).

All larval samples were crushed and stored in a $CHCl_3$–MeOH mixture (2:1, v/v) under nitrogen at −30°C until fatty acid analysis could be performed. Samples of microalgal mixture (n = 3) and microcapsules (n = 3) were filtered on GF/F (Whatman) glass fiber filters and stored similar to larvae before analysis.

Fatty Acid Analysis

The separation of the polar and neutral lipids was performed by micro-column liquid chromatography as described by Marty et al. (1992). Total lipids were evaporated to dryness and dissolved three times using 500 µL of chloroform/methanol (98:2). Neutral and polar lipids were separated on a silica gel 6% (w/w) hydrated microcolumn (30 × 5 mm) using chloroform/methanol (98:2) and methanol successively as eluting solvents. The fractions were collected under nitrogen in screw-capped flasks containing a known amount of 23:0 as internal standard for quantitative determinations. Fatty acid composition and quantification of polar and neutral lipids were determined using gas chromatography (CG), after purification of fatty acid methyl esters (FAMEs) by HPLC. FAMEs from the neutral and polar lipid fractions were transesterified with 10% (w/w) BF_3 in methanol (Metcalfe and Schmitz 1961) for 10 min at 100°C. After cooling, FAMEs were extracted with hexane. The organic phase was evaporated under nitrogen and dissolved in chloroform/methanol (98:2) for purification by HPLC (Hennion et al. 1983, modified). FAMEs present in each lipid fraction were injected in a CG System HP6890 series equipped with a split/splitless injector, a flame ionization detector, and a DBWAX capillary column (30 m × 0.25 mm ID; 0.2-μm film thickness). The carrier gas was H_2, at an initial pressure of 80 kPa. The oven was programmed to stay at the initial temperature of 60°C for 2 min, rise from 60 to 160°C at a rate of 50°C/min, stay for 2 min and from 160 to 170°C at 1.5°C/min, then 170–185°C at 2°C/min, next 185–240°C at 3°C/min, and finally remain at 240°C for 10 min. Injector and detector temperatures were 230°C and 250°C, respectively. The flow rates of compressed air, hydrogen and make up gas (nitrogen) were 300, 30, and 20 $mL \cdot min^{-1}$, respectively. Fatty acids were identified by comparison of their retention times with those of standards. The C:X (n-Y) notation was adopted, where C was the number of carbons, X the number of double bonds, and n-Y the position of the first double bond from the terminal methyl group.

ng/larvae			45.446	5.613

Values in bold are, respectively, the major fatty acid present in olive oil [18:1 (n-9)] and the deuterium-labeled arachidonic acid added [20:4 (n-6)-d8]. Results are expressed in percentages (%) and in ng supplied to each larva (ng/larva) in experiment 1. Values are means ± SD (n = 3).

Incorporation yield was calculated using the following equation:

$$\text{incorporation } \%: \frac{(\text{AA–GAM}_n\text{–algae}_n)\text{ng FA} \times \text{larvae}^{-1}}{(\text{AA–GAM–algae})\text{ ng dietary FA} \times \text{larvae}^{-1}} \times 100$$

where the numerator is equal to fatty acid difference between larvae fed the microcapsules + algae and larvae starved or fed the algae and the denominator is the fatty acid supplied by the microcapsules.

RESULTS

Ingestion and Digestion of Microcapsules

After feeding on FITC-GAM for 4 h, larvae were observed under fluorescent microscopy. The ingestion of FITC-GAM was

Values in bold are, respectively, the major fatty acid present in olive oil [18:1 (n-9)] and the deuterium-labeled arachidonic acid added [20:4 (n-6)-d8]. Data are means ± SD (n = 3).

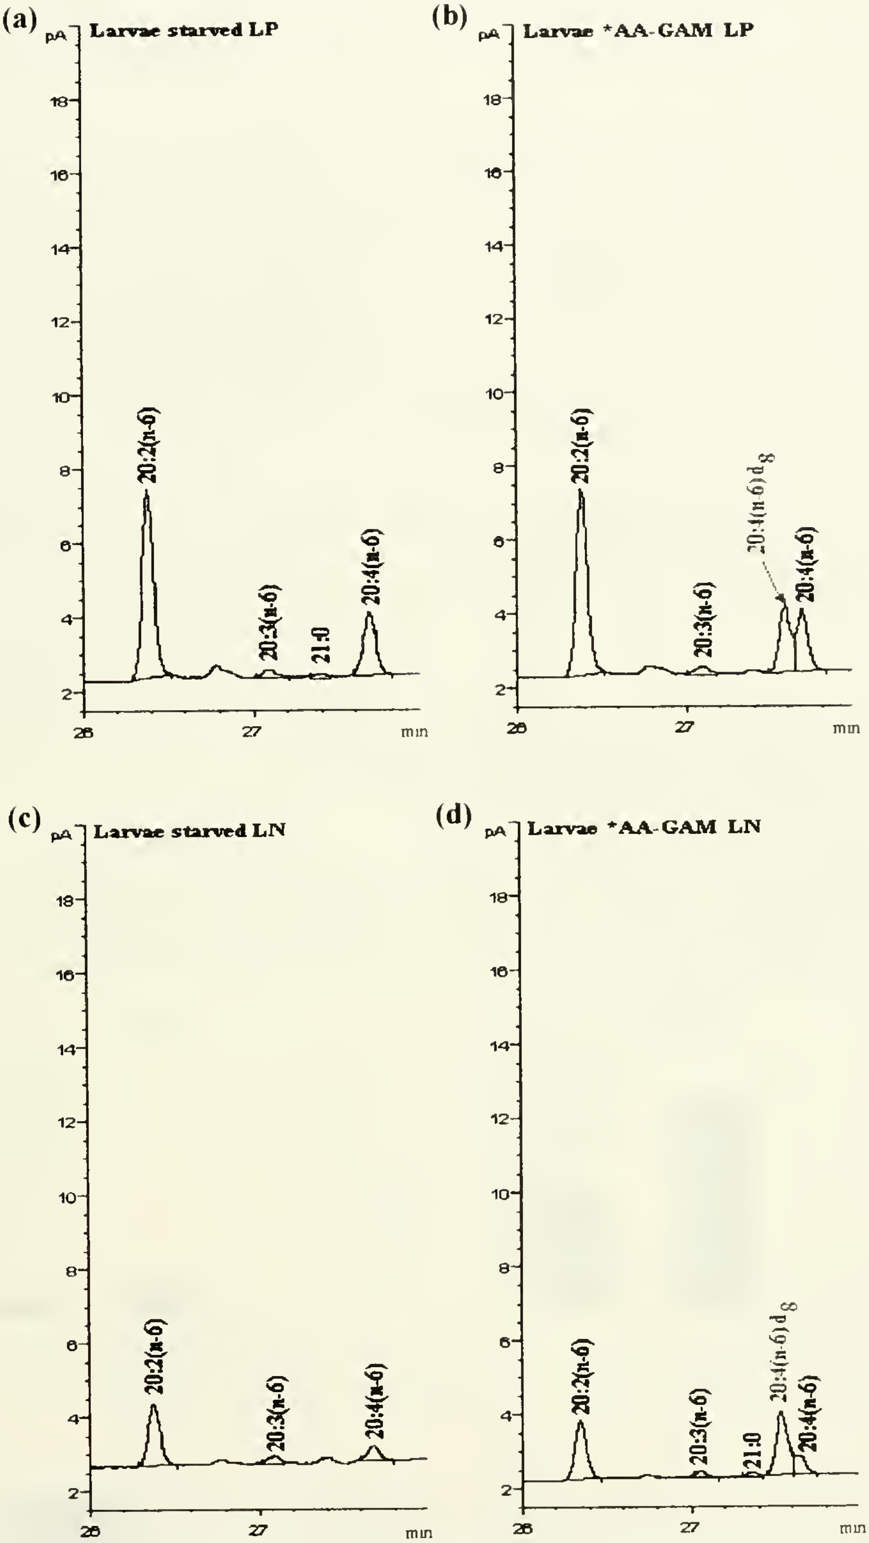

Figure 4. Partial chromatograms of FAMEs prepared from larvae of *V. pullastra* corresponding to retention time between 26 and 28 min. Figure shows the incorporation of 20:4(n-6)d_8 in polar (b) and neutral (d) lipids in larvae fed with microcapsules with respect to starved larvae (a) and (c).

proved by an accumulation of yellow fluorescence (the dye color) inside the larva (Fig. 1). A sequence of photographs taken throughout a period of 20 min showed the decrease of yellow fluorescence in the digestive gland of a larva fed with microcapsules, due to digestion (Fig. 2).

Growth and Survival

Throughout the 7-day experiment, larvae were sampled with the daily water renewal to determine growth (anterior-posterior shell length) and survival. Growth and survival were similar for the batches fed either microalgae supplemented with microcapsules or the microalgal diet (Fig. 3).

*Fatty Acid Composition of *AA-GAM*

The mean fatty acid compositions of *AA-GAM are listed in Table 1. The fatty acid profile of microcapsules fabricated with 50 μL of olive oil and 5 mg of deuterated arachidonic acid 20:4(n-6)-d_8 showed a predominance of 18:1(n-9) (65.7 ± 0.31%), 16:0 (10.8 ± 0.07%), 18:2(n-6) (10.1 ± 0.33%), and 20:4(n-6)-d_8 (5.4 ± 0.24%). A single microcapsule contained 3.8 pg total fatty acids.

Dietary Fatty Acid Supply

The diet consisting of *AA-GAM exclusively was used in the 24-h experiment and supplied 60 GAM·μL^{-1}, which corresponded to 29.86 ng·larva^{-1} for the 18:1(n-9) and 2.43 ng·larva^{-1} for 20:4(n-6)-d_8 (Table 1).

Table 2 shows the fatty acid composition of the two different diets (algal diet and *AA-GAM–supplemented diet) used in the 7-day experiment. The first supplied 7.77 ng·larva^{-1} of 18:1(n-9) and the second supplied 10.71 ng·larva^{-1} of 18:1(n-9) and 0.24 ng·larva^{-1} of 20:4(n-6)-d_8.

Assimilation of Microcapsules in the 24-h Experiment

The FID-CG analysis allowed the separation and the quantification of deuterated *AA in polar and neutral lipis of larvae (Fig. 4). Larvae fed *AA-GAM exclusively showed incorporation of 20:4(n-6)-d_8 in polar and neutral lipid fractions (0.10 and 0.12 ng·larva^{-1}, respectively). The amount of the major fatty acid in olive oil, 18:1(n-9), also increased in neutral and polar lipids when compared with that of starved larvae: 1.08 ng·larva^{-1} versus 0.33 in neutral lipids and 0.66 ng·larva^{-1} versus 0.28 in polar lipids (Fig. 5a). Incorporation yield percentages of 20:4(n-6)-d_8 were nearly equal in both lipid fractions (4.30% for polar lipids and 4.80% for neutral lipids), whereas for 18:1(n-9) they were 2.53% and 1.31% for neutral and polar lipids, respectively (Fig. 5b).

Fatty Acid Composition of Larvae Fed with Different Diets

Larvae fed with *AA-GAM–supplemented diet showed an increase in the incorporation of the two monitored fatty acids [20:4(n-6)d_8 and 18:1(n-9)] in both lipid fractions when compared with those fed the microalgal diet (Fig. 6).

With regard to 20:4(n-6)-d_8, incorporation profiles were similar in both lipid fractions throughout the 7-day experiment (16.3% for neutral lipids and 16.8% for polar lipids between days of culture 18 and 19). Assimilation percentages were higher during the early days of the culture and decreased in the late days from 16.3 to 5.6% in neutral lipids and from 16.7 to 6.1% in polar lipids (Fig. 7).

Incorporation of 18:1(n-9) was better in neutral than in polar lipids. Throughout the experience, the incorporation yield decreased in both fractions, although the phenomenon was more pronounced in polar lipids (Fig. 7).

The lipid content, the percentage of neutral and polar fractions and the fatty acid composition of larvae were similar in both 7-day experiments (Table 3). Supplementation with microcapsules did not affect the incorporation of the essential PUFA provided by microalgae. However, larvae fed microcapsules appeared to have a higher FAME content if compared with larvae fed microalgae only.

DISCUSSION

Numerous artificial particles have been tested to supplement or partially replace the living algal diet for mollusks. These included yeast (Epifanio 1979), flour (Albentosa et al. 1999), dried algae

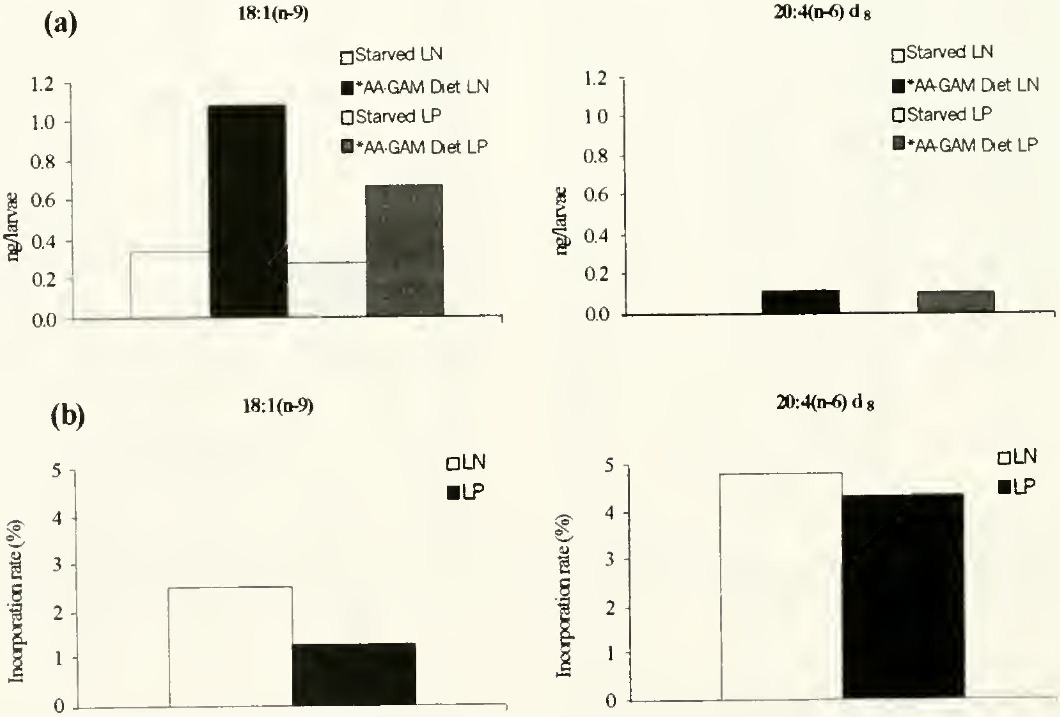

Figure 5. Bar diagrams showing the incorporation of both traced fatty acids in experiment 1. In (a), comparison of their contents as neutral and polar lipids in starved larvae and those fed *AA-GAM, expressed in ng/larva. In (b), incorporation rates as neutral and polar lipids in larvae fed *AA-GAM, expressed in percentages. In all cases, n = 1.

(Laing & Millican 1991), emulsions, and liposomes (Coutteau et al. 1996, Caers et al. 1999, 2000, Soudant et al. 2000). Development of particles like gelatin-acacia spraybeads (Buchal & Langdon 1998) was mostly devoted to identifying essential molecules and to understanding their metabolism. In this article, we report data on the incorporation efficiency of the essential PUFA AA using GAM. Because mollusks contain AA in their corporal fatty acid, we incorporated deuterated AA (*AA), which can be easily discerned from the natural one by direct GC analysis, allowing a good estimation of its assimilation. This straightforward methodology avoids the use of radioactivity and its additional measurements. Indeed, it may be applied to other essential fatty acids. Although deuterated metabolites of AA were not detected in our study, their determination is possible with this methodology.

Small-scale GAM fabrication is easy and suitable for experimental studies on metabolism, in particular for lipids, which are easily encapsulated. Olive oil was chosen as lipidic support because its composition is very simple. Oleic acid (OA) represents 65% of the total fatty acid present in olive oil. Moreover, olive oil lacks most very long-chain PUFA that are essential for marine mollusks (Trider & Castell 1980, Enright et al. 1986, Soudant et al. 1996). Therefore, the fatty acids from this oil would not interfere

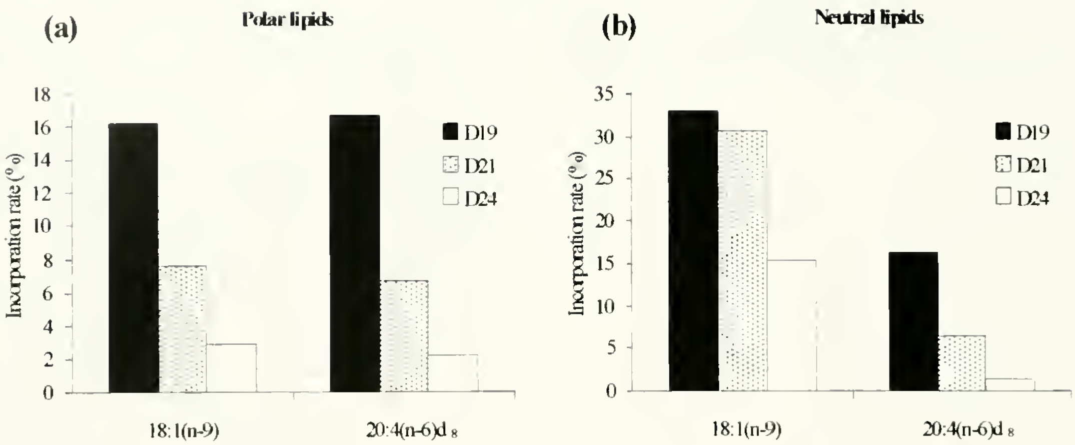

Figure 7. Incorporation rates of 18:1(n-9) and 20:4(n-6)d_8 in polar and neutral lipids of larvae fed with *AA-GAM + microalgae. (n = 1).

with larval development. The size of GAM obtained was compatible with mollusks' ingestion and they did not show harmful effect on larvae. On short-term observation (7 days), no deleterious effect was observed on growth. Growth and larval mortality were similar both in the presence and in the absence of GAM in our experiments.

The gradual disappearance of the fluorescent labeling observed in the digestive system of larvae (Fig. 2) was probably due to the digestion and assimilation of microcapsules by the larvae. In previous studies, Sudan red-stained GAM faded in the stomach and digestive diverticula of *Crassostrea virginica* larvae during the early 24 h after feeding, and disappeared completely within 48 h (Chu et al. 1982). Also, *Crassostrea gigas* spat were demonstrated to assimilate ^{14}C-labeled lipids incorporated in corn oil GAM (Knauer & Southgate 1997c).

Digestion and assimilation were eventually confirmed by tracing the deuterated arachidonic acid supplied by *AA-GAM. Results showed that *V. pullastra* larvae were able to incorporate this fatty acid into their endogenous lipids as both neutral and polar fatty acids. The results obtained in both 24-h and 7-day experiments established incorporation of 20:4(n-6)-d_8, which could only be detected in larvae if *AA-GAM had been assimilated. However, larvae fed with *AA-GAM also showed an increase of OA, the other tracer fatty acid of GAM, in both neutral and polar lipids when compared with those starved or fed algae.

Contrary to neutral lipids, which may correspond to transient storage of ingested food, polar lipids are mostly located in membranes. Thus, incorporation in polar lipids better indicates true assimilation in both experiments. These results confirmed ingestion, digestion and assimilation of the fatty acids furnished by GAM.

With regard to the second experiment, it is noteworthy that essential PUFAs supplied by algae were found to be accumulated at the same level in neutral and polar lipids of larvae regardless of the diet. This shows that the incorporation of PUFA provided by the algae was not modified by the microcapsules, probably meaning that the amount of algae filtered by the larvae did not decrease by the presence of GAM. During the time course of this experiment, the polar lipid content increased continuously, which resulted in a regular growth. The neutral lipid content showed a clear drop between day 18 and 19 and then tended to reach a maximum at day 21. This may suggest the existence of a high energetic demand at this point of the larval development.

Fatty acid incorporation rates were observed to vary depending

[a] Data are expressed as mean for three analysis.

on the fatty acid supplied, as well as on the stage of larval development. OA incorporation was mainly observed in neutral lipids whereas *AA was equally distributed in neutral and polar lipids. OA is a monounsaturated fatty acid, thought to play a mainly energetic role in the reserve lipid fraction. The equal distribution of *AA in polar and neutral lipids is more surprising since, like vertebrates, some marine bivalves (*Pecten maximus*) have shown a preferential incorporation of AA in polar lipids, especially in the phosphatidyl inositol class (Soudant et al. 1998). However in *V. pullastra*, the natural AA supplied by the food was found at a similar level in neutral and polar lipids of 24-day-old larvae. The preferential location of arachidonic acid in polar lipids may be species specific. Furthermore, it is known that the fatty acid composition of diet is largely reflected in neutral lipid composition and to a lesser extent in polar lipids of animals. This is because polar lipids are regulated according to the needs of structural maintenance of membranes. Fatty acids supplied by the food would be first incorporated in neutral lipids and then, depending on the needs, transferred to polar lipids. The percentage of AA in polar lipids of mollusks fed with algae tended to decrease in the course of the experiment, perhaps because those needs were satisfied by the algae or, maybe, the needs of the larvae just dropped naturally with development. This would also explain the weak incorporation of *AA in polar lipids in the case of larvae fed with *AA-GAM.

OA and *AA incorporation in both neutral and polar lipids was high during the early days of the experience but decreased toward the later days. These data coincided with the fact that the amount of neutral and polar lipids per larva leveled off beween days 21 and 24, corresponding to a decrease in growth rate and lower biosynthesis needs. Moreover, the decrease of the natural AA percentage in polar fatty acids and its stable percentage in neutral lipids may explain the decrease of incorporation of tracer fatty acids from GAM. It is during this period that larvae are ready to undergo metamorphosis and change into spat.

Comparing the values of incorporation of both fatty acids supplied by GAM between experiments, we observed that incorporation increased in the second experiment. This may be explained by the presence of microalgae in the second experiment, which facilitated the retention of artificial GAM either by favoring the filtration or by adhesion of GAM on algae. Similar results were obtained by Knauer and Southgate (1997b), who reported an efficiency increase from 57–80% when *Dunaliella* was added to GAM.

An appropriate dosage of lipid components incorporated in microcapsules could be useful as a nutritional supplement for lipid-poor microalgal diets. The possibility of using microcapsules containing labeled fatty acids also allows us to trace the molecules and to study their distribution and possible metabolic conversion to structural and reserve lipids. This would contribute to go deeply into both energetic and structural needs for fatty acids in molluskan larval development, and to design nutritionally optimal lipidic diets to obtain spat of good quality.

ENHANCING HARD CLAM (*MERCENARIA* SPP.) POPULATION DENSITY IN THE INDIAN RIVER LAGOON, FLORIDA: A COMPARISON OF STRATEGIES TO MAINTAIN THE COMMERCIAL FISHERY

WILLIAM S. ARNOLD,[1]* DAN C. MARELLI,[1] MELANIE PARKER,[1] PHILIP HOFFMAN,[1] MARC FRISCHER,[2] AND JOHN SCARPA[3]

Pierce, Florida, 34946

ABSTRACT Hard clams of the genus *Mercenaria* support an important commercial fishery in the Indian River Lagoon on the east central coast of Florida. The fishery is relatively young but has proven to be quite sporadic, with two periods of exceptional landings (mid-1980s and mid-1990s) bounded by periods of almost complete fishery collapse. In response to a request from commercial fishery participants, three strategies for enhancing the abundance of harvestable hard clams in the lagoon were compared. The first strategy involved harvesting adult clams from a low-density population and transplanting them at high density in a concentrated area, in an effort to increase fertilization efficiency and thereby maximize reproductive success. That approach does not appear to be viable in the Indian River Lagoon because mortality of transplanted clams approached 100% and because Indian River hard clams display a remarkably high incidence (>80%) of gonadal neoplasia. Neoplasia reduces the life span of Indian River hard clams relative to their northern congeners and probably reduces fecundity of those clams that do survive. The second strategy involved seeding juvenile clams at very high densities (843–7165 m^{-2} depending upon seed size), again with the intent of maximizing fertilization efficiency but with the additional goal of maximizing residual reproductive value. Various planting treatments were tested in an effort to minimize mortality of seed clams, but losses were still high (generally >70%), and the yield did not appear to justify the cost. The final strategy involved spawning large numbers of hard clams in the laboratory, fertilizing the resultant eggs, and immediately releasing the larvae at a predetermined location in the lagoon. Large numbers of larvae did appear to survive the 8-day larval life span, but it remains to be seen whether those larvae will translate into harvestable hard clams. In any event, enhancement of hard clam populations appears to be feasible only when the density of naturally occurring clams is so low that reproductive viability is compromised. Otherwise, natural reproductive potential will swamp any artificial efforts at population enhancement.

KEY WORDS: *Mercenaria*, Indian River Lagoon, population enhancement, spawner transplant, seeding, larval release

INTRODUCTION

Hard clams of the genus *Mercenaria* support an economically and culturally important fishery in the Indian River Lagoon on the east central coast of Florida. This is a relatively new fishery that developed in the early 1980s (Fig. 1) and was originally centered near the town of Grant in southern Brevard County (Fig. 2). The clam population that supported the original fishery collapsed in the late 1980s, probably in response to decreased salinity caused by the release of St. Johns River floodwaters into the Indian River basin (Barile and Rathjen 1986). Another substantial set of hard clams was detected in the northern Indian River Lagoon, between Cocoa and Titusville, in the early 1990s. That population supported a profitable and productive fishery throughout the mid-1990s (Fig. 1), but the population again collapsed and again the proximate cause appeared to be decreased salinity resulting from above-average rainfall in the watershed. As of the year 2001, the fishery for naturally occurring hard clams in the Indian River Lagoon has remained depressed, although a small number of fishermen continue to pursue the few clams that are available.

The Indian River is a shallow, narrow, bar-built lagoonal system that stretches from Oak Hill to Stuart along the central Atlantic coast of Florida. For our study, we considered only that area of the Indian River Lagoon (IRL) system that is located north of Sebastian Inlet (Fig. 2) and that is composed of the Indian River (IR), the Banana River (BR), and Newfound Harbor. Prehistorically, the IRL was a single continuous basin, and the IR and BR were connected to the south at Dragon Point and to the north through Banana Creek. In recent years, development and bridge construction have resulted in the subdivision of the IRL into a series of basins that are defined by the causeways that span the lagoons. Water exchange between basins is restricted to the areas under the bridges that connect the causeway dikes (Evink & Morgan 1982). Additionally, the pattern of water exchange between the IR and BR has been altered in the last 40 years. Development of the Kennedy Space Center essentially severed the Banana Creek connection between the two lagoons (McCall et al. 1970), and construction of the Canaveral Barge Canal in the early 1960s (Yusof 1987) created a new connection south of Banana Creek.

Reported clam landings from the Indian River Lagoon for the past 20 years suggest that at least under certain conditions, the capacity for production of hard clams in the lagoon is substantial. However, no single basin of the lagoon appears to be consistently productive. Instead, an individual basin may support a dense clam population for several years, after which the population collapses and remains depressed until another major set of juvenile clams occurs either in that basin or in another area of the lagoon. Environmental conditions can vary substantially among basins, creating a potential mismatch between successful spawning events (Hesselman et al. 1989) and the environmental conditions necessary to support the survival and development of that spawn.

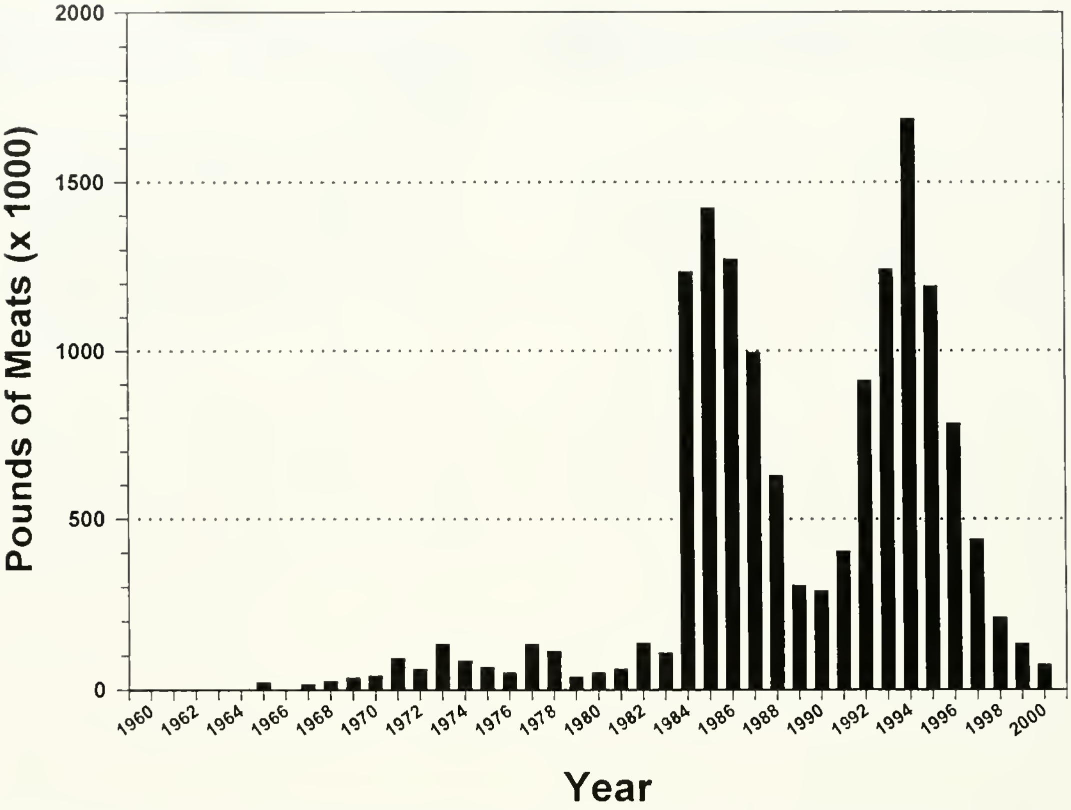

Figure 1. Commercial hard clam (*Mercenaria* spp.) landings from Brevard County, Florida. Data from 1960 through 1985 were provided by the National Marine Fisheries Service. Data from 1986 onward were provided by the Florida Marine Research Institute's Fisheries Dependent Monitoring Program.

Salinity is one of the key environmental variables affecting the success of hard clam populations. Adult clams are not well adapted to salinities below 20 practical salinity units (p.s.u.), and embryonic and juvenile clams tend to be even more sensitive (Castagna & Chanley 1973). In the Indian River Lagoon, salinity may range from less than 15 p.s.u. (Barile & Rathjen 1986) to more than 40 p.s.u. (Young & Young 1977) with extreme conditions causing even those limits to be exceeded. Furthermore, the salinity conditions in one basin of the lagoon may be ideal for clams, whereas those in an adjacent basin may be inimical to clam survival (e.g., McCall et al. 1970, Barile & Rathjen 1986). Thus, a suitable match between environment and biology may be very localized, which is why a commercially successful hard clam spawn is a rare event in the Indian River Lagoon.

The diversity of water quality conditions in the lagoon may create difficulties for the natural clam populations occupying the IRL, but it also may create an opportunity for enhancement of those populations. Although it is difficult to predict when conditions will be suitable for reproduction, recruitment, growth, and survival of hard clams, gross conditions (e.g., salinity, dissolved oxygen, turbidity; Arnold et al. 2000) can be evaluated from the results of frequent water-quality monitoring activities. Such monitoring programs are ongoing in the lagoon, under the auspices of the St. Johns River Water Management District and the Florida Department of Agriculture and Consumer Services. These programs make it possible to identify water-quality conditions suitable for clams, although it is not possible to ensure that those conditions will occur at a time and place coincident with a spawning event.

A variety of options are available to increase clam abundance in the lagoon. Here, we compare three approaches that might be effectively applied in the IRL. The spawner transplant approach involves harvesting mature animals and subsequently replanting them in an area that is either more suitable for survival and reproduction or that will allow larvae to disperse to such areas (e.g., Carter et al. 1984). Generally, animals are harvested from a relatively large area (square kilometers) and replanted into a much smaller area (square meters), thus concentrating potential spawners in an effort to increase reproductive success. This strategy has been used in efforts to increase the population abundance of a variety of organisms, including hard clams (e.g., Carter et al. 1984), bay scallops (Peterson et al. 1996), and abalone (Tegner 1992). The rationale for the seeding approach is similar to that for the spawner transplant approach: the animals are concentrated in a small area in the hope of increasing reproductive success. Seeding differs from spawner transplants in that young, generally prereproductive animals are planted (e.g., Marelli & Arnold 1996). Thus, the residual reproductive value (Ricklefs 1979) of the planted animals should be maximized relative to a spawner transplant operation that may include a variety of age classes of the target organism. Seeding as an enhancement strategy also has a rich history in the population-enhancement literature, including numerous efforts involving hard clams (e.g., Castagna & Kraeuter 1977, Walker 1985, Peterson et al. 1995, Marelli & Arnold 1996). The third approach discussed herein involves the release of recently fertilized eggs directly into the lagoon, thereby circumventing the spawning process entirely. This strategy has been tested with abalone (Preece et al. 1997, Shepherd et al. 2000), but to our knowledge had not been tested with marine bivalves such as the hard clam prior to our study.

Figure 2. Indian River Lagoon, Florida, showing locations of spawner transplant and seeding studies in the Indian River and Banana River lagoons. Star indicates site where adult clams were collected for the spawner transplant study. Closed circles indicate sites of the spawner transplant and seeding studies in the Indian River lagoon and of the spawner transplant study in the Banana River lagoon.

MATERIALS AND METHODS

Spawner Transplants

In the spawner transplant component of this study, we harvested adult clams of a variety of sizes, marked the shells with spray paint to allow for later identification, and then replanted the clams into an area closed to shellfish harvest. The objective of this project was to concentrate reproductively mature clams to maximize the number of successfully fertilized eggs (Levitan 1995). During October 1998 (fall relay), we used professional clam harvesters to gather 5,000 clams from an area of the Indian River

Lagoon north of Titusville (Fig. 2). The harvested clams were returned to shore, where the shells were allowed to dry for several hours and then labeled with yellow spray paint for later identification. The labeled clams were split into two groups of 2,500; the following day, the clams in one group were planted at a site in the Indian River and clams in the other group at a site in the Banana River. To transplant the clams, we poured them over the side of our research vessel as we traversed the extent of a 100-m^2 study plot demarcated at each corner by a crab trap float. Similar transplants were conducted during January (winter relay; blue paint), April (spring relay; green paint), and August 1999 (summer relay; red paint) to assess the best season for conducting transplant operations.

Sampling of the adult relay plots was conducted 2 wk after each relay event and again 3, 6, 9, and 12 mo after each relay event (Tables 1 and 2), thus allowing us to assess reproductive status and mortality during each season of the year for each transplant date. To sample, we thoroughly hand-raked the contents of 20 randomly selected 0.25-m^2 quadrants within each plot, returned all recovered hard clams to the research vessel for identification and counting, and subsampled 15 randomly selected clams from each plot (2-wk samples excepted) for later reproductive analysis. The location of each sample quadrant was marked with a PVC stake to ensure that plots were not resampled. Note that the Indian River spawner transplant plots could not be effectively sampled after the passage of Hurricane Irene in October 1999 because the sample plots were destroyed by that storm. The Banana River spawner transplant plots appeared to be unaffected.

Clam samples for reproductive analysis were processed according to the following procedures. Live animals were returned to the laboratory, where the gonad was excised from each animal and stored for 24 hours in a solution of 5% formaldehyde in seawater. Large gonads were removed from the fixative solution after about four hours, lacerated to ensure penetration of the fixative, and returned to the fixative for the remaining 20 hours. Afterwards, the gonads were thoroughly rinsed in tap water to remove fixative, dehydrated through a series of alcohol concentrations, and infiltrated with JB-4 mounting plastic. Two 3.5-μm sections, separated from each other by at least 50 μm, were then cut from each embedded gonad using a diamond blade microtome and the sections mounted on labeled glass slides. Mounted sections were stained with hematoxylin and eosin, covered, and stored for later microscopic analysis.

Gonad sections were examined under a binocular light microscope and each sample assigned a qualitative ranking of gonad developmental stage as described by Arnold et al. (1997) and summarized in Table 3. This ranking scheme is a composite of gonad development ranking schemes previously used by Loosanoff (1937), Jaramillo et al. (1993), and Walker and Heffernan (1994), with the addition of categories for early spawning and for unreadable samples.

Seeding

On October 13, 1998, we planted three size-classes of seed clams under four protective conditions at our study site in the Indian River lagoon. Seed clams were obtained from the Division of Aquaculture, Harbor Branch Oceanographic Institution, Ft. Pierce, Florida. Seed size-classes were 2 mm mean shell height (SH = maximum distance from umbo to ventral margin), 8 mm mean SH, and 16 mm mean SH. Protective conditions included no cover, oyster shell cover, plastic mesh netting cover, and a combination of oyster shell and plastic mesh netting cover. Oyster shell was purchased from a commercial aggregate company and averaged approximately 5 cm in maximum shell diameter. Fifteen-millimeter mesh plastic netting (Vexar) was purchased from a commercial aquaculture supply company. Two replicates of each size-class by protective-cover combination were deployed, for a total of 24 treatments, each of which was assigned to an individual 1-m^2 plot. We planted approximately 7,165 2 mm SH clams (27 g wet weight), 2,340 8 mm SH clams (259 g wet weight), or 843 16 mm SH clams (119 g wet weight) in each plot, which equated to approximately $30 of clam seed per plot. Before planting, all clams in the 2 and 8 mm SH size-classes were marked with tetracycline (Marelli & Arnold 1996), and the valves of all clams in the 16 mm SH size-class were painted so that we could identify them later.

On October 27 and 28, 1998, we used a hydraulic suction dredge (e.g., Peterson et al. 1983) to sample five 0.0278-m^2 cores from each replicate plot to determine initial planting mortality. On November 11 and 12, 1999, we again collected five 0.0278-m^2 suction dredge samples from each replicate plot to estimate mortality and shell growth after one year. The location of each replicate was determined by using a string grid to ensure that the replicates within each plot did not overlap.

Larval Release

The larval release study was designed to determine the feasibility of directly introducing fertilized clam eggs into the lagoon and allowing them to grow and disperse as a natural population. This approach to clam population enhancement allows us to circumvent the expensive and labor-intensive process of growing clams in the laboratory, while still ensuring that large numbers of fertilized eggs will be available in the natural environment. Larval release also allows us to target areas of the lagoon that are suitable for the growth and survival of clams and to rapidly respond to changing conditions. However, to be able to determine the success

TABLE 1.

Planting and sampling dates for the hard clam (*Mercenaria* spp.) spawner transplant study in the Indian River lagoon.

Season	Plant Date	2-wk Sample	3-mo Sample	6-mo Sample	9-mo Sample	12-mo Sample
Fall	10/28/98 (100)	11/9/98 (127)	2/3/99 (107)	4/28/99 (114)	8/10/99 (57)	10/26/99 (17)
Winter	1/27/99 (100)	2/3/99 (59)	4/28/99 (238)	8/10/99 (53)	10/26/99 (18)	N/A (N/A)
Spring	4/20/99 (100)	4/28/99 (180)	8/10/99 (131)	10/26/99 (38)	N/A (N/A)	N/A (N/A)
Summer	8/3/99 (121)	8/10/99 (171)	10/26/99 (6)	N/A (N/A)	N/A (N/A)	N/A (N/A)

Numbers in parentheses indicate sample size of hard clams collected on that date. Note that on each initial seasonal sampling date, clams were randomly sampled from all of those harvested, whereas on later dates sample size reflects the number of clams actually collected from each study plot.

TABLE 2.

Planting and sampling dates for the hard clam (*Mercenaria* spp.) spawner transplant study in the Banana River lagoon.

Season	Plant Date	2-wk Sample	3-mo Sample	6-mo Sample	9-mo Sample	12-mo Sample
Fall	10/28/98 (100)	11/9/98 (73)	2/3/99 (73)	4/28/99 (96)	8/11/99 (97)	10/25/99 (3)
Winter	1/27/99 (100)	2/3/99 (200)	4/28/99 (144)	8/11/99 (91)	10/25/99 (16)	1/25/00 (2)
Spring	4/20/99 (100)	4/28/99 (161)	8/11/99 (87)	10/25/99 (31)	1/25/00 (10)	4/25/00 (1)
Summer	8/3/99 (121)	8/11/99 (229)	10/25/99 (20)	1/25/00 (7)	4/25/00 (9)	8/16/00 (2)

Numbers in parentheses indicate sample size of hard clams collected on that date. Note that on each initial seasonal sampling date, clams were randomly sampled from all of those harvested, whereas on later dates sample size reflects the number of clams actually collected from each study plot.

of this enhancement strategy, it is necessary to be able to track and sample the animals during the planktonic phase of their life.

Spawning

The larval release strategy requires the production of large numbers of viable hard clam embryos that can be successfully transported to and released at the site targeted for enhancement. Adult hard clams were collected from various areas of the Indian River Lagoon on several dates during 1999. The clams were transported to a holding area at Harbor Branch Oceanographic Institution, where they were conditioned in preparation for spawning. Conditioning consisted of holding the clams for several months in a small lagoon on the Harbor Branch campus. On the day before spawning, the clams were transferred from the holding lagoon to a refrigerated storage area and held overnight. On the following day, the clams were removed from the storage area, placed in equally spaced rows on each of three spawning tables, and submerged in approximately 10–15 cm of 28 p.s.u. seawater. During the next six hours, the clams were exposed to cycles of cool and warm water and induced to spawn. As each individual clam initiated spawning, the sex of the animal was identified and the clam was removed from the table and isolated in containers with other clams in small groups of males or females. The clams continued to spawn within the containers, and the resultant eggs were pooled and concentrated on a 35-μm-mesh sieve and exposed to a sperm concentration adequate to ensure fertilization of all eggs. Total egg production and fertilization success were determined microscopically, after which the developing embryos were transferred to 20 L aquarium bags and transported to the study site for immediate release.

TABLE 3.

Gonad staging scheme for female hard clams (*Mercenaria* spp.) collected from the Indian River Lagoon, including female clams transplanted to study sites in the Indian River and Banana River lagoons and sampled during various times of the year, and from their undisturbed conspecifics.

Reproductive Status	Description of Gonadal Tissue	Numerical Stage
No Data	Tissue unreadable	0
Inactive	Gonad tissue undifferentiated	1
Developing	Tissue differentiated, eggs present	2
Ripe	Tissue full of eggs	3
Early spawning	Eggs being shed, but follicles still full in appearance	3.5
Spawning	Many eggs shed, follicles appear partially empty	4
Spent	Follicles nearly empty	5

Larval Tracking

Hard clam embryos were transported from the spawning facilities at Harbor Branch to our study site in the Banana River lagoon and released at 2030 EDT on May 16, 2001, at a site approximately 1.75 m deep. Water temperature at the site was 28°C and salinity was 22 p.s.u., whereas the temperature of the water in which the larvae were transported was 25.8°C and the salinity was 27.7 p.s.u. Before larval release, five subsurface drifters (Davis 1985, Hitchcock & Arnold, unpublished data) were deployed in a box-and-one pattern (one drifter at each corner of a 10 m × 10 m box, with a single drifter in the center of the box), and their initial positions were recorded using a differential Global Positioning System. Then, at a depth of approximately 0.5 m, the clam larvae were gently poured from the bags into the center of the drifter array. Gradual mixing between the transport water and the lagoonal water was allowed in an attempt to minimize osmotic shock.

During daylight hours on May 16, we collected thirteen 200 L water samples from the targeted release area to determine the prerelease concentration of hard clam larvae in the study basin. On May 17 and 23, 2000, post-release water samples were collected to determine the distribution and density of the larval mass. For the May 17 sampling, when the larval mass was predicted to be relatively concentrated, the subsurface drifters were visually located and the position of each drifter recorded. Sample collection locations for hard clam larvae were then selected based upon the location and distribution of the subsurface drifters. On May 23, after diffusive processes were anticipated to have spread the larvae throughout the study basin, samples were collected at each of 23 grid nodes equally distributed throughout the basin.

On each sampling date, samples of hard clam larvae were obtained by using a Jabsco Model 34600-0000 diaphragm pump to collect volumes of water that ranged in size from 100–400 L, depending upon the projected density of larvae. Water was pumped through a 150-μm-mesh sieve to remove large objects, and then captured in a 63-μm-mesh plankton net. Each resultant sample was removed from the cod end of the plankton net and carefully distilled to a volume of approximately 30 mL, then transferred to a 50-mL screw-cap centrifuge tube, labeled, and placed on ice until arrival at the laboratory, where it was frozen at approximately −5°C. Within one month of the completion of the study, all of the frozen water samples were sent to the Skidaway Institute of Oceanography for determination of the presence and abundance of clam larvae. Samples were analyzed for the presence of hard clam larvae using a previously developed genetic probe that is both quantitative and *Mercenaria*-specific (e.g., Frischer et al. 2000).

RESULTS

Spawner Transplants

At both the Indian River and Banana River study sites, the mortality of relayed hard clams was severe, particularly during the summer and early fall of 1999. Also at both sites, considerable loss of clams from the plots was associated with the initial transplant. At each site, on all dates, we transplanted an average of 25 clams m^{-2}, and within 2 wk the densities for all plantings had decreased by more than 50% (Fig. 3). After the initial transplant event and the loss of clams associated with that event, clam densities stabilized throughout the winter, spring, and early summer at both sites (Fig. 3). During late summer and early fall of 1999, the clams experienced substantial mortality, possibly as a result of decreased salinity associated with Hurricane Irene (Fig. 4). As noted previously, that storm destroyed our study plots in the Indian River. It also appears to have had a severe detrimental effect on the clams planted in the Banana River, as clam density decreased substantially in all Banana River plots between the August 11 and October 25, 1999, sample dates (Fig. 3). Hurricane Irene swept through our study area on October 16, 1999, and salinity near our Banana River study site decreased to a study-period minimum of less than 15 p.s.u. at the end of October 1999 (Fig. 4).

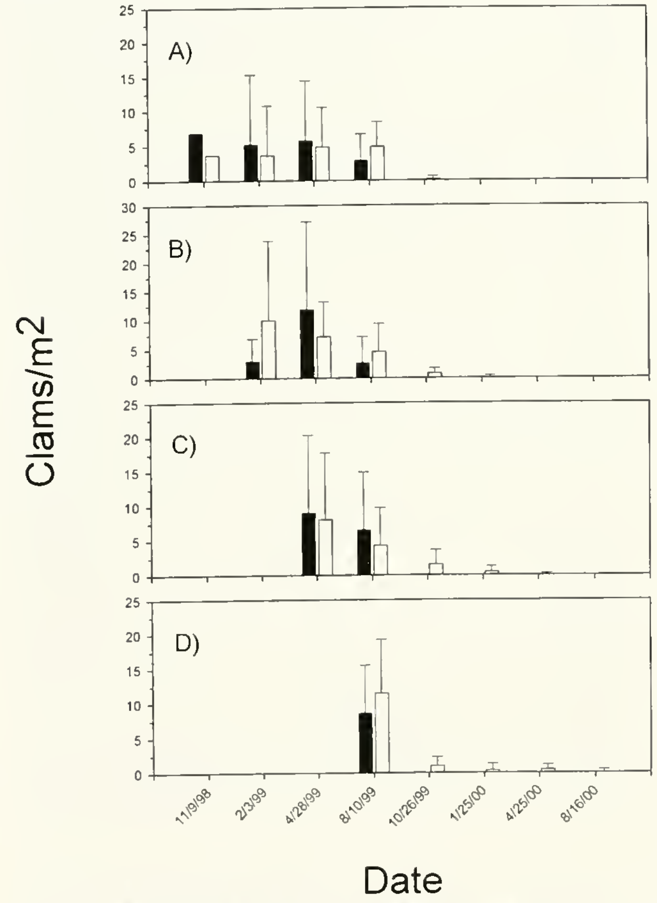

Figure 3. Mean density of hard clams (*Mercenaria* spp.) on various sampling dates after transplantation during (A) fall 1998; (B) winter 1999; (C) spring 1999; and (D) summer 1999 at the Indian River lagoon (filled bars) and Banana River lagoon (open bars) study sites. See Figure 2 for the location of each study site. Note that at the Indian River study site, all four study plots were destroyed by Hurricane Irene during October of 1999 and no further sampling was conducted after that date. Error bars represent one standard deviation. On the November 9, 1998, sampling date, samples were pooled and no standard deviation was calculated.

The high levels of mortality that we observed in our transplant plots may have been influenced by the inability of clams (especially large clams) to reburrow following initial harvest. The Indian River study site was characterized by a soft sand/mud substrate that appeared to provide little resistance to burrowing clams. Upon re-sampling that site two weeks after the fall transplant, 26% of all clams collected remained on the surface, and three months after the fall transplant 20% of all clams collected still remained on the surface. In contrast, the Banana River study site was characterized by a hard sand bottom that appeared to provide considerable resistance to clams attempting to burrow. Two weeks after the Banana River fall transplant, 47% of all clams collected remained on the surface, and three months after the fall transplant 34% of all clams collected remained on the surface. At both sites, failure to burrow was related to clam size. A comparison of the mean SH of buried versus unburied clams at each site two weeks after transplant during both fall and winter, indicated that the clams that failed to burrow were significantly larger than those that successfully reburrowed (*t*-test, see Fig. 5A, B, E, and F for respective *P* values). We detected no significant difference in SH between buried and unburied clams at either site three months after transplant (Fig. 5C and D), although only clams transplanted during the fall were compared. During the spring and subsequent sampling episodes, we discovered few clams at either site that were both alive and unburied.

After the initial episode of transplant mortality, overall mortality of relayed clams did not appear to be size-related. At the Indian River study site, the size distribution of hard clams did not differ significantly among sampling dates (Simultaneous Test Procedure; Sokal & Rohlf 1995) except during the summer transplant study (Fig. 6). During the final sampling episode (October 26, 1999) of the summer transplant study, the size distribution of planted clams differed significantly from the size distribution recorded during the previous two sampling dates and appears to have shifted towards a preponderance of small clams (Fig. 6). For all four of the transplant episodes at the Banana River study site, a significant shift in clam size distribution was detected for the October 25, 1999, sample date, and for all sample dates subsequent to October 25, relative to all sample dates preceding October 25 (Fig. 7). The only exception to this pattern was from the spring transplant study, for which the size shift was not detected until the January 25 sampling episode (Fig. 7).

During each seasonal harvesting event, a subsample of 15 clams from each plot was returned to the laboratory for analysis of reproductive condition and for a comparison with control samples collected from the natural population on the same date. However, the results from only the fall planting date at both study sites are included in the present analysis because that is the only planting date for which adequate sample numbers were available for all sample dates from both sites. The female clams in the control samples had a pattern of reproductive development typical of Indian River hard clams (Hesselman et al. 1989). During fall and winter, when Hesselman et al. (1989) reported that spawning occurred in Indian River hard clams, most clams that we sampled (control and transplant) were either spawning or were spent (Fig. 8). During spring, the season of peak spawning in Indian River

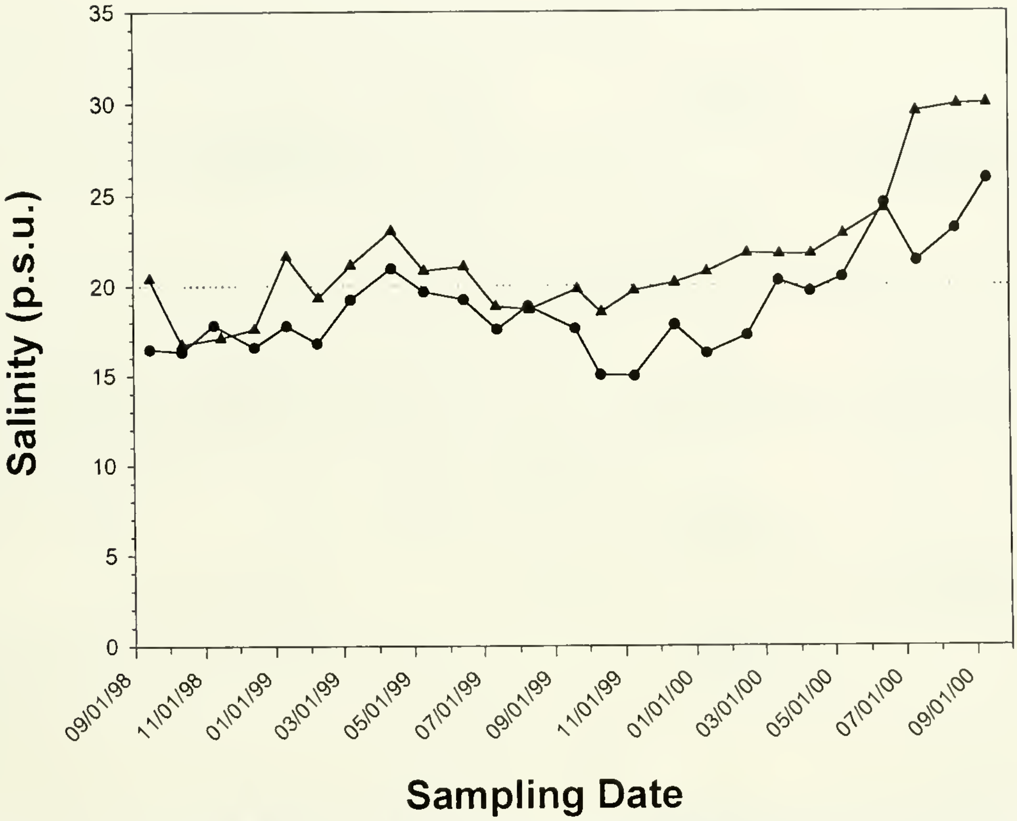

Figure 4. Salinity recorded at the Indian River lagoon (closed triangles) and Banana River lagoon (closed circles) study sites during September 1998 through October 2000. The dotted line provides a 20 p.s.u. reference. Data courtesy of the St. Johns River Water Management District Surface Water Quality Monitoring Program.

hard clams (Hesselman et al. 1989), most of the clams from the control sample were ripe, and lesser proportions were either spawning or spent. In contrast, most animals collected from the Indian River and Banana River transplant plots during spring were in some stage of spawning. Finally, during summer the vast majority of control and transplant clams that we sampled were in the spent condition, which agrees well with the observation of Hesselman et al. (1989) that most Indian River hard clams are reproductively spent during summer.

Gonadal neoplasia is extensive in Indian River hard clams (Hesselman et al. 1988, Bert et al. 1993), and this condition appears to be related to hybridization between the two species of *Mercenaria* (*M. mercenaria* and *M. campechiensis*) that occupy the lagoon (Bert et al. 1993). We recorded neoplasia in 85% of the male clams and almost 92% of the female clams that we collected from the natural clam population of the lagoon. Male clams suffered 93% and 86% neoplasia when harvested after transplant to the Indian River and Banana River, respectively. Female clams suffered 96% and 93% neoplasia when harvested after transplant to the Indian River and Banana River, respectively.

When all samples of clams collected for reproductive analysis during the course of the spawner transplant study were pooled, there were significantly more female than male clams (0.53 males: 1.00 females, $\chi^2 = 42.13$, df = 1, $P < 0.0001$). However, sex ratio was dependent upon clam size-class. For all clams that were ≤ 60 mm SH, we detected no significant difference in sex ratio (0.75 males: 1.00 females, $\chi^2 = 1.43$, df = 1, $P = 0.232$). In contrast, for clams > 60 mm SH, the sex ratio was significantly skewed towards female clams (0.50 males: 1.00 females, $\chi^2 = 42.89$, df = 1, $P < 0.0001$).

Seeding

Mortality of 2 mm hard clams was substantial within 2 wk of planting under all treatment conditions (Table 4). Only under mesh protection did the 2 mm size-class suffer less than 90% mortality, but even with mesh protection the small clams experienced a mean mortality of 85.6%. Survival of clams in the 8 mm size-class was not much better; those clams also experienced >90% mortality in the open plots and at least 50% mortality within 2 wk after being planted in the remaining plots. In contrast, clams in the 16 mm size-class experienced <10% mean mortality in the mesh plots and a mean mortality of 11.3% in the open plots. However, those clams suffered 30.4% mean mortality under the combined protective cover and >70% mean mortality in the shell plots.

Hurricane Irene also severely impacted our seed clam plots. Nevertheless, on November 11, 1999, we attempted to reconstruct the experimental plots and we did conduct suction dredge sampling of the reconstructed plots. We found no live clams in the seed plot 1 y after planting. However, we cannot determine whether that lack of clams was due to the effects of Hurricane Irene or due to factors independent of the hurricane.

Larval Release

Spawning

On May 16, 2000, approximately 550 million hard clam eggs were spawned and collected. The eggs were then exposed to an

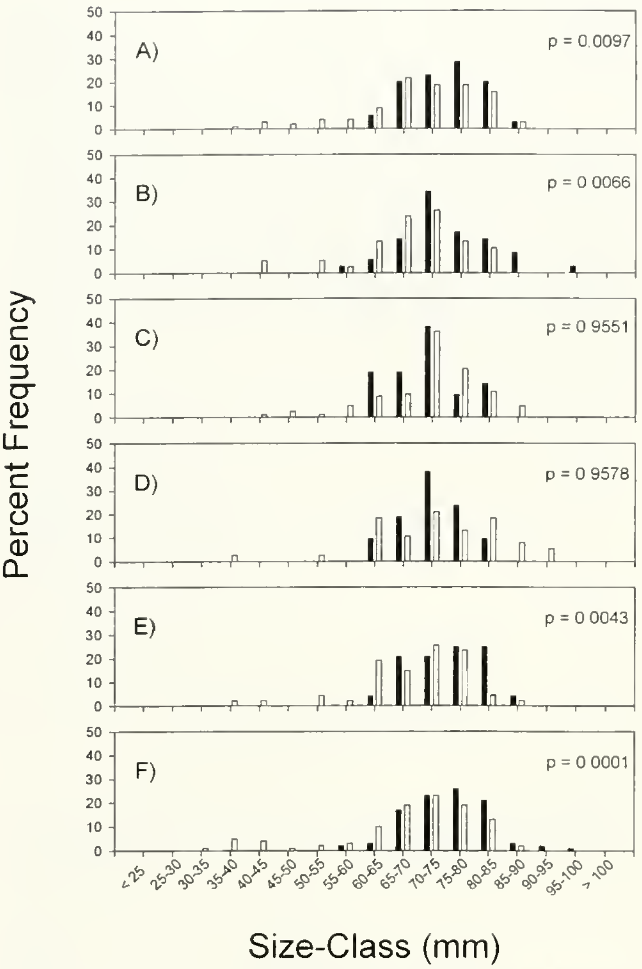

Figure 5. Percent frequency of occurrence of hard clams (*Mercenaria* spp.) at each of the Indian River lagoon and Banana River lagoon study sites during fall and winter sampling events. Filled bars represent the percentage of clams that were recovered on the surface of the plots, and open bars represent the percentage of clams that were buried upon recovery. (A) Indian River fall planting, 2-wk sampling; (B) Banana River fall planting, 2-wk sampling; (C) Indian River fall planting, 3-mo sampling; (D) Banana River fall planting, 3-mo sampling; (E) Indian River winter planting, 2-wk sampling; and (F) Banana River winter planting, 2-wk sampling. The P values included in each plot represent the probability (t-test) that the mean size of clams recovered on the surface was not significantly different than the mean size of clams that were buried upon recovery. A $P \leq 0.05$ indicates a statistically significant difference in the mean size of surficial vs. buried clams.

amount of sperm sufficient to ensure fertilization of all eggs as determined by microscopic examination. Spawning occurred in three "batches" beginning at 1200 EDT and ending at 1600 EDT. Transport from Harbor Branch (1800 EDT departure) to the Banana River release site (2030 EDT release) required approximately 2.5 h, so the clams ranged in age from 4.5 to 8.5 h at the time of release.

Larval Release

Larvae were released at a site in the Banana River lagoon between SR 520 and SR 528 (28°23.320′N latitude, 80°37.951′W longitude) at 2030 EST on May 16, 2000 (Fig. 2). During the next 24 h, the drifters that tracked the water mass within which the larvae were released were transported towards the west until they approached the western shore of the lagoon (Fig. 9). As the drifters approached the shoreline, they gradually swung around to the north, but four of the five drifters contacted the bottom, hung up, and were retrieved. The fifth drifter passed through a small bridge at the western end of the SR 528 causeway and was retrieved to prevent its loss.

Analysis of water samples collected on May 16, before the release of cultured larvae, detected no evidence of naturally occurring hard clam larvae in the study basin. On May 17, after our larval release during the evening of the 16th, we detected larvae at only one sampling station (Fig. 9), probably because the larval mass remained tightly constrained in the area around that station. By May 23, the larval mass had spread throughout the basin (with the exception of the southeast corner), although several peaks of abundance were detected. Two of these peaks were in the northwest corner of the basin, where larval density exceeded 7 veligers L^{-1} (Fig. 10).

DISCUSSION

We tested three strategies for enhancing the abundance of harvestable hard clams in the Indian River Lagoon, Florida. The first strategy involved harvesting adult clams from low-density populations and concentrating them in high-density patches in an effort to increase fertilization success and the production of viable larvae. This strategy does not appear to be cost-effective because most of the clams that we transplanted did not survive the 12-mo monitoring period. Furthermore, the vast majority of the clams that we transplanted were infected with gonadal neoplasia, a disease that progressively reduces fecundity and probably proceeds to a fatal outcome (Yevich & Barry 1969, Hesselman et al. 1988, Eversole & Heffernan 1995). The second strategy involved planting small seed clams at relatively high densities, again with the intention of creating concentrated patches of reproductively active clams. This approach has one anticipated advantage (a longer life span for the spawners) and one unanticipated advantage (avoidance of gonadal neoplasia) when compared with the spawner transplant strategy. However, the first advantage may be offset by the high rates of mortality experienced by most size-classes of the seed clams, and the second advantage may be temporary because the seed clams become increasingly susceptible to gonadal neoplasia, as they grow older (Bert et al. 1993). Although survival rates were relatively high for the largest size-class of clams (16 mm mean SH), the considerable cost of those clams ($0.036 each) reduces the cost-effectiveness of this strategy. The third strategy involved circumventing the entire process of natural fertilization by releasing already fertilized eggs directly into the lagoon. Our results suggest that this strategy may be effective, but more information is needed. It appears that large numbers of clam larvae survived to an age at which settlement can be reasonably expected (8 days to set in culture conditions during May using Indian River water; B. Leeming, personal communication). However, the ultimate fate of those larvae has not been determined, and successful settlement needs to be demonstrated *in vivo* for this approach to have any validity.

The common currency with which to gauge the success of each of these strategies will be an increase in the abundance of hard clams available for harvest by the fishermen. Hard clams in the Indian River Lagoon require approximately 18 months to achieve the legal harvest size of 2.54 cm in shell width (Arnold et al. 1996).

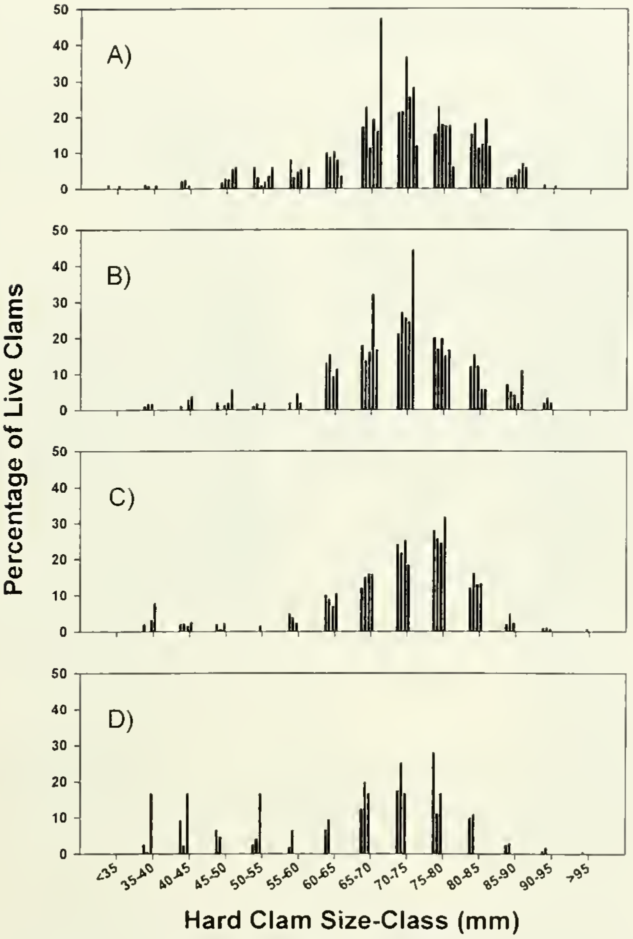

Figure 6. Percentage of live hard clams (*Mercenaria* spp.) recorded within various size-classes during each seasonal sampling event following the (A) fall; (B) winter; (C) spring; and (D) summer transplants in the Indian River lagoon. For each size-class category within each transplant season, sampling dates are plotted from left to right. Thus, the leftmost bar within each size-class represents the sample collected on the original date of harvest, and the rightmost bar represents the sample collected on the final sampling date. See Table 1 for sampling dates and sample size for each date. Note that samples were collected on only five dates for the winter transplant, four dates for the spring transplant, and three dates for the summer transplant because of the impacts of Hurricane Irene, which destroyed the sample plots on October 16, 1999. Otherwise, missing bars indicate that no clams were collected from that size-class on that date.

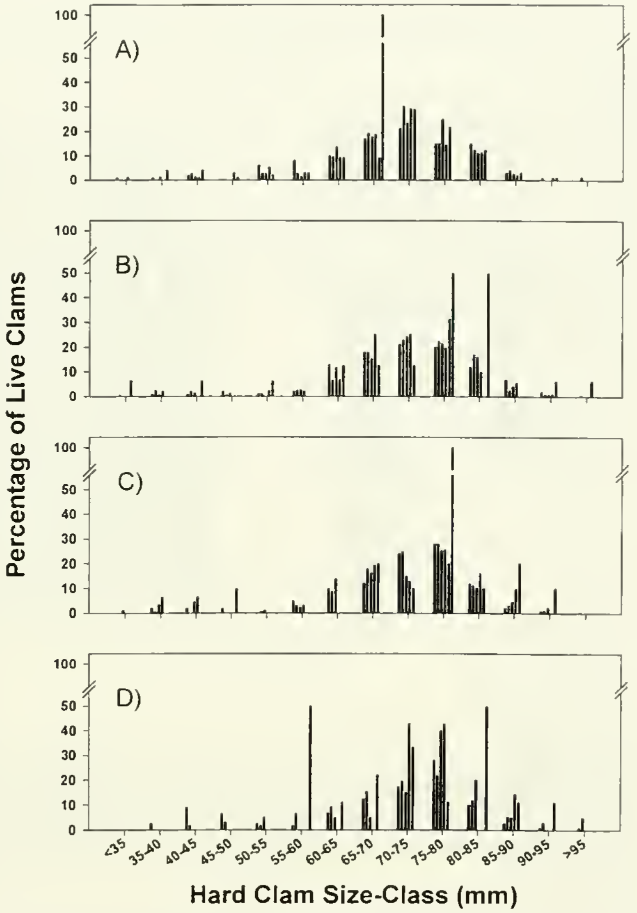

Figure 7. Percentage of live hard clams (*Mercenaria* spp.) recorded within various size-classes during each seasonal sampling event following the (A) fall; (B) winter; (C) spring; and (D) summer transplants in the Banana River lagoon. For each size-class category within each transplant season, sampling dates are plotted from left to right. Thus, the leftmost bar within each size-class represents the sample collected on the original date of harvest, and the rightmost bar represents the sample collected on the final sampling date. See Table 2 for sampling dates and sample size for each date. Missing bars indicate that no clams were collected from that size-class on that date.

For the adult transplants, it would have been possible to detect adult offspring as early as spring 2000, assuming that clams transplanted in fall 1998 spawned very soon after transplant. That is a reasonable assumption considering that a fall spawn has been described for Indian River hard clams (Hesselman et al. 1989) and was similarly indicated by our fall 1999 reproductive data. For the seeding study initiated in fall 1998, we would have expected that maternally derived offspring would be available for harvest no earlier than fall 2000. Hard clams as small as 27 mm SH are reproductively active in the Indian River Lagoon (Hesselman et al. 1989), but clams are generally male during the first year of life (Loosanoff 1937). Thus, we would not have expected egg production from the 16 mm size-class of seed clams for at least 6 months post-planting (i.e., spring 1999). For the larval release study conducted in May 2000, surviving animals would have been expected to achieve harvest size during fall 2001. Information from the fishery and preliminary results from our own sampling efforts provide no evidence of a substantial yield of harvestable hard clams, as might be expected from the above timetables. Of course, our study was conducted on a much smaller scale than would be necessary to realize a significant contribution to future year-classes (McHugh 1981). Our primary objective was to experimentally compare three possible approaches to hard clam population enhancement in the lagoon. From those results, we hoped to be able to choose a single approach that has the greatest likelihood of success and then to apply that approach on a scale appropriate for success.

For the Indian River hard clam fishery, success is a quantifiable parameter. The primary fishing grounds fall within the boundaries of Brevard County, and commercial clam harvest in that county is strictly regulated. Each clammer must be licensed, and only 500 licenses are allocated for the fishery. The goal of our enhancement work is to provide the clam harvesters with a resource base that

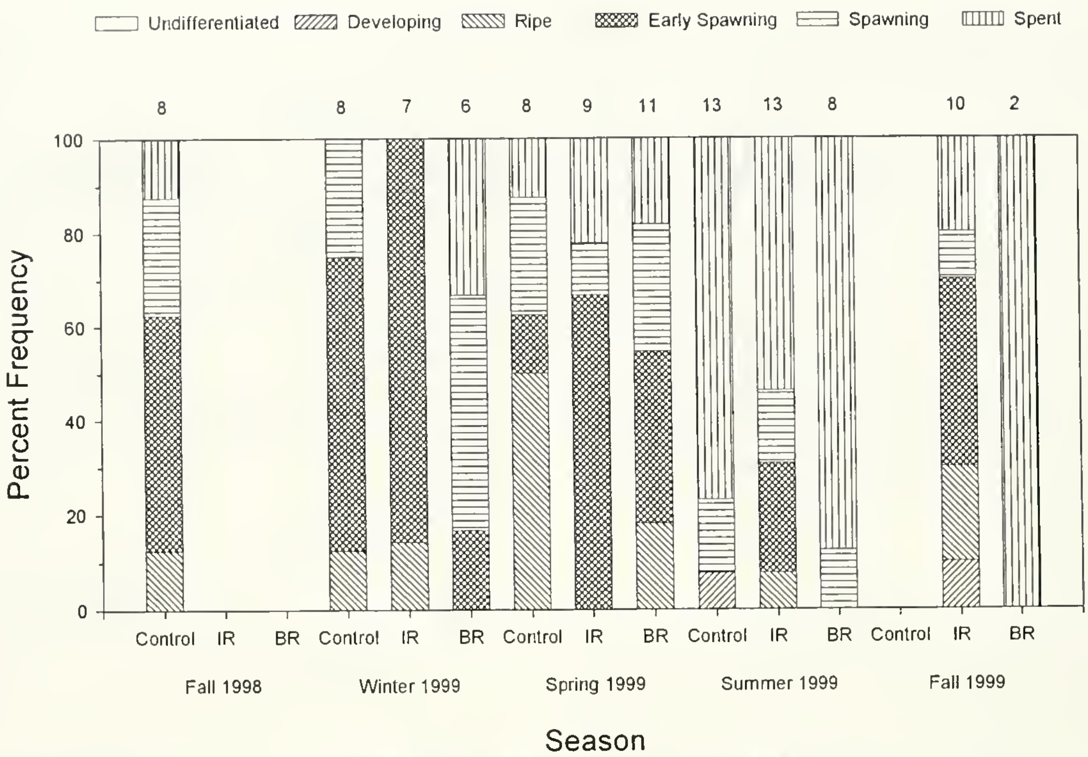

Figure 8. Reproductive stages of female hard clams (*Mercenaria* spp.) collected on various seasonal sampling dates after the fall transplant. Stages are as described in Table 3. Numbers across the top of the plot are sample sizes. Control, clams that were harvested from the natural population during each season; BR, clams that were transplanted to the Banana River lagoon study site during fall and sampled during each season; IR, clams that were transplanted to the Indian River lagoon study site during fall and sampled during each season.

would allow them to survive a nadir in the abundance of naturally occurring clams. If it is assumed that $20,000 is a minimum acceptable annual income for each clam fisherman and that the sale price for each clam is $0.20, then it can be estimated that 50 million harvestable clams must be produced each year to satisfy that harvest goal. Using the larval release strategy as an example, it is apparent that 50 million larvae must be released and must all survive to harvest size to meet that goal. Similarly, if only 1% of the larvae survive to produce clams of legal harvest size, then 5 billion larvae must be released. We have been able to consistently produce approximately 50 million eggs per spawning table per day during subsequent tests of the larval release strategy, and we have used four spawning tables per day during those trials. At that rate, it would require 25 spawning days to produce 5 billion larvae. Carriker (1961) estimated the mean survival rate of hard clam larvae to be 2.6% when rates of flushing were low, but the minimum survival rates that he reported were 0.1% or less. At those minimum larval survival rates it would be necessary to increase daily larval production by a factor of five and to increase the time span of larval release to approximately 50 days to achieve our stated goal. That may be possible, but it would require a broad-scale effort that includes participation by the clam fishermen. Additionally, our best-case larval production estimates require the provision of 800 broodstock per day, because we place approximately 200 clams on each spawning table (equivalent to about 135 female clams with a 2:1 ratio of females to males). Considering the present status of the hard clam fishery in the Indian River Lagoon, the limited availability of broodstock to support egg production may prove to be a serious problem that limits the effectiveness of the larval release strategy. Moreover, broodstock availability may also be adversely affected by the high incidence of gonadal neoplasia in Indian River hard clams. Large clams, which are economically less valuable than small clams and are therefore more available for use in the spawning program, are relatively rare in Indian River waters and produce fewer eggs than would be predicted based upon allometric considerations alone (e.g., Peterson 1983, 1986). The clams that we have successfully used in previous spawning efforts generally fall within the "topneck" commercial

TABLE 4.

Percent mortality of hard clam (*Mercenaria* spp.) seed 2 wk after being planted under various protective conditions at the Indian River study site.

Clam Size-Class	Open Plots	Mesh Plots	Shell Plots	Mesh/Shell Plots
2 mm (rep 1)	96.6	86.9	91.0	92.5
2 mm (rep 2)	98.0	84.2	92.5	98.3
2 mm (mean)	**97.3**	**85.6**	**91.8**	**95.4**
8 mm (rep 1)	91.7	53.8	71.7	84.9
8 mm (rep 2)	97.5	88.9	62.5	90.2
8 mm (mean)	**94.6**	**71.4**	**67.1**	**87.6**
16 mm (rep 1)	20.9	5.2	65.2	48.7
16 mm (rep 2)	1.7	7.6	80.9	12.2
16 mm (mean)	**11.3**	**6.5**	**73.0**	**30.4**

Protective treatments are listed across the top of the table and the results from replicate treatments (and the mean of the paired replicates) are presented within the body of the table.

The boldface rows represent the mean of the two observations.

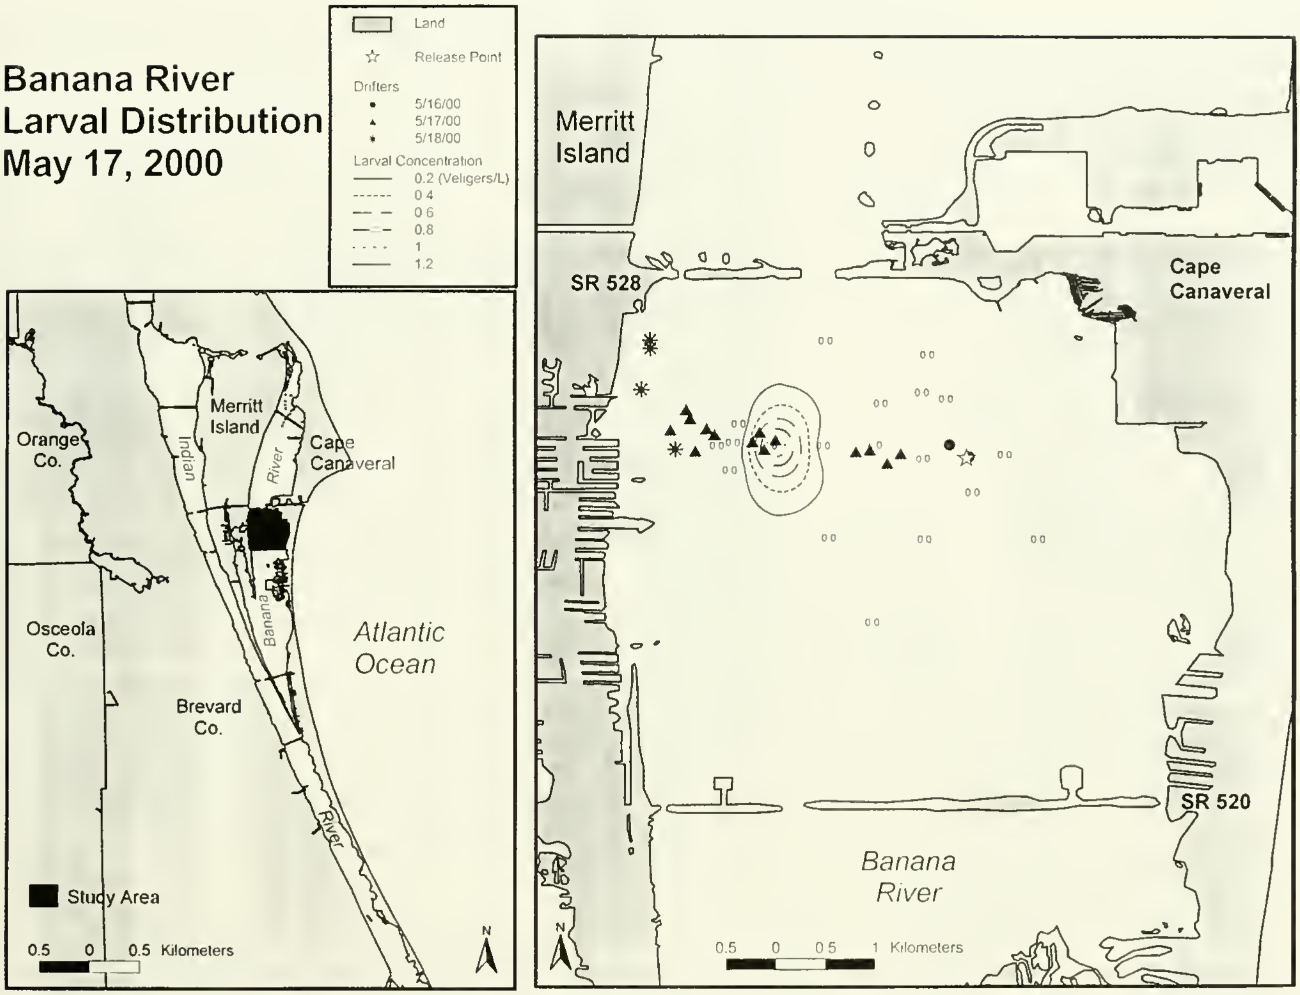

Figure 9. Contour plot of the distribution of hard clam (*Mercenaria* spp.) larvae as estimated by sampling conducted on May 17, 2000, in the Banana River lagoon, Florida. Data are presented as number of clam larvae L^{-1}, and larval concentrations are depicted at the location of each sample station. Also plotted are the locations of the subsurface drifters that were deployed during the evening of May 16, 2000.

classification (average SH = 60 mm). There is a strong market demand for these clams, and seafood processors are reluctant to sell them to us even at a premium price for fear of upsetting previously established buyers. During times when native Indian River broodstock are readily available from seafood processors because of high levels of harvest in the natural fishery, there is little need for an enhancement program, and the contribution that could be realized from enhancement would be swamped by natural production (Kassner & Malouf 1982).

Our estimate of the yield of harvestable clams from larval release does not take into account post-settlement losses, which typically exceed 80% and may approach 100% under some conditions (Gosselin & Qian 1997). However, hard clam populations continue to thrive in Florida and throughout the eastern seaboard of the United States, so conditions suitable for survival must occur. Perhaps it is more appropriate to consider our enhancement efforts within the context of natural clam densities in the lagoon. During the early 1980s in the area near Grant and during the mid-1990s in the area north of Cocoa, clams were extremely abundant and peak densities exceeded 10 clams m^{-2} (Arnold, unpublished data). However, during the time frame of the present study, clams were practically nonexistent in the vicinity of the Banana River study site (Arnold et al. 1997) and were similarly rare in the vicinity of the Indian River study site. As a result, the artificial densities that we initially established in each planting study (spawner transplants and seeding) substantially exceeded the background density at each study site. The 550 million eggs that we contributed during our larval release study equate to an average contribution from the spawn of more than 75 female "cherrystone" size hard clams (Bricelj 1992), assuming 100% fertilization of naturally spawned eggs. Two factors increase the value of the fertilized eggs that we released. First, it is unlikely that 100% fertilization efficiency is realized in the natural environment (Levitan 1995). Second, because of the prevalence of gonadal neoplasia, egg production in Indian River hard clams may be considerably less than that presented by Bricelj (1992) for northern US waters. If we estimate mean production to be 1 million eggs per female, and we estimate a fertilization efficiency of 1% at the low clam densities ($<<1$ m^{-2}) currently found in the lagoon, then the number of larvae that we released is equivalent to the number of larvae produced by approximately 55000 female clams or a bed of >80000 clams assuming a 2:1 female:male sex ratio.

We did not anticipate the rate of loss of transplanted clams that was actually realized during this study. Similar transplants have

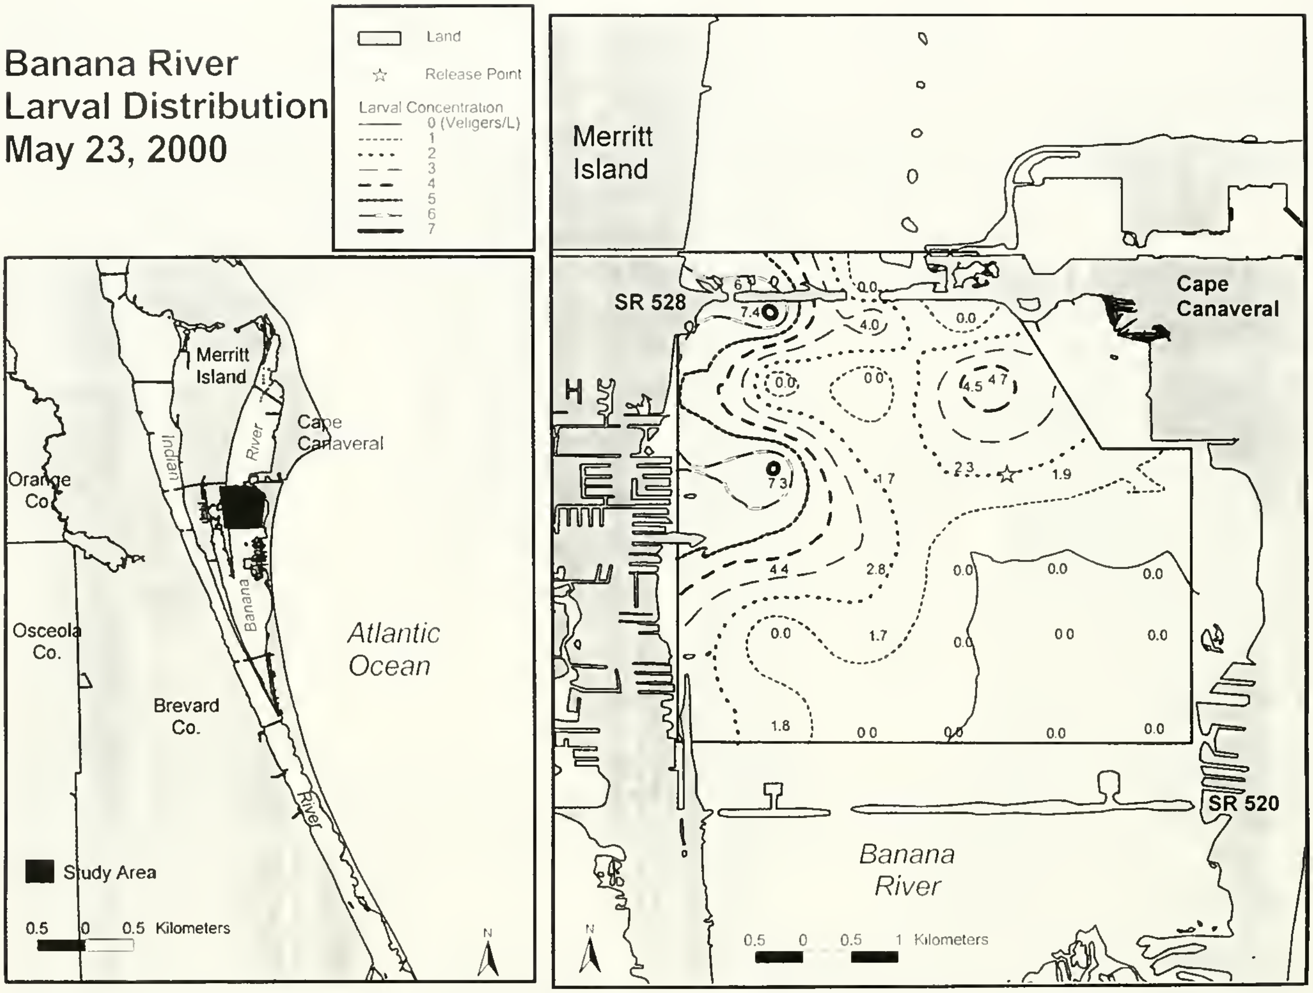

Figure 10. Contour plot of the distribution of hard clam (*Mercenaria* spp.) larvae as estimated by sampling conducted on May 23, 2000, in the Banana River lagoon, Florida. Data are presented as number of clam larvae l^{-1}, and larval concentrations are depicted at the location of each sample station.

been conducted in other areas throughout the range of *Mercenaria*, either for eventual harvest of the relayed clams (e.g., Rice et al. 2000) or to increase or expand larval production (e.g., Kassner & Malouf 1982, Ganz 1991). However, the high frequency of gonadal neoplasia in the clams that we collected for transplant will mitigate against the success of this approach. Gonadal neoplasia is common in Indian River hard clams (Hesselman et al. 1988), particularly in the northern lagoon where we collected clams for transplant (Bert et al. 1993). Although gonadal neoplasia has been reported in hard clams collected from northeastern US coastal waters (e.g., Barry & Yevich 1972), the frequency of occurrence was less than 5% versus greater than 80% in our study. That disease appears to substantially reduce the reproductive potential of hard clams (Hesselman et al. 1988) and probably contributes to the relatively short life span of hard clams in Indian River waters (Jones et al. 1990). Considering that the reproductive potential of *Mercenaria* increases with age (Bricelj & Malouf 1980, Peterson 1983, 1986), the high frequency of gonadal neoplasia in Indian River hard clams appears to render spawner transplants an ineffective strategy for enhancing the abundance of harvestable clam populations in the lagoon.

In all cases, gonadal neoplasia was more prevalent in the transplanted clams than in their undisturbed conspecifics, and the difference in the frequency of neoplasia between the transplants and their undisturbed conspecifics was greater in the Indian River than in the Banana River. This difference was minor and may reflect sampling bias related to differences in the frequency of neoplasia that have been reported for various size-classes and genotypes of hard clams (Bert et al. 1993). Nevertheless, gonadal neoplasia was considerably more prevalent in clams collected during our study than in clam collections reported by either Hesselman et al. (1988) or Bert et al. (1993). Neoplasia is more common in hybrid hard clams (Bert et al. 1993) and hybrid clams are more common in the northern Indian River Lagoon where we collected our transplant animals (Bert & Arnold 1995). Our spawner transplant study would perhaps have been more successful if we had collected clams from more southerly Indian River waters, but we were limited in our choice of harvest sites by the availability of clams.

Seeding as a means of increasing the abundance of hard clams has been attempted in various areas throughout the range of *Mercenaria*, including both coasts of Florida (Menzel & Sims 1962, Menzel et al. 1976, Marelli & Arnold 1996), Georgia (Walker 1985), North Carolina (Peterson et al. 1995), Virginia (Castagna & Kraeuter 1977), New York (Flagg & Malouf 1983), and Rhode Island (Rice et al. 2000). With the exception of the work in North Carolina (Peterson et al. 1995), these efforts have met with limited success due to the high rate of loss of seeded clams even when protective measures are used. In North Carolina, relatively large seed clams (14–22 mm shell length) were planted at relatively low density ($1\ m^{-2}$) in shell hash habitat in late fall, resulting in 35% survival after 14 months (Peterson et al. 1995). However, clam density below $5\ m^{-2}$ is considered to be inadequate for commercial harvest in Florida waters (Arnold et al. 2000), and increasing the density of planted seed clams might result in a loss of economic viability attributed to this approach. Moreover, achieving even the limited enhancement goals that we have set for our project (50 million harvestable clams) would require seeding almost 15,000 hectares of submerged land with almost 1.5 billion clams. Even if the available clam hatcheries could produce that many clams, the cost of the clams alone would be exorbitant. At least for the 500 hard clam fishermen currently licensed to work Brevard County waters, seeding for direct harvest does not appear to be a cost-effective means of ensuring a minimum annual income, although that approach may be feasible for projects of a smaller scale.

We are familiar with only one application of larval release as a means of stock enhancement. Shepherd and colleagues (Preece et al. 1997, Shepherd et al. 2000) released various densities of abalone larvae at several sites in South Australia and monitored their survival. They found that because larval and post-larval survival was density-dependent, the releases of relatively low densities of larvae were more successful than were the high-density releases. The overall conclusion of those authors (Shepherd et al. 2000) was that larval release was not a viable strategy for abalone stock enhancement because of the density-dependent nature of larval mortality. Those results, and results from our own analyses of diffusive processes acting on artificially introduced hard clam larvae (Hitchcock & Arnold, unpublished data), suggest that a point release of the larvae is not the best strategy. Instead, higher survival rates may be obtained by spreading the larvae throughout the target basin, thereby enhancing diffusive processes that will take place anyway (Hitchcock & Arnold, unpublished data). We will test that approach in future experiments.

Efforts to enhance the population abundance of commercially important marine molluscs have been ongoing for decades, and the published record of those efforts indicates that success has been rare if not nonexistent. Clearly, efforts to enhance even moderately dense populations are superfluous, as the reproductive potential of the natural population is sufficient to swamp any directed enhancement efforts. Only when population density is very low, such as it would be in an essentially collapsed population, might such efforts yield success. At that point, we shift from an enhancement effort to a restoration effort, and the goals of the project shift from increasing the abundance of an ecologically functional population to restoring reproductive viability in an ecologically dysfunctional population (Arnold 2001). Nevertheless, user groups and management agencies continue to request that population enhancement efforts be undertaken, and we will continue our efforts to determine if or under what conditions we can meet those requests.

ACKNOWLEDGMENTS

Kate Hagner, Tracy Idocks, Micah Humphrey, and Melissa Harrison of the Florida Marine Research Institute provided invaluable field and laboratory assistance. Commercial clam harvesters Perry McMahon, Bill Leeming, Peter Barile, Doug Telgen, Mason Bowen, Bill Bowler, John Condos, David Panizzi, Jay Anderson, George Vincent, Allen Ellingham, Richie Luck, George Rotsch, James Horst, Pete Roy, and Riley Bergman assisted with clam collections for the spawner transplant study. Frederico Prahl, Sandy Zeiner, Richard Baptiste, and David Vaughan of the Division of Aquaculture, Harbor Branch Oceanographic Institution were essential to successful spawning and fertilization of hard clam eggs. Gary Hitchcock of the University of Miami assisted with larval tracking and was instrumental in the design and deployment of the shallow-water drifters. Winnie White (FMRI) prepared the maps and provided GIS support. Dick Moravec (FMRI) provided assistance with vessels and vehicles, and Gerry Bruger (FMRI) ensured that our electronic database management was seamless and uneventful. This study was made possible by the generous financial support of the commercial clam harvesters of Brevard County, Florida. This is Harbor Branch Oceanographic Institution contribution number 1483.

ABUNDANCE OF OCEAN QUAHOG, *ARCTICA ISLANDICA*, ASSESSED BY UNDERWATER PHOTOGRAPHY AND A HYDRAULIC DREDGE

STEFÁN ÁKI RAGNARSSON* AND GUDRÚN G. THÓRARINSDÓTTIR
Marine Research Institute, Skúlagata 4, P.O. Box 1390, 121 Reykjavik, Iceland

ABSTRACT Abundance of ocean quahog (*Arctica islandica*) was estimated with underwater photography and a hydraulic dredge at 15 m depth in Önundarfjördur, NW Iceland. Abundance estimates based on counts of siphons from the underwater photographs were much higher than from analysis of the dredge catches. A total of seven taxa were identified from photographs, of which only ocean quahogs and brittle stars were found in sufficient abundance for further analysis. The large scale spatial distribution of ocean quahogs and brittle stars was contagious, where the data corresponded well with a negative binomial distribution but differed significantly from a Poisson distribution. The Morisita index of dispersion was used to analyze distribution patterns within each photograph. These analyses revealed that even on small spatial scales the distribution of ocean quahog could be contagious.

KEY WORDS: ocean quahog, distribution, abundance, underwater camera, hydraulic dredge, *Arctica islandica*

INTRODUCTION

The ocean quahog, *Arctica islandica*, is an important commercial species in Icelandic (Thórarinsdóttir & Einarsson 1996) and US waters (Kennish & Lutz 1995). Stock assessments of ocean quahog have generally been performed using hydraulic dredges. However, accurate quantitative abundance estimates cannot be provided if the efficiency of the dredge is not known. Besides, efficiency may vary with environmental conditions and between different types of hydraulic dredges (Eleftheriou & Holme 1984, Kennish & Lutz 1995, Anonymous 1998). Abundance of ocean quahog has also been estimated quantitatively from grab samples (Arntz & Weber 1970, de Wilde et al. 1986) but because of the small surface area the grab collects, relative to the low abundance of ocean quahogs in sediments, this laborious method requires a very large sample size to obtain reasonable quantitative estimates.

Many studies have been performed in the last decade using underwater photographic techniques to estimate abundance of epifaunal bivalves, such as scallops (Langton & Robinson 1990, Stokesbury & Himmelman 1993, Goshima & Fujiwara 1994) and deep burrowing crustaceans, based on counts of burrows (Chapman et al. 1975, Hughes & Atkinson 1997). However, to our knowledge only one photographic study has estimated abundance of infaunal bivalves (Wigley & Theroux 1970). Estimation of abundance from photographs is more difficult for infaunal bivalves than for epifaunal bivalves because identification depends solely on siphon characteristics and the protruding parts of the shell. However, siphon characteristics can be very distinctive and infaunal bivalves have been identified to species and genus level by using these features (Siferd & Welch 1992).

The stock size of ocean quahogs off Iceland has been estimated using a hydraulic dredge (Eiríksson 1988, Thórarinsdóttir & Einarsson 1996). The stock size in Önundarfjördur NW Iceland was assessed by this method in 1994 (Thórarinsdóttir & Einarsson 1996). Assessments conducted with dredges provide only information about the larger scale (>10 m^2) distribution patterns of ocean quahogs. However, variation in distribution patterns may occur on much smaller spatial scales (0.1–10 m^2). At these scales, distribution of ocean quahogs could be influenced by small scale variation in sediment grain size, bottom topography, and the presence of other infaunal bioturbators.

Assessments of ocean quahog stocks using underwater photography has the clear advantage that quantitative information on abundance of ocean quahogs can be assessed more rapidly and cheaply compared with surveys conducted with hydraulic dredges. The aim of this study was to assess whether underwater photography can be used to estimate the abundance of ocean quahogs and secondly to assess how reliable these estimates are by comparing them with estimates obtained with hydraulic dredge within the same area. Furthermore, large and small scale distribution patterns of ocean quahogs and brittle stars were investigated.

MATERIALS AND METHODS

The study was performed in July 1999 in Önundarfjördur NW Iceland (66°02′N–23°34′W) at a depth of 15 m. A 35 mm vertically oriented underwater camera (Photosea 1000A) loaded with a roll of 10 m (250 exposures) of 200 ASA film (KODAK) and an obliquely oriented 150 watt strobe (Photosea 1500S) were placed on a steel frame. A videocamera directly connected to a monitor was also attached to the frame. While the vessel was drifting, the frame was repeatedly (at 30-sec intervals) lowered until the trigger weight touched the bottom, activating the camera and the flash to take a photograph (at a speed of 1/100 sec). Because the flash from the strobe could be clearly seen in the video monitor, the camera equipment was hauled up ≈2 m immediately after each photograph was taken. Photographs were taken at a constant distance (0.9 m) from the bottom (the distance from the camera to the trigger weight) and therefore the area of seabed covered in each photograph was always the same (0.46 m^2). The position of the start and the end of each photographic transect was located by a global positioning system.

To analyze the photographs, they were displayed using a slide projector onto a board (144 cm × 100.5 cm), the size of the displayed image matching the size of the board. The board was divided into 24 squares (i.e., sampling units), each of 0.019 m^2 and all animals on the photographs were counted and identified to the lowest taxonomic level possible. To estimate numbers of ocean quahogs per photograph, all siphons were counted. The siphon of the ocean quahog is very short and consists of inhalant and exhalant apertures, which lie close to each other on the inner fold of the mantle. These are the only parts of the bivalve that can be seen on the sediment surface (Fig. 1).

Only two species were found in sufficient abundance for statistical analysis, ocean quahogs (*Arctica islandica*) and brittle stars

(Ophiuroidea). The large scale distributions of the ocean quahog and brittle stars were compared with Poisson (random) and negative binomial (contagious) distributions using a chi-square test (Elliot 1977). To calculate the goodness-of-fit (chi-square) of the Poisson distribution, only variance and average abundance statistics are required. The negative binomial distribution is based on two parameters, arithmetic mean and the exponent k, which is related to the spatial distribution, and is calculated iteratively using the maximum-likelihood equation (Elliot 1977). In the negative binomial distribution, the variance is greater than the mean, indicating that the distribution of individuals is patchy, whereas if it is the same as the mean, the distribution is random (Poisson). The significance of departures from random and negative binomial distributions were tested using chi-square tests. The extent of contagion in the distribution of ocean quahog was furthermore assessed using the variance to mean ratio (Elliot 1977).

The abundance of ocean quahogs was in general sufficiently high to allow analysis of small-scale distribution patterns within each photograph using the Morisita index of dispersion (Elliot 1977). This index is ideal for this analysis because it is independent of the mean and total number of individuals per photograph and the number of sampling units (i.e., photographic squares) was always the same. The index is greater than one for a contagious distribution, less than one for a regular distribution, and equal to one for a random distribution. Data for analysis were based on abundance of individuals within each of the 24 squares of the photograph. Photographs with less than 20 individuals were not considered suitable for this analysis.

A single cage hydraulic dredge was used to make a comparative investigation of the abundance of ocean quahogs in the same area where the underwater photography took place. The dredge had an overall dimension of 590 × 103 × 230 cm, with a 150 cm wide cutting blade. The bar spacing in the dredge was 34 mm. To determine ocean quahog densities, the distance covered by the dredge was calculated. Ocean quahogs from the catch were weighed, and the total catch weight was divided by the size of the area covered in the tow (5 min duration) to give biomass caught in kg m^{-2}. Individuals in a subsample of 25 kg were counted, measured and weighed. The towing speed was 2.4 nautical miles per hour.

RESULTS

Six invertebrate taxa were identified from a total of 180 seabed photographs. Of these only ocean quahogs (*Arctica islandica*) and brittle stars (Ophiuroidea) were found in high numbers (Table 1). The brittle stars could not be identified down to species level from the photographs. The remaining species, *Asterias rubens* (starfish), *Buccinum undatum* (whelk), *Cucumaria frondosa* (sea cucumber), and *Hyas araneus* (spider crab) were all found with mean abundance less than 0.1 m^{-2}. Ocean quahog was present in 97% of the photographs (max = 148 m^{-2}; Fig. 2a) and brittle stars in 71% of photographs (max = 252 m^{-2}; Fig. 2b). The large scale distribution patterns of ocean quahogs and brittle stars agreed with the negative binomial distribution but differed significantly from the Poisson distribution (Table 1). Furthermore, the variance-to-mean ratio exceeded unity for both ocean quahog and brittle stars (Table 1). The findings from both these analyses suggest that the large scale distribution of ocean quahogs and brittle stars were patchy.

The Morisita index of dispersion ranged greatly between photographs. In 90% of photographs, the Morisita index ranged from 0.68 to 1.62 for ocean quahogs and from 0.46 to 2.58 for brittle stars. These results indicate that dispersion patterns within photographs can be very variable i.e., in some photographs the dispersion patterns of ocean quahogs were highly contagious whereas in others more regular (Fig. 3).

The estimated mean biomass of ocean quahogs in the dredge catch was 1.6 kg m^{-2}, equivalent to 14 indiv. m^{-2} (mean live weight of an individual caught by the dredge was 118 g). Because of the selectivity of the hydraulic dredge, 85% of the clams caught ranged in shell length between 70 to 95 mm, the mean shell length was 82 mm, and no clams <30 mm were observed. Ocean quahog was the only bivalve species found in the dredge samples.

DISCUSSION

This study shows that underwater photography can be used to estimate the abundance of infaunal bivalves, although it may be limited to areas dominated by a single species because identification depends solely on siphon characteristics. Bivalves of size comparable to ocean quahog have not been found in Önundarf-

TABLE 1.

Analysis of the distribution patterns of ocean quahogs and brittle stars.

	Poisson				Negative Binomial		
	Mean	V/M	df (n = 1)	Chi-square	df	k	Chi-square
Ocean quahog	52.8	13.5	177	1343.64*	4	3.68	6.74
Brittle star	43.5	28.9	128	4682.8*	5	1.08	10.37

The goodness of fit of the observed frequency distributions compared with the negative binomial distribution and the Poisson distribution were assessed with the chi-square test.

* $P < 0.005$, mean, mean number of individuals m^{-2}; V/M, variance to mean ratio.

jörður in previous surveys (Thórarinsdóttir & Einarsson 1996), suggesting that all siphons seen on the photographs belonged to ocean quahog. Several smaller sized species have been recorded in Önundarfjörður (Gardarsson et al. 1980) but the siphons of these are likely to be too small to be seen on the photographs.

The abundance estimates of ocean quahog based on dredge catch (14 m^{-2}) were about four times lower than based on the photographs (53 m^{-2}). The proportion of individuals (i.e., efficiency) caught by the dredge relative to the total number of individuals in sediments (based on counts from photographs) was therefore 21%. Although this can be regarded as a crude method to calculate efficiency, Thórarinsdóttir and Ragnarsson (2001) obtained a very similar estimate (19%) using the same hydraulic dredge in a different area.

Dredge efficiency may vary with sediment type, current speed, the ratio warp length:water depth, towing speed, hydraulic pressure of the jet, vertical distribution of the clams, and the size of the dredge. This may explain why efficiency estimates can differ so greatly between different studies (Medcof & Caddy 1971, Anonymous 1998).

Ocean quahogs are known to periodically burrow deeper in sediments until the siphons can no longer be seen on the sediment surface (Taylor 1976). Prolonged absence of food (e.g., during winter) has been suggested as one of the factors that triggers them to bury deeper in sediments (Oeschger 1990). Ocean quahogs are able to reduce their metabolic rate to 1% of the aerobic rate, enabling them to remain deeply buried without feeding over long periods of time (Theede et al. 1969, Oeschger 1990). Clearly, if a large proportion of the ocean quahogs are deeply buried, stock assessment with underwater photography or hydraulic dredges will always underestimate abundance.

Recent evidence suggests that the vertical movements of ocean quahogs within sediments are seasonal in Icelandic waters. Siphons were seen on the sediment surface from April to September 2000 but not between the period of November 2000 to February 2001 (Thórarinsdóttir, unpublished data). These findings suggest that ocean quahogs can burrow to greater depths during winter but may emerge to the sediment surface and start feeding when seawater temperature rises and the levels of phytoplankton biomass increases during summer (Thórdardóttir & Eydal 1996). If this proposition remains true, this may explain why catches of ocean quahog per hour towed tend to be much lower in winter than in summer as the catchability of this bivalve is likely to be lower while deeply burrowed in sediments (Thórarinsdóttir unpublished data). It is therefore likely that only a small proportion of individuals were deeply burrowed in sediments when this study was performed.

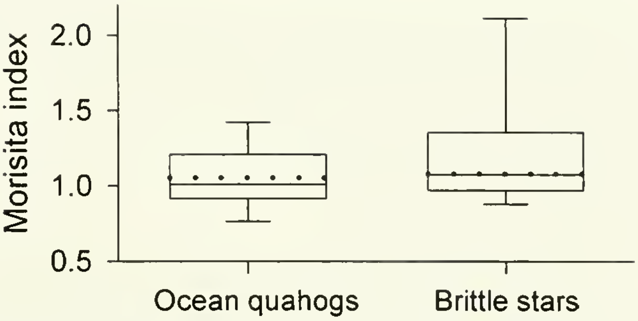

Figure 3. Small-scale distribution patterns (within each photograph) of ocean quahogs and brittle stars assessed with the Morisita index of dispersion. The box plot shows the range in the distribution of the Morisita index in all photographs with more than 20 individuals. The box and whiskers represents 50 and 80% of the data, respectively. Mean (dotted line) and median (solid line) are shown as well.

The present study demonstrates that ocean quahog and the brittle stars were contagiously distributed. Analysis of the distribution patterns within each individual photograph revealed that even on such small scales, the distribution of ocean quahogs and brittle stars can be highly contagious. In some photographs this was caused by the presence of physical features such as stones, which limited their distribution, whereas on other photographs, the underlying reasons for an aggregated distribution were not clear.

Patchy distribution of brittle stars is a common feature widely reported in other studies (e.g., Warner 1971, Piepenburg & Juterzenka 1994). Density-dependent effects (Fujita & Ohta 1990, Summers & Nybakken 2000), predation pressure (Aronson 1989), and local heterogeneity in environmental conditions (Summers & Nybakken 2000) have been suggested to explain contagion of brittle stars.

Stock assessments performed with underwater photographic techniques may provide more accurate quantitative estimates of ocean quahog abundance than using dredges. However, such investigations performed during winter months may greatly underestimate the abundance of ocean quahogs because a large proportion of individuals may be buried deeply in sediments. Furthermore, the small surface area covered by each photograph requires a relatively large sample size to obtain reasonable quantitative estimates. This method is not without limitations and may only be useful in areas where no large infaunal bivalve other than ocean quahog occurs, as identification depends solely on siphon characteristics. Future research should focus on investigating those factors that can influence stock assessment of ocean quahog such as vertical movement in sediments and the efficiency of hydraulic dredges.

ACKNOWLEDGMENTS

We would like to thank Karl Gunnarsson, Elena Guijarro Garcia, James Begley, Lorna Taylor, and Ástþór Gíslason for providing comments that improved this manuscript and Lorna Taylor for her help with the statistics. We also want to thank Elena for her assistance in the field and the crews of the vessels Stundvis and Skel IS.

TETRAPLOID INDUCTION BY MEIOSIS INHIBITION WITH CYTOCHALASIN B IN THE DWARF SURFCLAM, *MULINIA LATERALIS* SAY: EFFECTS OF TEMPERATURE

STEFANO PERUZZI AND XIMING GUO*
Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, New Jersey 08349

ABSTRACT Tetraploidy, which is useful for the production of all-triploids, can be induced in marine bivalves by manipulating meiosis. In this study, we tested the effects of temperature on cytochalasin B (CB)-induced meiosis inhibition in a model bivalve, the dwarf surfclam, *Mulinia lateralis* Say. Newly fertilized eggs of the dwarf surfclam were treated with CB (0.75 mg/L) at proper times to block the release of polar body I (PB1) or polar bodies I and II (PB1&2) at 19°C, 24°C, and 28°C. Inhibition of PB1 produced largely triploid and aneuploid-tetraploid (3.7n to 3.8n) larvae, and sometimes small percentages of pentaploids. Inhibition of PB1&2 produced primarily pentaploids and occasionally triploids and aneuploid-tetraploids. Most of the larvae with ploidy levels higher than triploid developed as trochophores only and died a few days after fertilization. At Day 25 post-fertilization, four tetraploids (2%) were detected among 196 juvenile clams in one of the eight PB1&2 groups. No tetraploids were observed in the eight PB1 groups produced. In general, higher (28°C) temperatures did not improve tetraploid production measured as survival to juvenile stage. Low temperature (19°C) made CB treatment less effective, producing all diploid juveniles by Day 17. This work indicates that tetraploidy can be tolerated in *M. lateralis* and scope for further work on this species therefore exists.

KEY WORDS: tetraploidy, triploidy, cytochalasin, temperature, clam, *Mulinia lateralis*

INTRODUCTION

Tetraploid induction in bivalves has been widely investigated because of its potential to provide an ideal approach to triploid production. All-triploid Pacific oysters have been produced by mating tetraploids and diploids (Guo et al. 1996). Triploids are of interest in shellfish aquaculture for their superior growth and improved meat quality. Since the original work on triploidy by Stanley et al. (1981) with the American oyster (*Crassostrea virginica*), triploids have been produced in over 20 bivalves by manipulation of polar body 1 (PB1) and polar body 2 (PB2) as reviewed by Beaumont and Fairbrother (1991) and Guo (1999).

Viable tetraploids have been produced with variable success in fish (reviewed by Pandian & Koteeswaran 1998), and in amphibians (Humphrey & Fanhkauser 1949, Fischberg 1958, Reinschmidt et al. 1979, Nishioka & Ueda 1983). In bivalves, tetraploid larvae have been produced by several methods, including meiotic and mitotic inhibition, meiotic inhibition of gynogenetically activated eggs, and cell fusion (Beaumont & Fairbrother 1991, Guo 1991). However, tetraploid embryos rarely survived beyond metamorphosis in bivalves. In the Pacific oyster *Crassostrea gigas*, tetraploid gynogenesis produced high percentages (95%) of tetraploid embryos, but no viable juveniles were later obtained (Guo et al. 1993). Similar results were obtained by inhibition of mitosis I (Guo et al. 1994), inhibition of PB1 (Stephens 1989, Guo et al. 1992a, 1992b), and blastomere fusion (Guo et al. 1994). There are probably many other failed attempts that have not been reported.

A small number of viable tetraploids have been obtained by manipulating meiosis in blue mussel (Scarpa et al. 1993), Manila clam (Allen et al. 1994), and zhikong scallop (Yang et al. 2000). These sporadic successes have been difficult to reproduce and no breeding populations of tetraploids have been established by manipulating meiosis in eggs from diploids. A different method of tetraploid induction was developed in the Pacific oyster in 1993, when inhibiting PB1 in eggs from triploids produced 2000 viable tetraploids (Guo and Allen 1994). This method produced small numbers of tetraploids in the pearl oyster *Pinctada martensii* (He et al. 2000) and the eastern oyster (Supan et al. 2000). Large numbers of tetraploid spat were subsequently obtained in the Pacific (Eudeline et al. 2000) and eastern (Guo et al. 2002) oysters, demonstrating the reproducibility of the Guo–Allen method. Although the Guo–Allen method is reproducible, it is limited to species in which triploids produce significant numbers of eggs. Therefore, effective methods for direct induction of tetraploids from diploids are needed in some species.

In the search of new candidate species for tetraploid induction and of conditions that might favor its production, we examined the suppression of PB1 alone and both PB1&2 in the dwarf surfclam, *Mulinia lateralis*, by use of cytochalasin B (CB) at different temperatures. Different levels of tetraploids have been produced by inhibiting PB1 at different temperatures in the Pacific oyster (Stephens 1989, Guo 1991). We expect that higher or lower treatment temperatures might affect cellular properties and chromosome segregation patterns, possibly enhancing the effectiveness of the chemical and finally improve survival of tetraploids.

Several characteristic of the dwarf surfclam make it suitable as model for genetic investigations in marine bivalves: a short generation time, a gametogenic activity that occurs over much of the year under cultured conditions, a relatively high reproductive rate, a sex differentiation easily discernible through the shell of sexually ripe specimens, easy conditioning, and small space requirements (Calabrese 1969).

MATERIALS AND METHODS

Broodstock and Gamete Collection

Adult *M. lateralis* were collected from wild populations of Rhode Island. They were conditioned in recirculating seawater at 20°C (salinity 30 ppt) for 2–4 wk before use. During this period, they were fed daily with *Isochrysis galbana* (C-ISO) at densities of 80–100,000 cells/mL. For natural spawning, ripe clams were selected, air-dried for 1 h and induced to spawn in individual beakers containing filtered (1 μm) and UV-sterilized seawater at 24°C. Clams that did not respond to thermal stimulation were dissected for gamete collection. Eggs were passed through a 100-μm-nytex screen to remove any tissue debris, collected, and rinsed on a 20-μm screen. Sperm were passed through a 20-μm screen, and their motility was checked under microscopy before fertilization. The total number of eggs per female was estimated under microscope by counting small aliquots, and the eggs checked for spontaneous development or possible contamination.

Artificial Fertilization, Chemical, and Thermal Treatments

Sperm were added to egg suspension at about 3–10 sperm/egg. Fertilization and incubation were conducted using filtered seawater with a salinity of 30 ppt at 19–28°C according to the experimental design.

Fertilized eggs were treated with CB, dissolved in dimethylsulfoxide (DMSO) at a final concentration of 0.75 mg/L. All CB treatments started approximately at 5–7 min post-fertilization (PF). The control group was used to gauge the timing of the treatment at all times. For PB1 inhibition, treatments lasted approximately 15–20 min or until about 75% of the untreated eggs released PB1 in the control group. For the retention of both PB1&2, CB treatments were extended for an additional period of 15–20 min, or until the majority of untreated eggs in the control group were ready for the first mitosis (as indicated by the formation of the first polar lobe). After each treatment, the eggs were separated from the chemical by passing them onto a 20-μm screen and gently rinsed with 0.5% DMSO in seawater. Finally, they were suspended in fresh seawater and left undisturbed.

Experimental Design

Experiments were performed using pooled eggs from 4–6 females and pooled sperm from three males. Soon after fertilization the gametes were divided into three groups: in the first group, fertilized eggs were allowed to develop as controls, and in the second and third group the eggs were treated with CB to block PB1 or both PB1&2.

Treatments were tested at normal (24°C), high (28°C), and low (19°C) temperatures. All experiments were replicated three times except for the experiment at low temperature that was conducted twice. Control groups were exposed to DMSO only at the same temperature as the treated groups and for as long as the longest treatment lasted.

Larval Culture and Growth-Out

Larvae were reared in 20-L buckets at 22–24°C and fed daily a diet of *Isochrysis galbana* at densities of 100–120,000 cells/mL starting at 24 h PF. Larvae were cultured at a maximum density of 20 larvae/mL and reached metamorphosis in approximately 8–10 days at a shell length of 180–250 μm. Culture water was completely changed every 48 h, and larvae were collected and washed gently on screens of proper size. D-stage larvae were separated from trochophores by using a 44-μm screen placed on top of a 25-μm screen. At Day 2, the percentages of development (D-larvae and/or trochophores) were calculated from at least 100 individuals per group. Larval survival was determined for all groups at each water change.

After metamorphosis, *M. lateralis* specimens were cultured in upwellers and then in trays contained in a well-aerated recirculating seawater system at a temperature of 19–20°C. Changes of culture water (approximately 1/5 of total volume) were performed every other day.

Determination of Ploidy

Ploidy status of larvae (Day 1–14 PF) and juveniles (Day 17–55 PF) was determined by flow cytometry with DAPI staining according to Allen and Bushek (1992). For larvae, several hundred were sampled after concentrating on a nytex screen and mixed with a DAPI/DMSO stain (Guo et al. 1993). Samples were kept frozen at −80°C and thawed to room temperature before analysis. They were vortexed, passed three times through a 26-gauge needle, and then filtered through a 25-μm-mesh filter. Larvae were analyzed in pooled samples (n = 500–1000), whereas juveniles (n = 100) were analyzed individually. Juvenile samples were prepared by mincing the whole body in a 1.5-mL test tube. Haploid sperm and diploid cells from untreated clams were used as standards at all times.

Statistical Analysis

Fertilization level was determined as percentage of divided eggs at 2–4 h PF. Cumulative survival at Day 2 (D-stage), Day 7, Day 17, and to juvenile was calculated relative to the number of fertilized eggs. Statistical analyses were performed using SYSTAT 10 (SYSTAT Inc.). Percentage data for fertilization and survival were arcsine-transformed and analyzed by ANOVA followed by Tukey's HSD post-hoc comparison. All differences were accepted as significant when $P < 0.05$.

RESULTS

Meiotic and Mitotic Events

At temperatures of 24°C, control eggs started to release PB1 around 12 to 15 min PF, and PB2 at 30–35 min PF. At higher (28°C) or lower (19°C) temperatures, timing was respectively shortened or delayed by 10–15 min. Nevertheless timing of PB1 and PB2 release varied among replicates according to egg quality. In CB-treated groups, no release of PBs was observed during treatments, and meiotic events were restored 3 to 5 min after complete removal of the chemical. Untreated eggs reached mitosis 40–50 min PF except at low temperatures (19°C), where eggs were slightly retarded in development and started cleaving at 55–65 min PF. As expected, mitotic events in CB-treated eggs, particularly in PB1&2 groups, were delayed compared with their control.

Survival and Development

Treatment temperatures did not significantly affect fertilization level within any of the experimental groups, and there was no difference among treated or control groups at any given temperature. Overall, fertilization level ranged between 75% and 99% and varied among replicates (Table 1).

At Day 2, no differences in survival were found between control and treated groups at 24°C or 28°C. At 19°C, the percentage development in the PB1&2 group was 21%, which was significantly lower than in control (53%, $P = 0.009$) and PB1 (51%, $P = 0.01$) groups. At 28°C, eggs in most of the PB1&2 groups survived as trochophores only and did not develop any further, unlike most of the control or PB1 groups where variable proportions of D-larvae (among all larvae) were found (Table 2). At this temperature, survival in the PB1 group was generally low (13–

HT3-PB1&2	0	100

34%) and extremely variable in the control (5–69%). In one control group (HT1-C), all the larvae developed as trochophores only. Overall, percentages of D-larvae at 24°C were significantly higher in control groups (100%) than in PB1 (70%, $P = 0.01$) and PB1&2 (46%, $P = 0.002$) groups, whereas no differences were found between treated groups. At lower temperatures (19°C), again control groups had higher percentages of D-larvae (100%) than PB1 (82%, $P = 0.001$) or PB1&2 (74%, $P < 0.001$) groups. D-larvae percentages were not analyzed for the high-temperature experiment where 100% trochophores were observed in all PB1&2 groups and one control. Trochophores in the CB-treated groups appeared to be deformed and/or swam in a circular motion.

Larvae in all groups metamorphosed between Day 7 and Day 10. At Day 7 and until Day 17, survival of larvae did not differ among treated and control groups at any temperature and varied among replicates (Table 1). Percentage survival to juvenile was generally low within the high-temperature groups, averaging 2.2% and 0.2% in the control and PB1 groups, respectively. An unexpected and complete mortality was encountered after Day 7 in one of the control groups (NT2-C).

In general, the number of surviving juvenile and juvenile clams (Days 16–54) varied greatly among replicates but equally among groups (Table 1).

Ploidy of Larvae and Juveniles

Ploidy of larvae was analyzed on Day 1 and Day 2 to detect possible difference due to differential mortality. No differences in ploidy composition were found between Day 1 and Day 2, and only data from Day 2 are presented.

Ploidy of 2-day-old larvae from treated groups varied greatly among treatments and replicates, ranging from diploidy to pentaploidy (Fig. 1A–D). In particular, PB1 inhibition produced variable proportions of triploid, aneuploid-tetraploid and some pentaploid larvae (Fig. 1A and B), whereas pentaploids were most commonly observed and dominant ploidy in PB1&2 groups. The aneuploid-tetraploid peaks were between 3.6–3.8n, sometimes overlap with 4n. One PB1&2 group had distinctive aneuploid (3.7n) and pentaploid peaks (Fig. 1C), whereas others had clear diploid, triploid, tetraploid and pentaploid peaks (Fig. 1D). After separation of D-stage larvae and trochophores, the flow cytometric analysis of isolated larvae, showed that all or nearly all tetraploid and pentaploid larvae developed as trochophores only (Fig. 2B and D), whereas virtually none or small proportions (Fig. 2C and E) were detected among the D-stage larvae. Control groups from treatments at 19°C and 24°C contained diploid larvae only, unlike controls at 28°C that showed variable proportions of diploid, triploid and pentaploid larvae in two of the three replicates (HT1 and HT2), indicating some influence of temperature on meiotic events. In general, there was no clear pattern that higher or lower temperatures affected the proportions of poly-

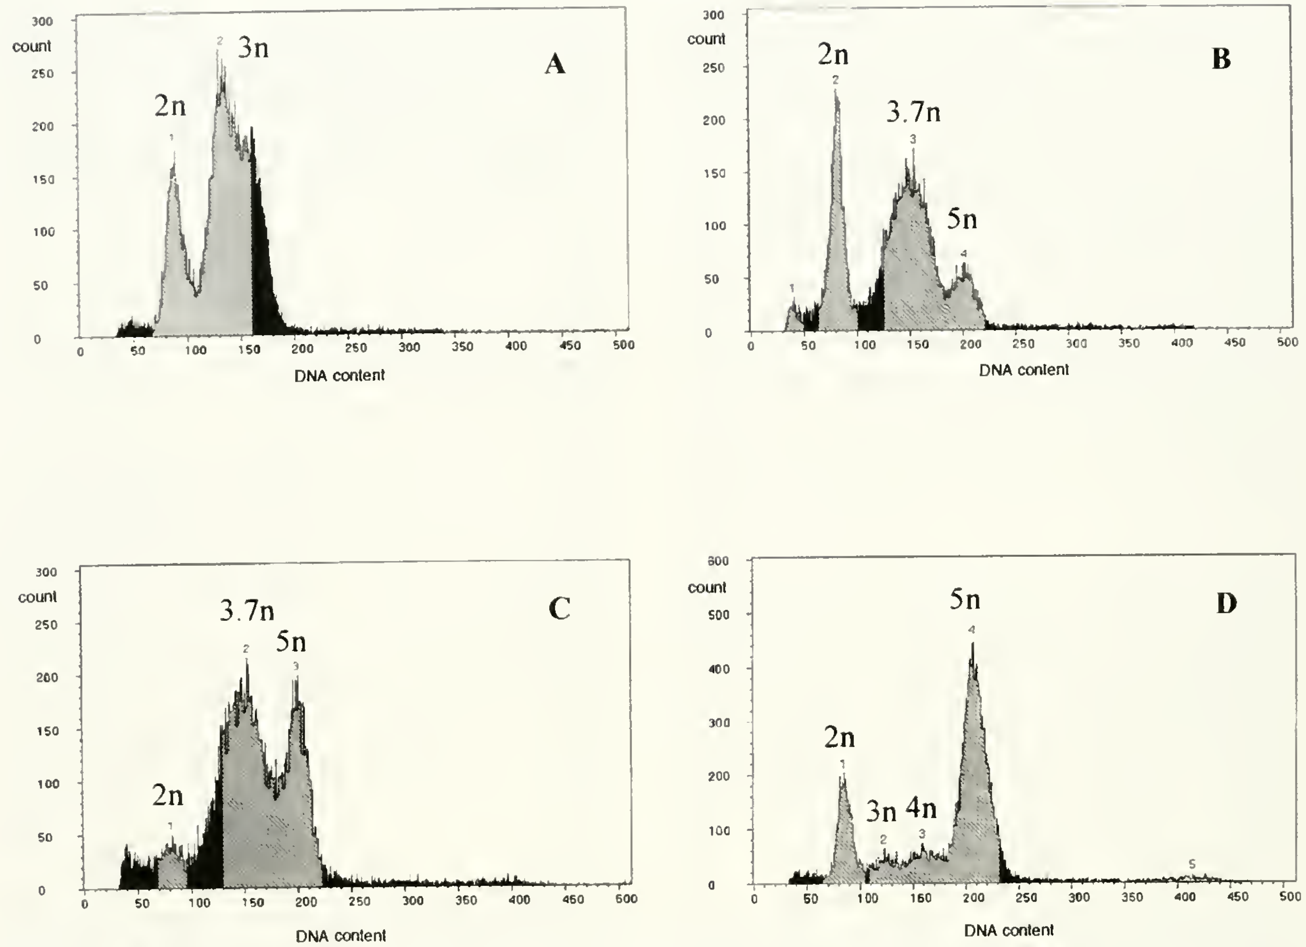

Figure 1. Flow cytometry analysis of 2-day old *Mulinia* larvae from inhibition of PB1 (A, B) and PB1&2 (C, D) showing various ploidy levels induced.

ploids among the treated groups, although precise characterization of ploidy composition was difficult in this study because of the occurrence of aneuploids and tremendous variation among replicates.

The majority of trochophores died within the first 3 days, although some survived to Day 4. Ploidy analysis of larvae was performed several times before metamorphosis and showed virtually no detectable aneuploid, tetraploids, or pentaploids among the surviving larvae after Day 4. Diploids remained the most frequent ploidy in most groups. Distinctive triploid peaks were observed in most PB1 groups at 24°C and 28°C.

After metamorphosis, individual measurements of juvenile and juvenile clams (Days 16–55) showed variable percentages of diploids and triploids in CB-treated groups (Table 3). Of 100 juvenile sampled from one of the PB1&2 groups, two were tetraploid (2%; Table 3 and Fig. 3B). To confirm this finding, another group ($n = 96$) of individuals were analyzed and resulted again in 2% of tetraploids. This group contained juvenile with a measured shell height of 1.5–2.5 mm (Fig. 3A).

At juvenile stages, mean percentages of triploids in PB1 groups did not differ significantly between 24°C and 28°C (Table 3). Eggs treated with CB to inhibit PB1&2 produced viable triploid juvenile in the experiment at 24°C only. No triploids were found among any of the surviving juvenile in the experiment at low temperature (19°C). Three triploids were found among 100 juvenile in one of the control groups (HT2-C) at 28°C, thus confirming the results obtained during early rearing.

DISCUSSION

A low percentage of tetraploid clams (2%) was obtained in one of the eight groups treated to inhibit PB1&2. Although the tetraploid production was low in frequency and inconsistent among replicates, this result provides the first evidence that tetraploid *Mulinia* can survive beyond metamorphosis and reach juvenile stage. This finding provides another example that a small number of viable tetraploids can be produced by manipulating meiosis in normal zygotes. Similarly, small numbers of tetraploids have been obtained in the blue mussel (Scarpa et al. 1993), Manila clam (Allen et al. 1994), and zhikong scallop (Yang et al. 2000).

The production of tetraploids from inhibition of both PBs is unusual. Mature eggs of marine bivalves are arrested at prophase I. Before fertilization, eggs of oysters and clams are actually tetraploids and, theoretically, pentaploids should be produced after fertilization and successful inhibition of PB1&2. The production of pentaploids by blocking both PBs has been demonstrated in the Pacific oyster (Cooper & Guo 1989), in blue mussel (Scarpa et al. 1993), and in this study. Two possible explanations exist why tetraploids were produced in PB1&2 groups. First, it is possible that the CB treatment produced pentaploids, which subsequently reverted to tetraploids through chromosome loss. There is indica-

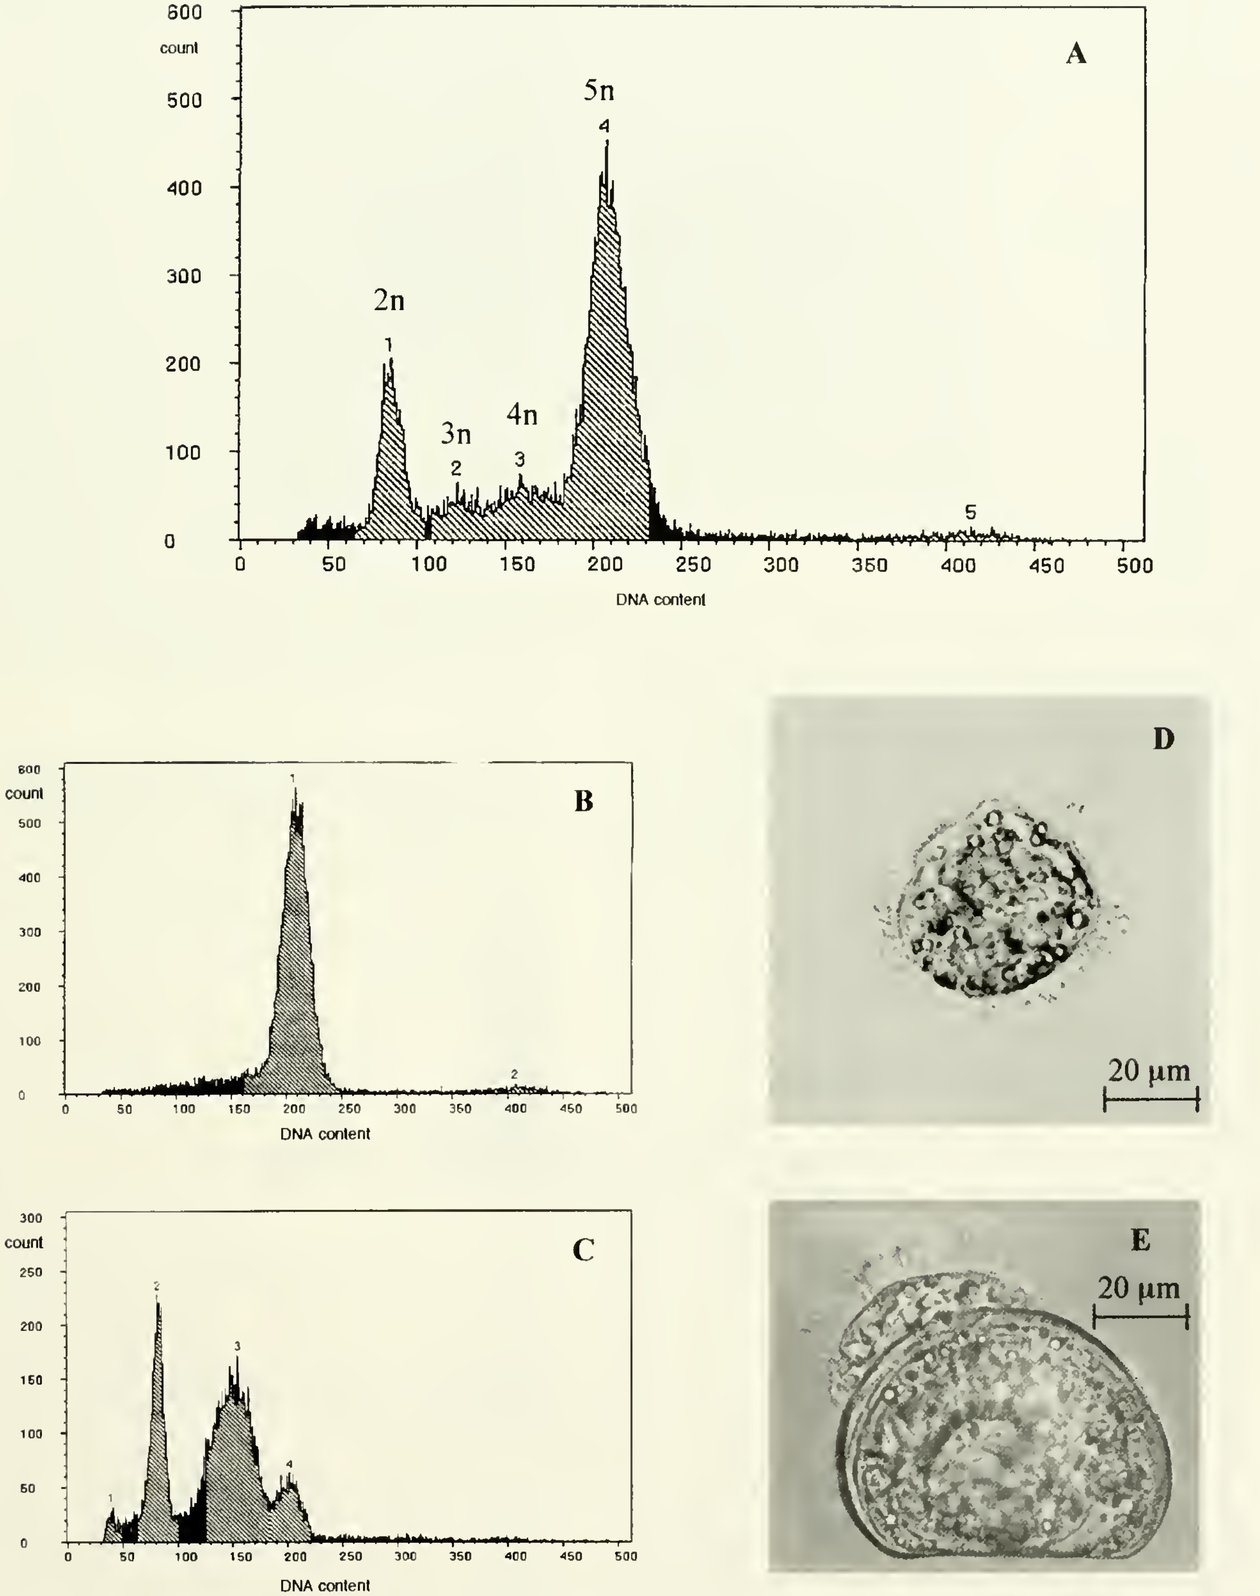

Figure 2. Flow cytometry analysis of 2-day old *Mulinia* larvae from PB1&2 inhibition: A, a sample containing both trochophores and D-larvae; B, trochophores only; C: D-stage larvae only; D: a representative abnormal trochophore; and E: a representative D-stage larva.

tion that tetraploid oysters may revert to triploids or triploid/tetraploid mosaics (Guo et al. 2002). However, reversion is thought to be rare event in triploid and tetraploid oysters (Allen et al. 1997). Secondly, it is possible and even likely that the CB treatment for the inhibition of PB1&2 was not 100% effective and that only PB1 was inhibited in some of the eggs (Guo et al. 1992b, Scarpa et al. 1993). In fact, treatments targeting specific meiotic events are rarely 100% effective because of unsynchronized development of zygotes, which is why triploid induction is rarely 100% effective (Lu 1986, Allen et al. 1989). Therefore, the tetraploids we obtained might be from accidental inhibition of PB1 alone. Interestingly, however, treatments specifically targeting PB1 did not produce viable tetraploids in this study.

Inhibition of PB1 is known to result in a complex segregation pattern that leads to the production of triploids, tetraploids and variable proportions of aneuploids larvae (Guo et al. 1992a, 1992b). These findings were later confirmed in zhikong scallop by Yang et al. (2000). Our study showed that PB1 inhibition had similar effects producing a comparable spectrum of nuclear DNA content in 2-day-old trochophores and D-larvae from CB-treated eggs. Triploids and aneuploids were most commonly observed unlike tetraploids that were rarely detected by flow cytometric analysis. The pentaploid larvae were most likely produced from the incidental inhibition of both PB1 and PB2. Although their ploidy status was not confirmed by chromosome counting, the putative aneuploids (approx. 3.7n) were either hypertriploid or hypotetraploid and possibly produced through tripolar segregation patterns under CB treatment (Guo et al. 1992b). Aneuploids were not found among control groups. Variable proportions of aneuploids were also observed by flow cytometry after PB1 inhibition in zhikong scallop (Yang et al. 2000) and confirmed by chromosome counting. Similar results were obtained on other mollusks by previous workers (Guo et al. 1992a, 1992b, Scarpa et al. 1993, Allen et al. 1994).

Our results show that the higher ploidy levels observed by flow cytometry were mainly represented by populations of trochophores, which declined rapidly over the same period. Clearly, few if any tetraploid embryos survived to D-stage in most groups. The proportion of aneuploids and pentaploids declined abruptly during the first week, and only diploids and triploids were detected among the surviving juvenile. A similar decrease in the proportion of pentaploids and increase in triploids in CB groups was observed in other studies (Scarpa et al. 1993, Guo & Allen 1994). Generally, aneuploidy probably causes imbalance of gene dosage and is often lethal in mollusks with survival depending on specific tolerance to chromosome loss or gain (Guo & Allen 1994, Wang et al. 1999). The failure of tetraploid and pentaploid larvae to survive beyond early developmental stages and metamorphosis has been explained by the unbalanced cytoplasm/nucleus ratios or the cell-number (egg-volume) deficiency hypothesis (Guo 1991, Guo & Allen 1994, Guo et al. 1994). Guo's hypothesis states that the cleavage of eggs of a given size with large tetraploid (or pentaploid) nuclei results in reductions in cytoplasm/nucleus ratio or cell number, both fatal for further development in bivalves. Accordingly, high percentages or large numbers of tetraploids (up to 100%) have been produced using larger eggs from triploids in the Pacific (Guo & Allen 1994, Eudeline et al. 2000) and eastern (Guo et al. 2002) oysters. Supan et al. (2000) also reported the production of tetraploid eastern oysters, but specific numbers and percentages were not available.

Under our experimental conditions, high or low temperature did not improve tetraploid induction as measured by viable tetraploids produced. Effects on ploidy of early larvae were not clear partly because of the tremendous variation within treatments. The presence of large proportions of aneuploids made ploidy determination by flow cytometry difficult. We did not do chromosome counting in this study and had no accurate estimates what chromosome numbers were actually induced under different temperatures. Nevertheless, ploidy of surviving juveniles indicates that high (28°C) and normal (24°C) temperatures produced similar percentages of triploids and that low (19°C) temperature made CB treatment ineffective. Low temperatures did not produce viable polyploids in this study. This result would suggest that a lower temperature might influence the cellular properties and chromosome segregation patterns in this species. In a previous study in the Pacific oyster, high levels of tetraploids were produced under low temperatures (Stephens 1989). High temperatures (28°C) negatively affected the development of larvae deriving from eggs treated to block both PB1&2 and finally provoked complete mortality. It is likely that this result was induced by a combination of long chemical treatment and high temperature. Generally, control groups exposed at the same temperature and for the same duration did produce viable larvae. However, the same temperature was partially effective in blocking PB release and induced 3% triploidy in one control group. Poor egg quality might have favored these

conditions too. Heat shocks in the range of 32–40°C are most commonly required in blocking the release of PBs in other mollusks (Quillet & Panelay 1986, Yamamoto & Sugarawa 1988, Guo et al. 1994).

In summary, this study indicates that temperature has little effects on the final outcome of tetraploid induction in *M. lateralis*. Temperature affects the timing of meiotic segregation and therefore should affect tetraploid induction frequency. We could not detect such effects in this study probably due to random variation in treatment and eggs quality. Considering the low induction efficiency (2%), manipulating meiosis may not be a viable approach to tetraploid production in this species. Nevertheless, this study provides the first evidence that tetraploids are viable in *M. lateralis* and offers encouragement for further research on tetraploidy in this species.

ACKNOWLEDGMENT

We are grateful to Dr. Huiping Yang for assistance with clam culture and sampling and Dr. Standish K. Allen Jr. for constructive comments. The authors thank Dr. Timothy Scott for providing clam broodstock. This work is supported by a grant from the New Jersey Sea Grant Consortium (R/BT-2001) and by a grant from New Jersey Commission on Science and Technology's R&D Excellence Program (No. 00-2042-007-20). ABSTRACT Chromosome preparations of the Olympia oyster *Ostrea conchaphila* Carpenter were studied using conventional Giemsa, silver staining, and C-banding techniques. The karyotype consists of six metacentric (1, 2, 4, 6, 8, and 10) and four submetacentric (3, 5, 7, 9) chromosome pairs. The silver-stained nucleolus organizer regions (Ag-NORs) were terminally located on the short arms of the submetacentric pair 5 (56% of cases) and on the long arms of submetacentric pair 7 (6% of cases). Constitutive heterochromatin was observed as telomeric C-bands on the short arm of the NOR-bearing chromosome pair 5 and as centromeric blocks of several chromosome pairs. Comparative analysis of patterns of karyotype, Ag-NORs, and C-bands of this species and of five other flat oysters, *Ostrea angasi, O. chilensis, O. denselamellosa, O. edulis,* and *O. puelchana,* for which data have been previously published, were performed, allowing the inference of cytotaxonomic relationships within Ostreinae.

KEY WORDS: *Ostrea conchaphila*, cytogenetics, cytotaxonomy, Ostreinae

INTRODUCTION

Studies on oyster cytogenetics have been performed so far on 26 species of Ostreacea (see Nakamura 1985, Ieyama 1990, Thiriot-Quiévreux 2002). The first data only concerned chromosome number and gross morphology (Ahmed & Sparks 1967, Menzel 1968). Later, morphometric measurements of chromosomes enabled the comparison among karyotypes at the interspecific and intraspecific level (e.g., Ladron de Guevara et al. 1996, Li & Havenhand 1997). During the last decade, the development of banding techniques has allowed the fine characterization of individual chromosomes (e.g., Leitão et al. 1999a).

According to the morphologically based classification of Harry (1985), which is currently used, the family Ostreidae includes three subfamilies, that is, Lophinae, Ostreinae, and Crassostreinae. These oysters are sequential hermaphrodites and contain both broadcast spawners (Crassostreinae) and brooders (Lophinae and Ostreinae). Recent techniques such as molecular phylogenetic analysis provided novel insights into oyster evolution and systematics (Littlewood 1994, Jozefowicz & Ó Foighil 1998, Ó Foighil & Taylor 2000). Karyological analysis among cupped oysters, the Crassostreinae (Leitão et al. 1999b), has proven complementary to these approaches and has provided additional evolutionary inferences.

Among the flat brooding oyster species, the Ostreinae, five species have been previously karyologically investigated: *Ostrea edulis* (Linné) (Thiriot-Quiévreux 1984), *O. denselamellosa* (Lischke) (Insua & Thiriot-Quiévreux 1991), *O. puelchana* (Orbigny) (Insua & Thiriot-Quiévreux 1993), *O. chilensis* (Philippi) (Ladron de Guevara et al. 1994), and *O. angasi* (Sowerby) (Li & Havenhand 1997).

The Olympiá oyster, *O. conchaphila* (Carpenter 1857), previously known as *O. lurida* (Carpenter 1864), has been studied by Ahmed and Sparks (1967) and Ahmed (1973) using squash techniques and tentative grouping of chromosomes. *Ostrea conchaphila*, native to the western United States and Canada, ranges from the southeast Alaska to Baja California (in tidal channels, estuaries, bays, and sounds). Commercially important in the late 19th century, this species was cultured in the state of Washington until near-collapse of the industry in the 1950s (Baker 1995).

In the present work, the karyotype, nucleolus organizer regions (NORs), and constitutive heterochromatin distribution were studied in *Ostrea conchaphila* (Carpenter 1857) and a comparison with previously published karyological data on the five other flat oyster species mentioned above was performed to analyze cytotaxonomical relationships within Ostreinae.

MATERIALS AND METHODS

Specimens of the Californian Olympia oyster *Ostrea conchaphila* (G0) were imported from the Pacific Institute (Olympia, WA). Oysters were strictly confined to the quarantine facilities of the IFREMER hatchery of La Tremblade, Charente-Maritime, France, according to international recommendations. After reproduction, the progeny (G1) used in this experiment was reared in the same quarantine facilities for at least 5 mo before sampling.

Whole juvenile animals (ca. 2.5 cm length) were incubated for 7–9 h in a 0.005% solution of colchicine in seawater. The gills were then removed by dissection and treated for 30 min in 0.9% sodium citrate in distilled water. The material was fixed in a freshly prepared mixture of absolute alcohol and acetic acid (3:1) with three changes of 20 min each. Fixed pieces of gill from each individual were dissociated in 50% acetic acid with distilled water solution. The suspension was dropped onto heated slides at 44°C and air-dried (Thiriot-Quiévreux & Ayraud 1982).

For conventional karyotypes, gill preparations were stained with Giemsa (4%, pH 6.8) for 10 min. The silver-staining method for NORs was performed on unstained slide preparations according to the procedure of Howell and Black (1980). This method only detects those NORs that were active at the precedent interphase (Miller et al. 1976). Chromosomal Ag-NORs can serve as characters for inferring phylogenetic relationship (e.g., Amemiya

---

& Gold, 1990). Constitutive heterochromatin regions (C-bands) were revealed using the method of Sumner (1972) with the counterstain propidium iodide. The evolutionary significance of the heterochromatin has previously been discussed in vertebrates (e.g., Hsu & Arrighi 1971, Saffery et al. 1999, Chaves et al. 2000).

Images of Giemsa-stained metaphases and C-banding were acquired with a CCD camera (Axioplan, ZEISS) coupled to a ZEISS Axioplan microscope. Digital images were processed using Adobe Photoshop 5.0 (Windows) using functions affecting the whole of the image only. Microphotographs of Giemsa stained metaphases and C-banding were taken with a ZEISS Axioplan microscope. Digital images were processed using Adobe photoshop 5.0 (Windows). Microphotographs of suitable NOR-stained metaphases were taken with a ZEISS III photomicroscope.

After karyotyping, chromosome measurements of 10 suitable metaphases were made with a digitizer table (Summa Sketch II) interfaced with a Macintosh. Data analysis was performed with an Excel macro-program. Relative length was expressed as 100 times the absolute chromosome length (in μm) divided by the total length of the haploid complement. Centromeric index was calculated by dividing 100 times the length of the short arm by the total chromosome length. The arm ratio was determined (length of short arm divided by length of long arm). Both centromeric index and arm ratio are given because each expresses centromere position and allows comparison with other karyological studies. Terminology relating to centromere position (m: metacentric, sm: submetacentric) follows that of Levan et al. (1964).

To elucidate similarities between Ostreinae species, a hierarchical agglomerative flexible clustering program was used (Lance & Williams 1966). Both NOR and centromeric index information of *O. conchaphila* and five previously studied Ostreinae species were used to cluster species. The Manhattan metric was used to discriminate and then to associate individual species. Manhattan distance appears appropriate to this kind of combination of quantitative (centromeric index values) and qualitative (NORs positions) data and to measure an association between individual objects (species) (Legendre & Legendre 1998).

RESULTS

Analysis of 60 mitotic metaphase spreads from 15 individuals of *O. conchaphila* confirmed the diploid chromosome number of $2n = 20$, scored by Ahmed and Sparks (1967). For karyotyping, the chromosomes of 21 well-spread metaphases were paired on the basis of chromosome size and centromere position. From these, the 10 best spreads were used for chromosome measurements and classification (Table 1). The karyotype (Fig. 1A) consists of ten chromosome pairs. Pairs 1, 2, 4, 6, 8, and 10 were metacentric. Pairs 3, 5, 7, and 9 were submetacentric.

The Ag-NORs were examined in another 122 metaphases from 10 animals. A variable number of one to three Ag-NOR chromosomes were identified (Fig. 1B). The NOR site was located terminally on the short arms of the submetacentric pair 5 and on the long arms of the submetacentric chromosome pair 7. The most frequent case (56% of observed silver-stained metaphases) was one active silver-stained NOR chromosome in pair 5. The Ag-NORs located on pair 7 occurred in few cases (6%).

Constitutive heterochromatin was observed in 31 karyotypes made from well-spread C-banded metaphases from 13 animals. Telomeric C-bands were always observed on the short arm of the NOR-bearing chromosome pair 5. In addition, centromeric blocks were also found in chromosome pair 2 in 84% of observed metaphases, pairs 1, 4, and 5 in 68%, pairs 6 and 8 in 58% of the C-banded karyotypes and in fewer cases in pairs 3, 7, and 9 (35%), and in pair 10 (26%) (Fig. 1C).

To compare the karyological data from *O. conchaphila* and from the other five flat oyster species previously studied, ideograms (Fig. 2) were constructed from relative length and centromeric index values of *O. conchaphila* (see Table 1), *O. edulis* (after Leitão 2000, French population of La Tremblade hatchery, Charentes Maritimes, France), *O. angasi* (after Li & Havenhand 1997), *O. chilensis* (after Ladron de Guevara et al. 1994), *O. denselamellosa* (after Insua & Thiriot-Quiévreux 1991), and *O. puelchana* (after Insua & Thiriot-Quiévreux 1993). The location of Ag-NORs was also included because chromosomal NOR have been used as characters for inferring hypothesis of cytotaxonomic relationships (e.g., Amemiya & Gold 1990, Leitão et al. 1999 b).

The comparison of the relative length and centromeric index of the 10 chromosomes pairs of the studied species showed that pair 1 was similar among all species, pair 2 was also similar except for *O. puelchana*, pair 3 and 4 were similar except for *O. conchaphila*, but taking into account the close relative length and the standard deviation of pair 3 and 4 of *O. conchaphila*, they may be inverted. Pair 5 was variable among species, pairs 6 and 7 were identical except for *O. denselamellosa*, but in this case, the pairs 6 and 7 cannot be inverted because of their different relative length and the

TABLE 1.

Chromosome measurements and classification in 10 cells of *Ostrea conchaphila*.

Chromosome Pair No.	Relative Length		Arm Ratio		Centromeric Index		Classification
	Mean	SD	Mean	SD	Mean	SD

9	8.79	0.63	1.52	0.25	31.27	3.37	sm
10	6.56	0.65	2.43	0.26	42.18	2.60	m

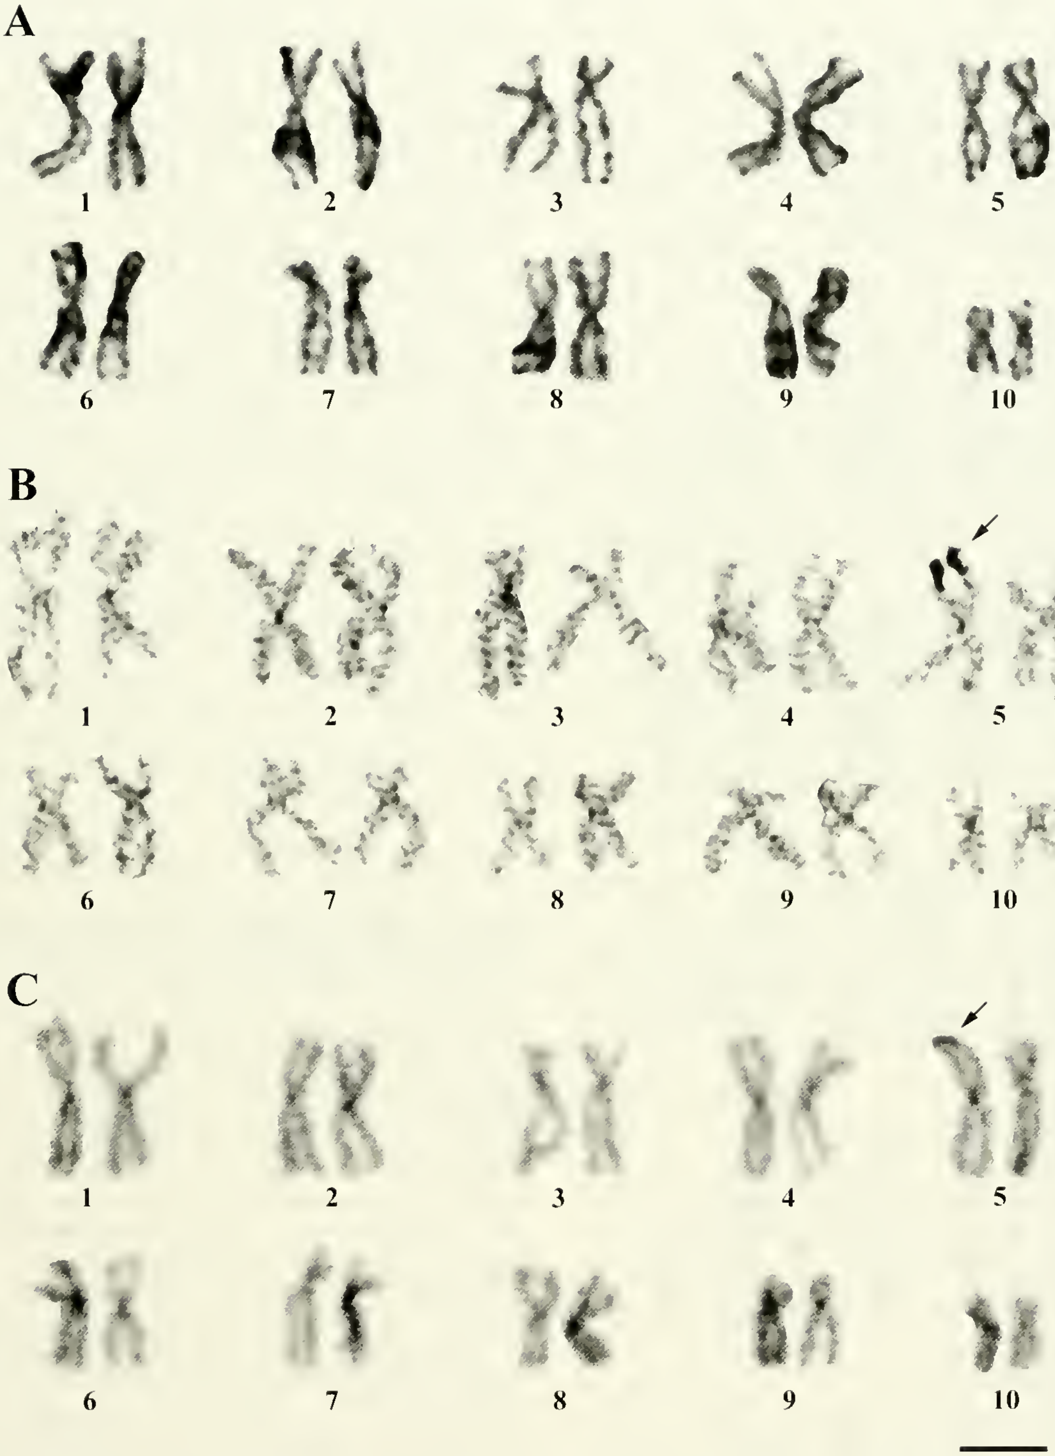

Figure 1. Karyotypes of *Ostrea conchaphila*. A, Conventional Giemsa staining; B, silver-stained nucleolus organizer regions (Ag-NORs); C, C-banding. Note the simultaneous presence of Ag-NOR and C-bands in a telomeric position on the short arms of pair 5 (arrows) and the centromeric heterochromatic blocks on chromosome pairs 1, 2, 4, 5, and 9. Scale bar = 5 μm.

C-banding of pair 6. Pair 8 was variable among species. Pair 9 was identical except for *O. angasi* and pair 10 was variable.

A statistical analysis based on Ci and NORs (Fig. 3) highlighted the clustering of *O. edulis* and *O. angasi* and of *O. denselamellosa* and *O. chilensis* with *O. conchaphila* placed near this cluster. *O. puelchana* is separated from the other species by the highest dissimilarity.

DISCUSSION

This is the first report on karyotype after chromosome measurements and NORs and C-banding patterns of the Olympia oyster. The diploid chromosome number $2n = 20$ observed is characteristic of the genus *Ostrea* and is common throughout the Ostreacea (Nakamura 1985, Thiriot-Quiévreux 2002). The karyotype,

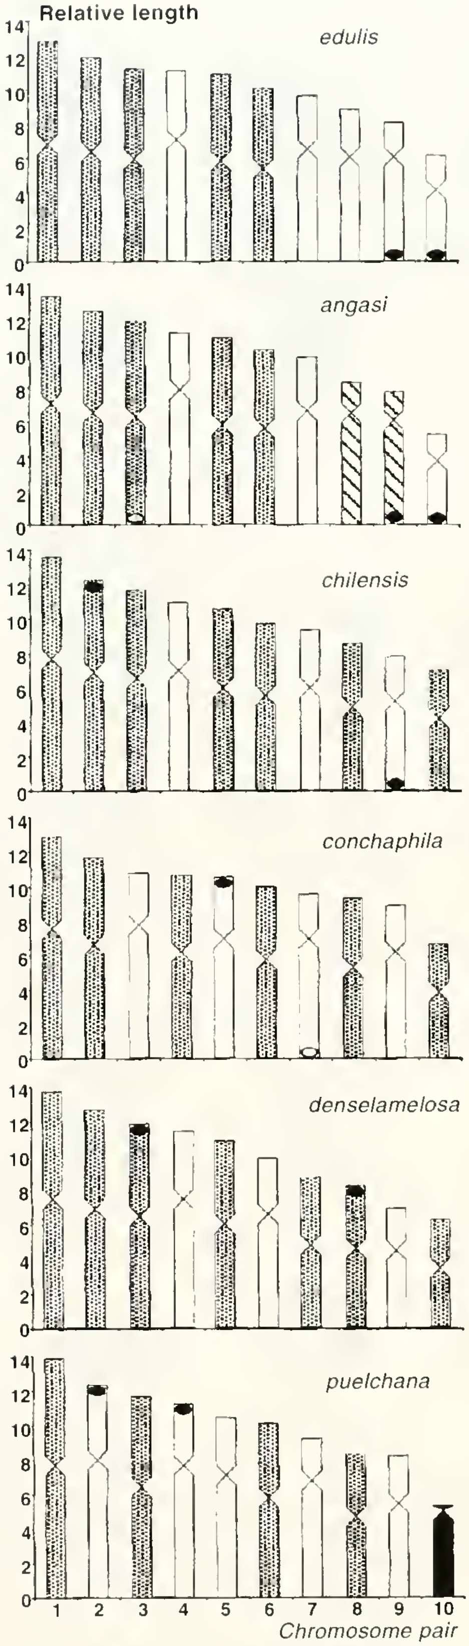

Figure 2. Ideograms of six flat oysters constructed from relative length and centromeric index values. Stippled chromosome: metacentric, white chromosome: submetacentric, striped chromosome: subtelocentric, black chromosome: telocentric. Circles indicate Ag-NORs, dark circles the most frequent case.

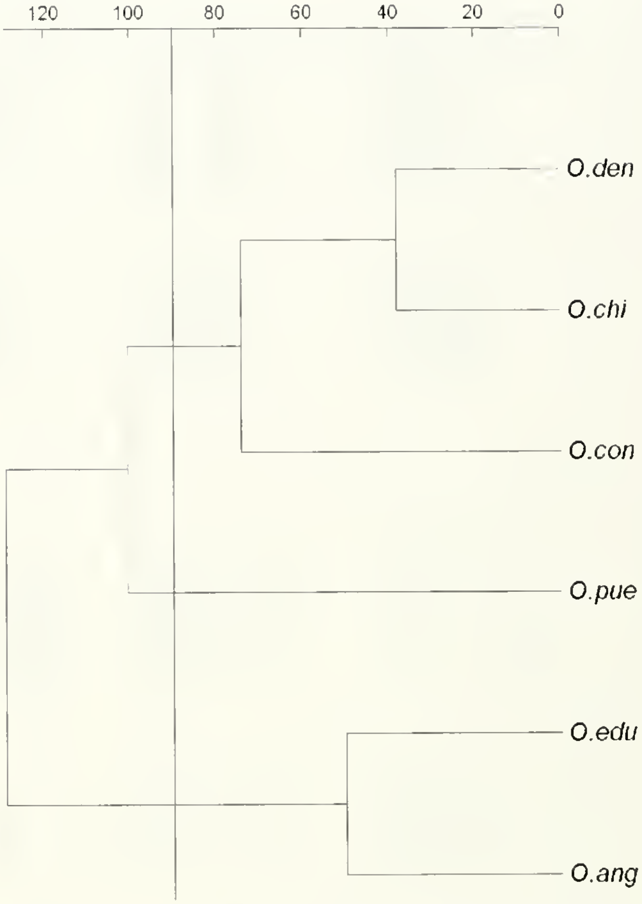

Figure 3. Hierarchical agglomerative flexible clustering of *Ostrea* spp. O. den: *Ostrea denselamellosa;* O. chi: *O. chilensis;* O. con: *O. conchaphila;* O. pue: *O. puelchana;* O. edu: *O. edulis;* O. ang: *O. angasi.*

including six metacentric and four submetacentric chromosome pairs, and the NOR and C-band distribution differ from the other ostreinid species studied. The comparison of the relative length and centromeric index of the 10 chromosome pairs of the studied species shows that, if one postulates that shared chromosome pairs with the same relative length and centromeric index may be considered as primitive, pairs 1, 3, and 4 are primitive and pairs 5, 8, and 10 the most derived. However, these chromosome homologies should be confirmed by other banding techniques.

The comparison of karyotypes and location of Ag-NORs among species highlighted first the chromosome similarity between the European species *O. edulis* and the Australian and New Zealand species *O. angasi*, already pointed out by Li and Havenhand (1997). Their karyotypes differ slightly (5m, 5 sm in *O. edulis* and 5m, 3 sm, 2 st in *O. angasi*), but the phenomenon of variation in the number of submetacentric and subtelocentric chromosomes have been reported in French populations (Thiriot-Quiévreux 1984). More striking is that the most frequent Ag-NOR patterns are similar in both species.

The isolated karyotype of *O. puelchana* is remarkable because of the single telocentric chromosome. The occurrence of telocentric chromosomes has been only seen in one other species of Ostreidae. *Dendrostrea folium* (Lophinae) (Ieyama 1990).

The three other flat oysters bear high karyotype resemblance, that is, seven metacentric and three submetacentric pairs for *O. denselamelosa* and *O. chilensis* and six metacentric and four submetacentric pairs for *O. conchaphila*. Their NOR chromosomal location revealed that there is a higher resemblance between the NOR patterns of *O. chilensis* and *O. conchaphila* than between these two species and *O. denselamellosa*. *O. chilensis* and *O. conchaphila* showed terminally located NORs on the short arms of one chromosome pair and on the long arms of another chromosome pair. On the contrary, in *O. denselamelosa*, Ag-NORs were always terminally located on the short arms of chromosome pairs.

Data on constitutive heterochromatin distribution only concerned three species, *O. denselamellosa* (Insua & Thiriot-Quiévreux 1991), *O. angasi* (Li & Havenhand 1997), and *O. conchaphila* (this study). Centromeric C-bands were observed in chromosome pairs 3, 6, 8, 9, and 10 in *O. angasi* and in pairs 6, 8, 9, and 10 in *O. denselamellosa*. Occasional C-bands were seen on the centromere of pairs 4 and 7 in *O. angasi* and on telomeres of pairs 3, 5, 6, 8, 9, and 10 in *O. denselamellosa*. A substantial proportion of the eukaryote genome consists of constitutive heterochromatin. This genomic fraction includes, among other repetitive sequences, satellite DNA. Sequence analysis of these repeats suggests that the sequences are rapidly evolving, and hence they are valuable as evolutionary markers; consequently, constitutive heterochromatin analysis can give insights about the phylogeny relationships of related species (Saffery et al. 1999, Chaves et al. 2000). The observation in *O. denselamellosa* and *O. conchaphila* of the simultaneous presence of Ag-NORs and C-bands on telomeric position in the same chromosome pair, that is, pairs 3 and 8 in *O. denselamellosa* and pair 5 in *O. conchaphila*, might corroborate the close karyological relationship between these two species noted above.

The cytotaxonomic relationships pointed out here are incongruent with the morphologically based classification of Harry (1985), who stated that *O. chilensis* and *O. angasi* were junior synonymous of *O. puelchana* in the subgenus *Eostrea* of the genus *Ostrea* and that *O. edulis* and *O. denselamellosa* were included in the subgenus *Ostrea* ss. The species *O. lurida* was considered as a junior synonymous of *O. conchaphila* in the genus *Ostreola*. Li and Havenhand (1997) have also previously disagreed with Harry (1985), placing *O. angasi* as a separate species, very close to *O. edulis*.

Our results show greater congruence with molecular phylogenetic analyses of the Ostreinae, based on partial mitochondrial 16S rDNA (Jozefowicz & Ó Foighil 1998) and nuclear 28S rDNA (Ó Foighil & Taylor 2000) datasets. This is most evident for *O. edulis* and *O. angasi*, where a sister species relationship for these European and Australian flat oysters is strongly supported by both karyological and gene tree data. The ostreinid mitochondrial gene trees place the six karyologically-characterized flat oysters into two clades: one containing (among other taxa) *O. puelchana*, *O. conchaphila*, and *O. denselamellosa*, the other composed of *O. edulis*, *O. angasi*, and *O. chilensis*. With the exception of positioning of *O. chilensis*, which in our study is closer to *O. denselamellosa*, these results are in broad agreement with the topology generated by our statistical analysis based on Ci and NORs.

All Ostreinae species are of the brooding type with an extended planktotrophic larval development with the exception of *O. chilensis*, which shows a greatly abbreviated pelagic phase (Walne 1963). This peculiarity is not reflected at the karyological level. However, *O. puelchana* is the only brooding oyster with a distinct dwarf male and it shows a unique phenomenon of settling the larvae on an expansion of the anterior shell margin (Pascual et al. 1989). These unique morphologic features could be related to the karyological isolation of *O. puelchana*.

ACKNOWLEDGMENT

This work was partially supported by a Portuguese grant from the Ministry of Science and Technology (FCTI): SFRH/BPD/1582-2000. We are grateful to S. Lapègue and D. Cheney for supplying live oysters. The authors thank S. Sabini and S. Heurtebise for excellent technical assistance, R. Ben Hamadou for statistical analysis, V. Thiriot for collaboration in Fig. 2, P. Chang for English editing, and D. Ó Foighil for constructive comments.

THE INHERENT EFFICIENCY OF OYSTER DREDGES IN SURVEY MODE

ERIC N. POWELL,[1]* KATHRYN A. ASHTON-ALCOX,[1] JOSEPH A. DOBARRO,[2] MEAGAN CUMMINGS,[1] AND SARAH E. BANTA[1]

[1]Haskin Shellfish Research Laboratory, Rutgers University, 6959 Miller Ave., Port Norris, New Jersey and [2]Rutgers University Marine Field Station, Great Bay Blvd., Tuckerton, New Jersey 08087

ABSTRACT To develop a quantitative stock assessment for the New Jersey oyster (*Crassostrea virginica*) seed beds, oyster dredge efficiency was measured on 10 different oyster beds in the Delaware Bay. Depending on size class and location, mean dredge efficiency for market-size oysters varied from 7.8 to >85%. The sampled beds could be allocated into two groups, one characterized by low dredge efficiency and the other characterized by high dredge efficiency. The low-efficiency group, Group 1, had mean dredge efficiencies for market-size oysters that ranged from 10.9 to 19.5%. The high-efficiency group, Group 2, had mean dredge efficiencies for market-size oysters that always exceeded 45%. A strong tendency existed for market-size oysters to be captured with higher efficiency than smaller oysters. In addition, live oysters tended to be captured with higher efficiency than boxes (articulated valves). Although a conclusion cannot be reached unequivocally, the differential in dredge efficiency observed between Group 1 and Group 2 beds may represent the difference between dredge efficiencies on beds routinely fished and those not routinely fished. An effect of salinity regime cannot be excluded as a possible explanation, however. The differential in dredge efficiency between the two bed groups, about a factor of 4.5 for market-size oysters indicates that variations in bed consolidation may have a large influence on dredge efficiency and may significantly bias estimates of abundance if not taken into account in stock assessments.

KEY WORDS: oyster, dredge efficiency, stock assessment, survey, fishery

INTRODUCTION

Dredges are frequently used survey tools. Knowing the efficiency of the dredge is, therefore, paramount in a quantitative estimate of stock abundance. Dredge efficiencies have been evaluated for a number of bottom-dwelling commercial species, including scallops, *Placopecten magellanicus* and *Zygochlamys patagonica* (Giguère and Brulotte 1994, Lasta and Iribarne 1997), surf clams, *Spisula solidissima* (NEFSC 2000a), ocean quahogs, *Arctica islandica* (NEFSC 2000b), and blue crabs, *Callinectes sapidus* (Vølstad et al. 2000).

The stock assessment for the New Jersey oyster seed beds uses a standard 1.27-m oyster dredge (Fegley et al. 1994). Quantification of this survey depends upon knowing the efficiency of the dredge under survey conditions. Oyster dredges are not among the most efficient of sampling gear. Estimates of dredge efficiency range between 2 and 32% in survey mode (Chai et al. 1992). As used by the industry in the normal routine of fishing, the dredge efficiency consistently falls into the lower portion of this range (Banta et al. in press).

To develop a quantitative stock assessment for the New Jersey oyster seed beds, we performed a series of measurements of dredge efficiency for a standard oyster dredge (Fig. 1). Because previous estimates had varied over a wide range, we conducted these measurements on a number of oyster beds covering a range of salinities and degrees of fishery impact to evaluate whether changes in bed environment and fishing history affect dredge efficiency.

METHODS

Field Program

Dredge efficiency measurements were conducted in summer 1999 and summer 2000 on 10 different oyster beds in the Delaware Bay. Eight of these were in New Jersey waters and two were in Delaware waters (Fig. 2).

Normally, three separate experiments were conducted on each bed. Time constraints limited the number to less than three in several cases. Each experiment was conducted in an identical manner in the following way.

The oyster boat F/V Howard W. Sockwell carried out a 1-min dredge tow using a standard 24-tooth 1.27-m dredge (Fig. 1). Tooth length was approximately 44 mm, and the mouth opening was 1.27 m × 51 cm. The bag consisted of 17 rows of 50.8 mm rings. During the dredge tow, a data logger recorded DGPS position and time at 5-s intervals. A second boat, the R/V Zephyrus, ran immediately parallel but about 5 m off the oyster boat. A buoy was dropped from the R/V Zephyrus at the point immediately opposite dredge deployment and another immediately opposite dredge retrieval as the tow progressed.

The dredge haul was brought on board and a one-bushel sample taken for analysis. The remainder of the haul was measured volumetrically and discarded overboard. A full oyster dredge holds about 12 bushels of material. Presumably, dredge efficiency declines as this volume is approached. In this study, dredge volumes exceed 8.5 bushels at only two sites, Bennies and Arnolds, where dredge volumes routinely fell between 9 and 10 bushels. However, efficiency estimates for these sites did not materially diverge from efficiency estimates for other sites, suggesting that tow distances were short enough so that dredge capacity did not influence measured efficiency.

A buoyed 23-m transect line was dropped from the R/V Zephyrus near the first buoy and the line payed out towards the second buoy. Limitations in visibility prevented divers from routinely sampling within the tow path. As a consequence of the need to maintain a consistent sampling protocol, the diver line was positioned about 5 m from the dredge path so that all diver samples were taken near to and in parallel with the tow path. Twelve collection sacks were affixed at equal intervals along this line. Divers were then deployed to sample along the transect line using an 0.5- × 0.5-m quadrat (0.25 m^2). A random 0.25-m^2 sample was taken at the location where each collection sack was affixed. Divers attempted to retrieve all of the loose bottom material, including all live oysters and boxes (dead, articulated valves). Collection was facilitated by the use of small hand-held scratch rakes. The divers were instructed to take only the loosely consolidated

---

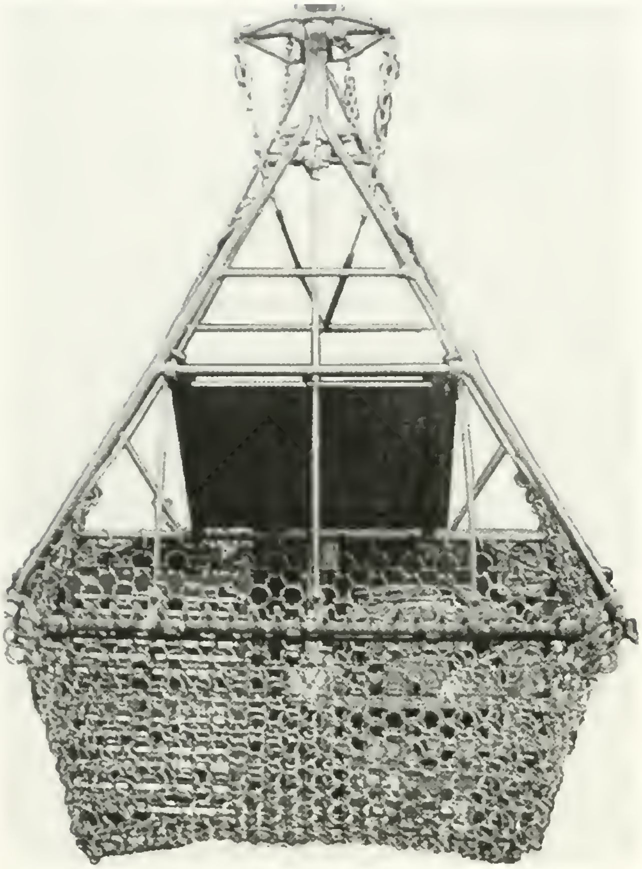

Figure 1. A standard 1.27-m New Jersey oyster dredge.

material on the surface that would normally be taken by the dredge. In most cases, quantitative retrieval was simple because the consolidated portion of the bed was near the surface. In a few cases, unconsolidated shell extended downwards for some distance. In these cases, the diver took the upper portion of the shell until the collection sack was filled.

Laboratory Analyses

Each bushel sample and each diver sample was sorted into live oysters, boxes, and shell and other debris and the respective volumes measured. The longest dimension of each oyster and box >20 mm was measured. Swept area was calculated for each dredge tow from the 5-s position logs and the dredge width.

Population abundance (N) is normally related to survey abundance (n_s) by a catchability coefficient: $N = qn_s$. The conversion requires four parameters: A, the area of the survey; d, the distance traveled per tow; w the cross-section sampled by the dredge; and e, the efficiency of capture by the dredge (NEFSC unpubl.). Thus, $q = A/dw\ 1/e$. Because, in this study, the dredge boat and diver samples were individually normalized to a 1 m^2 area ($A/dw = 1$), catchability q becomes the reciprocal of efficiency e, and was calculated as follows:

$$q = \frac{1}{e} = \frac{\left(\dfrac{\sum_{i=1}^{12} \textit{number of oysters or boxes (diver sample)}^{-1}}{\textit{number of diver samples} * 0.25\ m^2}\right)}{\left(\dfrac{\textit{number of oysters or boxes (bushel)}^{-1} * \#\ \textit{bushels}}{m^2\ \textit{dredge swept area}}\right)}$$

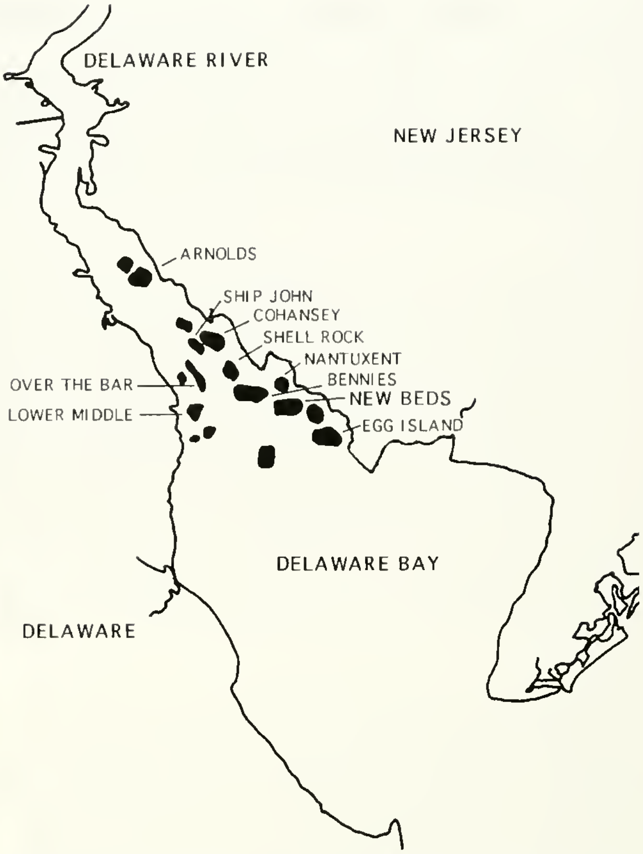

Figure 2. Location of the 10 oyster beds where dredge efficiency measurements were conducted in survey mode. Banta et al. (in press) obtained estimates of dredge efficiency under commercial use from New Beds.

Statistical Analysis

For statistical analyses, we used Spearman's rank correlation and ANOVA on ranked data. When appropriate, differences within the ANOVA were resolved with comparisons that used the least squares means. For some statistical analyses, live oysters and boxes were split into three size classes: juvenile (20–63.5 mm), submarket (63.5–76.2 mm), and market (≥76.2 mm).

RESULTS

Mean values of q for each seed bed are provided in Table 1. Values of q for live oysters ranged from 1.54 (an efficiency of 64.9%) to 11.27 (an efficiency of 8.9%). With one exception, all the size classes of oysters and boxes were correlated with one another (Table 2). The efficiency of collection of shell debris (disarticulated shell and shell fragments), however, was much more rarely correlated with the efficiency of collection of live oysters or boxes and the correlation coefficients were consistently lower. Divers had difficulty determining when to stop digging out shell and shell fragments on some beds, and this uncertainty in diver collection resulted in variation in the computed catchability for debris among diver samples.

Visual observation of Table 1 suggests that the sampled beds can be divided into two groups, those with relatively high values of q (low dredge efficiency) and those with relatively low values of q (high dredge efficiency). This observation was confirmed by ANOVA analysis comparing the efficiency of collection of mar-

Debris includes disarticulated shells and other shell debris. Dash indicates situations where diver sampling did not provide an adequate catch of that variable to permit an estimate of dredge efficiency.

ket-size oysters between oyster beds (Table 3). Note that, in general, the beds Arnolds, Cohansey, Over the Bar, Lower Middle, and Ship John, hereafter termed Group 1, are usually significantly different from the beds Shell Rock, Bennies, New Beds, and Egg Island, hereafter termed Group 2, in this analysis (Table 3). Market-size live oysters were not collected at Nantuxent Point, but perusal of the remaining data in Table 1 suggests that, had they been, Nantuxent Point would have fallen within the latter group of beds.

The average values of q for Groups 1 and 2 are shown in Table 4. With the exception of market-size boxes and debris, the efficiency of collection of live oysters and boxes on Group 1 beds is significantly lower (a higher q) than the efficiency of collection of live oysters and boxes on Group 2 beds.

The efficiency of capture of market-size oysters was higher (lower q) than for submarket-size ($P = 0.04$) and juvenile oysters $P = 0.003$). The latter two were not significantly different. The averages recorded in Table 4 also suggest that the efficiency of capture of live oysters is somewhat higher than boxes. In fact, values of q were significantly lower for all live oysters relative to all boxes ($P = 0.002$), live submarket oysters relative to submarket boxes ($P = 0.04$), and juvenile live oysters relative to juvenile boxes ($P = 0.006$). Market-size live oysters and boxes did not differ significantly, although the mean of the former falls well below the mean of the latter, especially for Group 2 beds. Accordingly, boxes were collected with a lower efficiency than live oysters overall.

The two groups of beds differ in average salinity. Group 1 beds are upbay of Group 2 beds. However, the intensity of fishing also follows the salinity gradient. Visual inspection of samples showed that oysters were much more clumped in samples from Group 1 beds as a consequence of the much lower frequency of dredging that has historically occurred on these beds. Clumping and reef consolidation might decrease dredge efficiency. If so, a correlation might exist between the amount of dredging on the bed during the preceding year and our measurement of dredge efficiency. We evaluated the significance of dredging using Spearman's rank correlations between the number of bushels taken per bed in 1999 and 2000 versus the measured value of q. The number of bushels taken is a reasonable surrogate for the total swept area of dredging (Banta et al., in press). All correlations were negative in accordance with the hypothesis that a higher value of q (lower dredge efficiency) should coincide with lower harvest rates. However, only the correlation with market-size live oysters was significant.

DISCUSSION

Oyster dredge efficiency varied over a wide range among the oyster beds sampled in the Delaware Bay. The range measured

No market-size oysters were collected at Nantuxent Point, hence this bed is not included in the table. Boxed area delineates the comparisons between Group 1 and Group 2 beds discussed in the text.

encompasses dredge efficiencies higher than those recorded by Chai et al. (1992) in the Chesapeake Bay. In that study, dredge efficiencies varied from 2 to 32%. In this study, depending on size class and location, mean dredge efficiency for market-size oysters varied from 7.8 to >85%. Such high efficiencies are achieved when the dredge is used in survey mode, with short one minute tows that do not result in the complete filling of the dredge. The oyster fishery, as it routinely fishes, rarely achieves a dredge efficiency above 5% (Banta et al., in press) because the tows are longer and the dredge is routinely full when retrieved.

The range of efficiencies measured is large. Extreme values, whether high or low, probably are due to patchiness in the sampled area. Diver samples were not taken from the dredge tow path, but rather along a transect run parallel and close to the dredge tow path. Nevertheless, the sampled beds could readily be allocated into two groups, one characterized by low dredge efficiency and the other characterized by high dredge efficiency. The low-efficiency group, Group 1, had mean dredge efficiencies for market-size oysters that ranged from 10.9 to 19.5%. The high-efficiency group had mean dredge efficiencies for market-size oysters that always exceeded 45%.

A strong tendency existed for market-size oysters to be captured with higher efficiency than smaller oysters. Presumably, a greater tendency exists for the smaller oysters to pass between the dredge teeth or through the rings of the collection bag and, thus, not be collected. Dredge efficiencies were particularly low for juveniles, many of which may be attached to smaller pieces of shell that are poorly sampled. Very likely, dredge samples routinely result in a significant bias against juveniles. In this study, market-size oysters were captured with about twice the efficiency of juveniles.

In addition, live oysters tended to be captured with higher efficiency than boxes. The difference was highly significant, particularly in Group 2 beds where boxes tended to be captured with an efficiency of about one-third the efficiency of living oysters. Two possible reasons exist for the lower capture efficiency of boxes: 1) collection by dredge may result in disarticulation. This possibility is not supported by experiments designed to evaluate this source of disarticulation, however (Powell et al. 2001); 2) some boxes taken by divers may be deeper in the reef than the dredge normally samples. Efficiency of collection of debris was significantly correlated with efficiency of collection of total boxes in accordance with this hypothesis (Table 2); however, the efficiency of collection of debris was also correlated with some live oyster variables. Thus, a conclusive explanation for the variation in efficiency of capture between boxes and live oysters is not provided by the present analyses.

Box counts are routinely used as a method to estimate mortality rates in shellfish populations (Merrill and Posgay 1964, Fegley et al. 1994, Christmas et al. 1997). The differential in dredge efficiency measured in this study could result in a significant bias in the live:dead ratio and a significant underestimation of mortality rate from box counts if diver collections are unbiased. On the other hand, Christmas et al. (1997) observed that disarticulation often took more than one year, whereas mortality estimates from box counts usually assume that boxes were produced in the current year. This bias would tend to counterweigh the potential bias imposed by dredge efficiency. However, Powell et al. (2001) ob-

TABLE 4.

Mean values of *q* (the reciprocal of dredge efficiency) for each of the size classes of live oysters and boxes, total live oysters, total boxes, and debris for two groups of beds.

	Live Oysters				Boxes

Group 1 contains Arnolds, Cohansey, Over the Bar, Lower Middle, and Ship John. Group 2 contains Bennies, Shell Rock, Nantuxent Point, Egg Island, and New Beds. Debris includes cultch and other debris. *P* values record the results of ANOVA analysis comparing the two groups with respect to the variable listed as the column heading. NS, not significant ($\alpha = 0.05$).

served that disarticulation rates might be higher in the Delaware Bay than observed in Chesapeake Bay by Christmas et al. (1997). Consequently, the potentially offsetting biases in the interpretation of box counts cannot, as yet, be fully evaluated.

Why Group 1 beds yielded such low dredge efficiencies in comparison to Group 2 beds cannot unequivocally be identified. Group 1 beds are all upbay of Group 2 and, thus, exist at lower average salinities. Unfortunately, Group 1 beds also have been impacted less over the long term by dredging because effort in the Delaware Bay oyster industry also follows the salinity gradient, with lower effort on the lowest salinity beds (HSRL 2000, Fegley et al. 1994, Banta et al., in press). We attempted to assess the influence of dredging using catch data for 1999 and 2000, without much success. However, whether the catch data for the year before sampling is the correct estimator of the effect of dredging is questionable. Visual observation, for example, shows that oyster clumps are larger and contain more living oysters on these upbay beds. These clumps, very likely, are more firmly attached to the underlying bed than are the oysters on Group 2 beds. Greater bed consolidation on the upbay beds (Group 1) would reduce the effectiveness of the teeth in scraping shell material up into the dredge and, consequently, reduce dredge efficiency.

Oyster catchers normally report that catch rates are lower on beds that have not been fished for a time and that catch rates improve after repeated dredging over a few days. Very likely, this repeated dredging breaks the bottom up and results in a substantial increase in the efficiency of capture. Although the conclusion cannot be reached unequivocally, it seems most likely that the differential observed between Group 1 and Group 2 beds represents the difference between dredge efficiencies on beds routinely fished and those not routinely fished. The differential is large, about a factor of 4.5 for market-size oysters, indicating that variations in bed consolidation may have a large influence on dredge efficiency and may significantly bias estimates of abundance if not taken into account in stock assessments.

ACKNOWLEDGMENTS

Special thanks to Larry Hickman, Captain of the F/V Howard W. Sockwell and to Bivalve Packing for providing the F/V Howard W. Sockwell and logistical support for this study. Special thanks also to Royce Reed, Captain of the R/V Zephyrus and to the New Jersey Department of Environmental Protection for providing vessel support for the dive team and help in sample collection. We particularly thank the dive team, Jack Keith, Dave Andrews, Geoff Graham, Bill Dixon, and Jessica Vanisko, who collected the 324 diver samples that constituted the quantitative collections for this study.

NOVEL REPEAT ELEMENTS IN THE NUCLEAR RIBOSOMAL RNA OPERON OF THE FLAT OYSTERS *OSTREA EDULIS* C. LINNAEUS, 1758 AND *O. ANGASI* SOWERBY, 1871

E. KENCHINGTON,[1]* C. J. BIRD,[2] J. OSBORNE,[2] AND M. REITH[2]
[1]*Department of Fisheries & Oceans, Bedford Institute of Oceanography, 1 Challenger Drive, P.O. Box 1006, Dartmouth, NS, B2Y 4A2, Canada;* [2]*Institute for Marine Biosciences, National Research Council of Canada, 1411 Oxford Street, Halifax, NS, B3H 3Z1, Canada*

ABSTRACT The nucleotide sequence of the ribosomal RNA operon, from the 18S rRNA gene through ITS-1, 5.8S rRNA gene, and ITS-2, was determined for single clones of the flat oysters *Ostrea edulis* from Europe and *O. angasi* from Australia. The genic regions, the 18S and 5.8S rDNAs, were identical between the two species and displayed a high degree of similarity with available sequence from *Crassostrea gigas*, *C. nippona*, *Saccostrea commercialis*, and *S. cucullata*. In ITS-1, the *Ostrea* species had a characteristic repeat region, with subrepeats of 54 base-pairs (bp) (*a*) flanking a 27-bp fragment (*b*), where *b* remained constant while *a* changed by 1 bp through successive iterations (*a'*, *a''*). In *O. edulis*, the pattern was *a*, *b*, *a'*, *b*, *a''*, whereas in *O. angasi* it was *a*, *b*, *a''*. Apart from the difference in repeats, the ITS-1 of the two *Ostrea* species was identical except for a single substitution and two 2-bp insertions/deletions. ITS-2 was identical between the two *Ostrea* species except for a single substitution and a 3-bp insertion/deletion, and contained a nearly complete repeat of *a* near the 5' end. These ITS sequences were markedly dissimilar to available sequence from the other oyster species examined, and the repeat region was unique to *Ostrea*, with possible functionality in transcription. On the grounds of sequence similarity, it is suggested that *O. edulis* and *O. angasi* are conspecific.

KEY WORDS: rDNA sequence, ITS, *Ostrea*

INTRODUCTION

The taxonomy and systematics of oysters is far from being resolved (Carriker & Gaffney 1996), and confusion over the recognition of species persists, although the recent application of genetic techniques has been very successful in providing valuable characters to address phylogenetic relationships of the major species groups and families (Buroker et al. 1979a, Buroker et al. 1979b, Brock 1990, Banks et al. 1993, Anderson & Adlard 1994, Littlewood 1994, Boudry et al. 1998, Jozefowicz & Ó Foighil 1998, Ó Foighil et al. 1999, Ó Foighil & Taylor 2000). Among the remaining contentious issues is the question of the phylogenetic relationship between *Ostrea edulis* Linné, 1758, the European flat oyster, and *O. angasi* Sowerby, 1871, the Australian flat oyster.

In the most recent comprehensive revision of the living oysters, Harry (1985) reduced *O. angasi* to a synonym of the Southern Hemisphere species *O. puelchana* D'Orbigny, 1841, placing it in a different subgenus from *O. edulis* based on larval morphological and developmental characters. However, this classification has not been universally accepted (e.g., Jozefowicz & Ó Foighil 1998), and further data have since become available to suggest a closer relationship between *O. angasi* and *O. edulis* than had been supposed. Comparison of karyotypes, nucleolus organizer regions, and constitutive heterochromatin from chromosome preparations of *O. angasi* and *O. edulis* shows a very high degree of similarity, which is not seen between *O. angasi* and its supposed Southern Hemisphere conspecifics *O. puelchana* and *O. chilensis* Philippi, 1845, or between *O. angasi* and the Indo-West Pacific *O. denselamellosa* Lischke, 1869 (Li & Havenhand 1997). Partial mitochondrial 16S rRNA gene sequences position *O. edulis* and *O. angasi* in a well-supported clade with a low degree of DNA sequence divergence relative to the other conspecifics (Jozefowicz & Ó Foighil 1998). These results are also supported by partial 28S rRNA gene sequences (Ó Foighil & Taylor 2000). Furthermore, the concept of *O. puelchana* (previously thought to be native to Argentina) as a single circumglobal species in the Southern Hemisphere has been convincingly challenged by partial mitochondrial 16S rRNA (Jozefowicz & Ó Foighil 1998) and 28S rRNA gene sequences (Ó Foighil & Taylor 2000). These data support resurrection of the regional taxa in the southern hemisphere, namely *O. chilensis* in Chile and New Zealand, *O. angasi* in Australia and *O. algoensis* Sowerby, 1871 in South Africa.

To date, genetic information on the living oysters has focused on the rRNA gene (rDNA) array. In the Bivalvia, and in many other taxa, the rRNA genes have been useful in inferring phylogenetic and taxonomic relationships (e.g., Field et al. 1988, Ghiselin 1988, Nakamura 1989, Rice et al. 1993, Kenchington et al. 1994, Kenchington et al. 1995, Steiner & Müller 1996, Campbell et al. 1998, Frischer et al. 1998). These genes are co-transcribed, producing a single transcript consisting of the 18S, 5.8S, and 28S rRNA coding regions (or their homologues), separated by two internal transcribed spacers (ITS-1 and ITS-2) with an external transcribed spacer (ETS) located upstream of the 18S rRNA gene (Fig. 1). The transcribed precursor rRNAs are separated by intergenic spacers (IGS or NTS) consisting of transcribed and nontranscribed spacer sequence. This rRNA cistron is tandemly repeated head to tail at one or more chromosomal sites termed nucleolus organizer regions (NORs) (Hadjiolov 1985). The primary transcript is cleaved via a series of processing reactions into the 18S, 5.8S and 28S rDNAs, which along with approximately 85 ribosomal proteins and 5S rDNA, form the 40S and 60S preribosomal subunits (Hadjiolov 1985).

Regions of the rRNA cistron are under varying degrees of functional constraint and therefore provide a wide range of phylogenetic resolution. The IGS, a noncoding region, is under the least selective constraint and is therefore expected to show the greatest sequence divergence, rendering it useful for intraspecific comparisons. The ITS regions are also rapidly evolving, but to a lesser degree than the IGS. In contrast, the coding region of the rRNA repeat unit, that is, the 18S, 5.8S, and 28S genes, is highly conserved within and among species both in sequence and in secondary structure, with the 18S being the most conservative over a

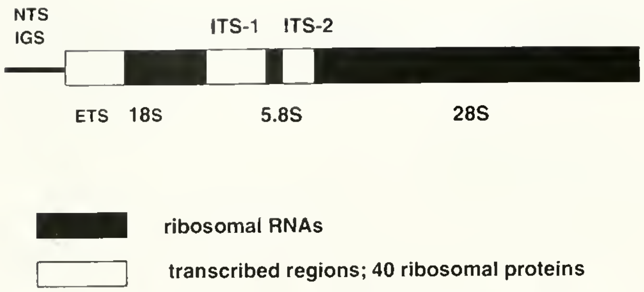

Figure 1. A schematic of the ribosomal RNA (rRNA) cistron indicating the genic regions in black and the noncoding regions in white.

broad taxonomic range (Appels & Honeycutt 1986). However, within the 18S rRNA gene, there are both conserved and variable regions associated with its secondary structure. Although some regions of this gene are conserved across all eukaryotes, other regions (loops) can be highly variable. Therefore, it has been suggested that this gene is valuable for phylogenetic investigations at a variety of taxonomic levels (Sogin et al. 1986), particularly when the time since divergence of the taxa is not known. A similar argument has been made for the much larger 28S rRNA gene (Hillis & Dixon 1991).

Here, we examine the nuclear rRNA cistron for sequence differences in the 18S, ITS-1, 5.8S, and ITS-2 regions to provide additional support for the level of differentiation between *O. angasi* and *O. edulis*. In the course of our studies, novel repeat elements were identified in the ITS which are described and discussed in context of their possible evolution.

MATERIALS AND METHODS

Sample Location

Specimens of *O. angasi* were collected from Cloudy Bay Lagoon, south end of Bruny Island, Tasmania, Australia on June 23, 1993 by Dr. John Thomson and shipped alive to our laboratory. Specimens of *O. edulis* were obtained from Department of Fisheries and Oceans research stock, originally imported from Europe via the United States to Canada during the late 1970s and used as broodstock at a hatchery in Port Medway, Nova Scotia. Animals were dissected and voucher specimens of the shells were archived at the Bedford Institute of Oceanography, Dartmouth, Nova Scotia.

DNA Extraction and Purification

High-molecular-weight DNA was extracted from the adductor muscle of a single animal of each species according to the protocol of Rice and Bird (1990). Briefly, tissue was ground in liquid nitrogen, proteins were removed by mixing with an equal volume of phenol:chloroform:isoamyl alcohol, followed by a final wash with an equal volume of chloroform:isoamyl alcohol to remove the phenol residues, and DNA was precipitated with sodium acetate in cold ethanol. The DNA was further purified on a cesium chloride gradient by high-speed centrifugation.

DNA Amplification

The 18S rRNA gene, ITS-1, 5.8S rDNA, and ITS-2 regions of the rRNA cistron were amplified as two fragments, one approximately 1825 base pairs (bp) and corresponding to the 18S rRNA gene, and the second approximately 1220 bp and containing the ITS spacers and 5.8S sequences. Synthetic oligonucleotides corresponding to conserved regions of the 18S rRNA gene and appended to restriction endonuclease sites were used as amplification primers for the first fragment (Bird et al. 1992). Deoxy-uracil monophosphate (dUMP) primers, with four trinucleotide repeat at the 5′ ends and complementary to the coding strand of the 18S (dUMP 18SF: 5′-CAUCAUCAUCAUGGTTTCCGTAGGTGAACCTGC-3′) and the 28S rDNAs (dUMP 28SR: 5′-CUACUACUACUAATATGCTTAAGTTCAGCGGGT-3′), were used to amplify the second fragment. The change in protocol to the dUMP primers was purely a matter of convenience because these primers were available in our laboratory at the time for another project (i.e., Patwary et al. 1998). Amplification was performed in a Perkin-Elmer (Irvine, CA) DNA Thermal Cycler programmed for an initial cycle of 5 min. at 94°C followed by 30 cycles of 2 min at 37°C, 3 min at 72°C, and 1 min at 94°C, plus a final cycle of annealing for 2 min at 37°C and one of extension for 5 min at 72°C. The same amplification conditions were used for each of the primer pairs and a negative control (no DNA template) was included in each run.

Cloning Polymerase Chain Reaction Products

Amplified DNA containing the 18S rRNA gene was ligated directly into the plasmid sequencing vector pCR 1000 using the TA Cloning™ kit, following manufacturer's instructions (Invitrogen Corp., Carlsbad, CA). Recombinant plasmids were maintained in the OneShot™ *Escherichia coli* INVαF′ cells provided in the kit. Transformants were grown on YT agar plates supplemented with kanamycin (100 μg mL^{-1}) and were detected by blue/white selection in the presence of X-gal and IPTG (Gold Biotechnology, St. Louis, MO).

Amplification products for the second fragment containing the ITS spacers and 5.8S gene generated with the dUMP primers were purified using the Geneclean II™ elution kit (BIO/CAN Scientific, Mississauga, ON). The purified DNA was directionally cloned into Epicurean competent cells (Stratagene, La Jolla, CA) using the CLONEAMP™ System (Life Technologies, Rockville, MD) for rapid cloning of amplification products.

The size of the inserts was screened by protoplasting (Sekar 1987), followed by digestion with *Not*I (New England Biosystems, Mississauga, ON) and *Kpn*I (Pharmacia, Peapack, NJ). A single colony was inoculated into 2xYT medium, following the protocols for a large-scale plasmid preparation (Maniatis et al. 1982).

DNA Sequencing and Alignment

Single clones of purified plasmid DNA containing the 18S rRNA gene were subjected to dideoxy sequencing according to the USB Sequenase version 2.0 protocol (USB Corporation, Cleveland, OH). Amplification primers plus the oligonucleotide primers described in Bird et al. (1992) were used to sequence the complete 18S rRNA gene in both directions. dITP was substituted for dGTP in the sequencing protocol to resolve compressions caused by secondary structure.

Purified DNA containing the ITS spacers and 5.8S rRNA gene was sequenced on an ABI 373 Automated DNA Sequencer, using the PRISM™ Dye Terminator Cycle Sequencing Kit (PE/ABI; Applied Biosystems, Foster City, CA) according to the manufacturer's instructions. M13 universal forward (5′-GTAAAACGACGGCCAGT-3′) and reverse (5′-TTCACACAGGAAACAG-3′) primers (USB) were used for initial sequencing. The DNA was sequenced completely in both directions by using a set of internal

primers that overlapped one another, providing at least 4 and up to 8 sequence streams from separate reactions for most regions of the fragment (Table 1). A consensus sequence from these reactions was produced via the software program Sequencher™ (Gene Codes Inc., Ann Arbor, MI).

Sequences were aligned with CLUSTALW (Thompson et al. 1994) and then checked manually. Repeat regions were identified by visual inspection, and a BLAST search (Altschul et al. 1997) was performed on these elements. Our data were compared with sequences downloaded from GenBank: *Ostrea edulis* 18S rDNA (Accession No. U88709); *Saccostrea commercialis* Iredale & Roughley, 1933, ITS-1, 5.8S rDNA (L28702); *Crassostrea gigas* Thunberg, 1793, ITS-1, 5.8S rDNA, ITS-2 (AF280609, AF280610); *C. nippona* Seki, 1934, ITS-1, 5.8S rDNA (AB041760); *C. cucullata* G.P. Deshayes, 1836, 18S (AJ389634).

RESULTS

Ostrea edulis Versus *O. angasi*

Nucleotide sequences of the rRNA operon, from the 18S rDNA through ITS-2, were similar in *Ostrea edulis* and *O. angasi*. Both the 18S (1823 bp, not shown) and 5.8S (159 bp, Fig. 2) rRNA genes were identical in their entirety. The ITS sequences were also very similar except for a large (81 bp) insertion/deletion in ITS-1 (Fig. 3), so that this sequence was 546 bp in *O. edulis* and 465 bp in *O. angasi*. Otherwise, ITS-1 differed between the species by a single substitution and two short (2-bp) insertions/deletions, while ITS-2 differed by only a single substitution and a 3-bp insertion/deletion, for a length of 476 bp in *O. edulis* and 479 bp in *O. angasi* (Fig. 4).

Further inspection of the ITS-1 sequence revealed the presence of three distinct regions (Fig. 3): (1) a short 5′ end of approximately 110 bp, which contained the single substitution and a 2-bp insertion/deletion; (2) a tract of repeated elements which differed in their number and arrangement between the species but were otherwise nearly identical in sequence; and (3) a post-repeat fragment of approximately 225 bp which had the second 2-bp insertion/deletion. The repeated elements were composed of two subrepeats ($a = 54$ nucleotides and $b = 27$ nucleotides) that occurred in tandem, with *b* always flanked on both sides by *a* (Fig. 4). Whereas the *b* sequences were conserved within and between repeats and between species, the *a* sequences of *O. edulis* showed a point mutation between *a* and *a*′, and a second mutation between *a*′ and *a*″. In *O. angasi*, *a*′ and the second *b* were missing, and the single *b* sequence was flanked at its 3′ end by *a*″ (Fig. 3). In *O. edulis*, the repeat sequence formed the pattern *a*, *b*, *a*′, *b*, *a*″, whereas in *O. angasi* it took the form of *a*, *b*, *a*″.

A 49-nucleotide portion of *a* also appeared in the ITS-2 sequences near the 5′ end (Fig. 4). This element was missing 3 bp at the 5′ terminus and 2 bp at the 3′ terminus, but otherwise differed from *a* in only 2 bp, plus a third bp in *O. angasi* which represented the only point mutation in ITS-2 between the species.

Comparison with Other Oyster Species

Both the 18S and 5.8S rRNA genes displayed considerable similarity with those of other oysters of the genera *Crassostrea* and *Saccostrea*. Our *O. edulis/angasi* 18S rDNA sequence differed from *Crassostrea gigas* (GenBank AB064942) at 43 sites over 1824 bps for 97.6% similarity, and from *Saccostrea cucullata* (GenBank AJ389634) by 49 sites over 1755 bp for 96.5% similarity. However, another sequence of *O. edulis* 18S rDNA from

Figure 3. Nucleotide sequence of the ITS-1 region from the oysters *Ostrea edulis* and *O. angasi*. Asterisks identify points of identical sequence and hyphens indicate points of sequence deletion. Numbers refer to the number of nucelotides from the 5′ end. The 54-bp repetitive element (*a*) is indicated in the *O. edulis* sequence by shading, and nucleotide changes in its second (*a′*) and third (*a″*) iterations are underline; the 24-bp subrepeat (*b*) is outlined.

GenBank (U88709), differed from our *O. edulis/angasi* sequence in 10 sites and was identical with the other oysters at 8 of those sites.

Similarly, the 159-bp 5.8S rRNA genes of *O. edulis/angasi* showed a high degree of similarity with the *Crassostrea gigas* sequence, which differed at only four positions (Fig. 2; 97.5% similarity). Partial sequence from *C. nippona* and *Saccostrea commercialis* was also nearly identical with that of *O. edulis/angasi.*

By contrast, considerable variability was evident among the spacer sequences of the oyster genera (Figs. 4 and 5). None of the other ITS-1 sequences showed repeat elements, and similarity was low in the region corresponding to the *a* and *b* elements. However, the sequences were more conservative in an area coincident with the *a″* repetitive element in *O. edulis* and *O. angasi*. Lacking repeats, the sequences from *Crassostrea* and *Saccostrea* were shorter (445–520 bp) than in *O. edulis* (546 bp), although the length of the *C. nippona* sequence approached that of *O. edulis* because of numerous insertions downstream from the repeat region (Fig. 5). For ITS-2, both *Ostrea* sequences were shorter than that of *Crassostrea gigas*, which was 611 bp (Fig. 4). Overall sequence similarity of the ITS-2 region between the *Ostrea* species and *C. gigas* was on the order of 82%; conserved regions at the 5′ and 3′ ends were identified. In *C. gigas*, the area corresponding to *a* contained six differences from *a* apart from the absent terminal nucleotides, including only one of the two point mutations in the *O. edulis* sequence. A BLAST search (Altschul et al. 1997) on the repeat elements could not identify similar sequence in other organisms.

DISCUSSION

Nuclear ribosomal sequences are often assumed to be homogenized within individuals and populations of a species through concerted evolution processes (Hillis & Davis 1988). Homogeni-

Figure 4. Nucleotide sequence of the ITS-2 region from the oysters *Ostrea edulis*, *O. angasi*, and *Crassostrea gigas* (GenBank Accession Number F280610). Asterisks identify points of identical sequence and hyphens indicate points of sequence deletion/insertion. Numbers are the number of nucleotides from the 5′ end. The segment that corresponds to the repetitive element (*a*) from the ITS-1 region of *Ostrea* is indicated by shading of the *O. edulis* sequence, and the two substitutions within it are underline, as is a third substitution of *O. angasi*.

zation is most likely to occur if the rRNA genes occur in a single tandem array on one chromosome. In both *O. edulis* and *O. angasi*, two NORs are located terminally on chromosome pairs 9 and 10 (Thiriot-Quiévreux & Insua 1992, Li & Havenhand 1997). Additionally, intraspecific variation in the number of NORs per cell and the size (copy number) has also been identified in *O. edulis* (Thiriot-Quiévreux & Insua 1992). From this, one would predict that sequence variation would exceed homogenization. However, sequence divergence in the rRNA genes is very low between *O. angasi* and *O. edulis*.

The sequences for the coding regions of the 18S and 5.8S rDNAs were identical between the *Ostrea* species. This similarity

Figure 5. Nucleotide sequence of the ITS-2 region from the oysters *Ostrea edulis*, *O. angasi*, and *Crassostrea gigas* (GenBank Accession Number F280609). Asterisks identify points of identical sequence and hyphens indicate points of sequence deletion/insertion. Numbers refer to the number of nucleotides from the 5′ end. The 54-bp nucleotide repetitive (*a*) elements in *O. edulis* are indicated by shading of the *O. edulis* sequence. The 27-bp nucleotide repeat (*b*) is outlined on the same sequence.

Figure 6. Partial nucleotide sequence of the 28S rRNA gene showing variable positioning between the oysters *Ostrea angasi* (GenBank Accession Number AF137046) and *O. edulis* (GenBank AF137047) as used by Ó Foighil and Taylor (2000) and as determined by Littlewood (1994).

prompted a re-examination of the partial 28S rRNA gene sequences produced for *O. edulis* by Littlewood (1994) and those cited by Ó Foighil and Taylor (2000) for *O. edulis* and *O. angasi* (deposited in GenBank). The sequences by Ó Foighil and Taylor (2000) show three variable positions between the taxa over 911 nucleotides. However, the Littlewood (1994) sequence for *O. edulis* does not differ from *O. angasi* at those positions (Fig. 6). Therefore, it would appear that *O. angasi* and *O. edulis* may have identical nucleotide sequences for the coding regions of the rRNA cistron given that the partial data from the 28S rRNA gene were taken from the variable domains (D1, D2, D3). The 10-bp difference between the *O. edulis* 18S rDNA sequence of this study and U88709 from GenBank is not considered further as the latter is not published and the methodology used to infer it is not known. The 18S rRNA gene was expected to be the most conserved of the coding regions and therefore is unlikely to differ so greatly within a species.

Variation was detected in the non-coding internal spacer regions. The ITS-1 and ITS-2 both show sequence divergence between *O. edulis* and *O. angasi* irrespective of the repeat elements in ITS-1. However, the differences between *O. edulis* and *O. angasi* in ITS-1 are small compared with those observed between congenerics *Crassostrea gigas* and *C. nippona* (Fig. 5). The major difference between the *Ostrea* species is in the repeat unit of the ITS-1.

Repeat elements in the ITS-1 spacer have been identified previously (Long & Dawid 1980), including those with the same subrepeat pattern (*a, b, a*), (van Herwerden et al. 1999). However, it is not known if the repeating elements in these oysters have a function. Those found in the IGS region of both *Drosophila melanogaster* (Kohorn & Rae 1982) and *Xenopus laevis* (Moss 1983) have an influence on the level of transcription (Busby & Reeder 1983, Grimaldi & Di Nocera 1988). The ITS-1 region has an ability to form ribonucleoprotein complexes with cellular proteins and this domain is critical to the efficient maturation of the precursor RNA (Lalev et al. 2000). It is likely that the repeat element in *Ostrea* will have some effect on transcription. The secondary structure formed in *O. edulis* is more thermally stable than that of *O. angasi*. Further, the conserved nature of the base repeat and the repetition of the *a* element in the ITS-2 strengthens the case for functionality of these elements.

In other parts of the genome, repeat regions commonly arise through a preferential gain of a few repeat units at one end of the tandem repeat array, generating a minisatellite sequence (Jeffreys et al. 1994). Slip-stranded mispairing (Levinson & Gutman 1987) is commonly proposed as a model for VNTR repeat formation, expansion and contraction. Chance mutations are necessary for repeat expansion and these produce a few tandem repeats that facilitate the first strand slippage event (Messler 1996, Taylor & Breden 2000). However, different mechanisms may be responsible for the formation of repeats with motifs longer than 5 bp (Jeffreys et al. 1994). Taylor and Breden (2000) have described a general model for minisatellite birth that results in the formation of a locus with long repeats flanked by one unit of the original noncontiguous repeat. The appearance of differently sized repeats in the ITS-1 of *O. edulis* and *O. angasi* can be most expeditiously explained by unequal or misaligned crossing over. Depending on the ancestral configuration, the *a′*, *b* pair has been either lost or gained in one of the two taxa since their geographic separation.

The implication of these data is that *O. edulis* and *O. angasi* are conspecific as suggested by Jozefowicz and Ó Foighil (1998). These findings parallel the example of *Saccostrea commercialis* and *S. glomerata* (Anderson & Adlard 1994), in which the taxa are morphologically similar, yet geographically separated, with identical flanking 18S, ITS-1, and 5.8S regions. Although *O. angasi* and *O. edulis* have identical coding regions, some variation was detected in the ITS-1 and in the ITS-2, primarily through the deletion of repeat elements in *O. angasi*. However, this level of spacer variability is minor compared with that observed among the *Crassostrea* species.

As with the *Saccostrea* species studied by Anderson and Adlard (1994), the species in this study are also geographically separated. *Ostrea angasi* is found in Australia, from Western Australia along the southern coast to Tasmania and north along the east coast to the Clarence River in New South Wales (Thomson 1954). *Ostrea edulis* is mainly European, occurring from Norway to Morocco, including the Mediterranean Sea and the Black Sea (Carriker & Gaffney 1996). As put forward by Jozefowicz and Ó Foighil (1998), this incongruity can be explained by undocumented anthropogenic transport. Although *O. angasi* is widespread in Australia, it is not common throughout its range (Thomson 1954) and its distribution is centered around the area first colonized by Europeans. Such a scenario would suggest that the ITS-1 of *O. angasi* underwent a deletion of the *a′*, *b* region in the approximately 200–300 y after the transfer of *O. edulis* to Australian waters. However, as only one individual of each *Ostrea* species was sequenced, we do not know whether the number of repeats in the ITS-1 varies intraspecifically. Further investigation into intraspecific variation in the ITS-1 may identify a European locale from which *O. angasi* originated and evolved. Closer examination of late Pleistocene deposits at the Largs site in the Lower Hunter Valley, New South Wales, which reportedly contain specimens of *O. angasi*, may also shed some light on this question. In the interim, we submit that *O. edulis* and *O. angasi* are conspecific.

ACKNOWLEDGMENTS

We thank Dr. John Thomson (then of HOTAC, Hobart, Tasmania, Australia) for sending specimens of *O. angasi*. We also thank Dr. P. T. O'Reilly and B. Vercaemer (Bedford Institute of Oceanography) for providing useful comments during the preparation of this manuscript. This is NRCC 42365.

ULTRASTRUCTURAL AND HISTOCHEMICAL CRITERIA FOR DETERMINING NORMALITY IN MATURE OOCYTES OF THE PACIFIC OYSTER *CRASSOSTREA GIGAS*

MARIA EUGENIA VALDEZ-RAMIREZ,[1]* ANNE DONVAL,[2] AND MARCEL LE PENNEC[2]

[1]*Centro de Investigaciones Biológicas del Noroeste, S. C. (CIBNOR) – Programa de Acuicultura Marina, P. O. Box 128, La Paz, B. C. S., 23000, México;* [2]*Institut Universitaire Européen de la Mer (IUEM) – UMR CNRS 6539 Technopole Brest-Iroise, 29280, Plouzané, France*

ABSTRACT In hatcheries of bivalve molluscs, female gametes are assessed according to the morphologic stages of oocytic development. Three stages of oocytes immature, mature, and overripe were studied. We identified each category, based on ultrastructural features of the vitelline coat, cytoplasmic membrane, and organelles. Vitelline inclusions in the ooplasm were identified by ultrastructural and histochemical methods. Cytologic alterations involved in the typical degenerative process of mollusc oocytes were observed, including initial damage in the cytoplasmic membrane, rupture and degeneration of the vitelline coat, and damage in ooplasm and vitelline globules. All of these characteristics seem to be associated with the natural process of oocytic degeneration, but they can also be the consequence of handling during reproduction by artificial means.

KEY WORDS: oocyte, ultrastructure, histochemistry, *Crassostrea gigas*, reproduction

INTRODUCTION

Poor quality of gametes is believed to be one of the main causes of irregularities of embryonic and larval development in bivalve mollusc hatcheries (Raven 1966, Galtsoff 1964, Dohmen 1983, Wilson et al. 1996, Gérard et al. 1997, Le Pennec et al. 1998). In aquaculture, the quality of the gametes is defined by its capacity to be fertilized and consequent development of a viable larva (Kjorsvik et al. 1990). Morphologic criteria are commonly used for identification of female gametes of good quality. Three types of oocytes can be identified at spawning: mature oocytes with a round form and healthy appearance, immature oocytes with a pear shape and heterogeneous appearance, and overripe or atretic oocytes (Dorange & Le Pennec 1989, Paulet et al. 1992). This is a simple, quick, and inexpensive method. Nevertheless, these criteria are not sufficient to assess the viability of spawnings of *Crassostrea gigas* (Valdez-Ramirez et al. 1999). Results obtained from hatchery production reveal great variations that do not correlate with the amount of mature or normal oocytes. Germ cells maturation can be disturbed by multiple endogenous and exogenous factors in bivalve molluscs (Pipe 1987, Dorange & Le Pennec 1989, Paulet et al. 1992). A visual inspection does not confirm that mature oocytes will develop after fertilization.

Daniels et al. (1973) described the normal and abnormal characteristics of female gametes of *Crassostrea virginica* in the cytoplasm components, in particular, yolk granule distribution. This study suggests that knowledge of the gamete cytology is significant to evaluate the reproductive capability of the species. For *Pecten maximus*, Dorange and Le Pennec (1989) described, by means of transmission electron microscopy (TEM), the ultrastructural features in the stages of oocyte development and the natural process of oocytic degeneration. These authors showed that, at the ultrastructural level, cytologic alteration could be observed in the plasmic membrane, nuclear envelope, and mitochondria that were not detectable by gross morphologic observations.

The main purpose of this study is to address some questions related to the quality of the oocytes of *C. gigas*. Specifically, we tried to identify and describe the cytologic and cytochemical anomalies that most commonly affect the viability and quality of female gametes.

MATERIALS AND METHODS

Samples of *Crassostrea gigas* (Thunberg 1793) were obtained from the Bay of Brest, Brittany, France during its natural spawning period, June and July. Oocytes were obtained by draining of gonads. The oocytes were kept in seawater for one hour to recover their shape, as they are compressed in the gonads. Some gametes were fertilized to obtain embryos and larvae. Fragments of gonads of different specimens were also used in this study.

Sample Preparation for Transmission Electron Microscopy

Samples (oocytes, embryos or fragments of gonads) were fixed for one hour in 2.5% glutaraldehyde buffered with 0.2 M sodium cacodylate adjusted to 1100 mOsm and pH 7.2 (Cross & Mercer 1993). Postfixation was completed in 1% OsO_4 using the same buffer for 60 min at 4°C. The samples were rinsed, followed by progressive dehydration in ethanol baths (70%, 95%, and 100%). They were embedded in resin (Spurr 1969). Resin polymerization was completed at 60°C for 48 h.

Semi-thin (1 μm) and ultrathin (60–70 nm) sections were cut with glass and diamond ultramicrotome knives (Ultracut-S Leica) according to the method of Cross and Mercer (1993). The semi-thin sections for study under light microscopy were stained with 0.5% toluidine blue. The ultrathin sections were contrasted with uranyl acetate and lead citrate stains (Reynolds 1963). Observations of ultrathin sections were made with a Transmission Electron Microscopy (TEM) (JEOL 100 Cx). In addition, a few semi-thin sections were also treated using techniques for the identification of vitelline globules.

Detection of Lipids

Before postfixation, some samples of oocytes were treated in a solution of methanol-chloroform (1:1) at 60°C for 12 h to extract the lipids (E samples). They were postfixed using the same procedure described above. The identification of the lipid globules was made by comparing sections from the same batch of oocytes from which lipids were not extracted (NE samples).

Detection of Proteins

The study of basic proteins was made on semi-thin sections treated with the 1.5% periodic acid at 40°C for one hour. They were stained by Ponceau 2r at 40°C for 3 h (Gori 1977). The protein globules revealed by staining were compared with the inclusions observed in ultrathin sections of samples from the same batch, by size, form, and their location in the cytoplasm of the oocyte.

Detection of Corbohydrates

The characterization of carbohydrate reserves in the oocytes was obtained by a PAS reaction (Periodic acid-Schiff) (Gabe 1968). Negative "glycogen" controls were prepared with amylase at 37°C for 3–6 h. After several rinses, these sections were treated at the same time as the positive glycogen controls.

RESULTS

Mature Oocyte

Mature or normal oocytes, measuring from 60 to 65 μm, contain a bulky nucleus (Fig. 1: 1). The germinal vesicle, in the prophase of first meiotic division, shows regular contours, approximately 25 μm in diameter. The nucleolus, when visible, is generally eccentrically located. Nuclear pores are sometimes observed. The cytoplasmic membrane bear numerous regular microvilli embedded in a vitelline coat (oolemma) (Fig. 1: 2). The fibrillar structure of the vitelline coat appeared highly electrondense at the periphery (Fig. 1: 2). This was observed in all the samples of unfertilized (Fig. 1: 2) oocytes and in those still in place in the gonad (Fig. 1: 1). Observations made of the vitelline coat ultrastructure in oocytes before fertilization (Fig. 1: 2), at the moment of fertilization (Fig. 1: 3), and 3 h after fertilization (Fig. 1: 4) showed no real differences in electron-density. The perivitelline space is sometimes visible between the vitelline coat and the plasmic membrane (Fig. 1: 5).

In the cytoplasm, mitochondria, endoplasmic reticulum, and many vitelline inclusions are visible (Fig. 1: 5). Mitochondria are very common and are distributed homogeneously. Their size is variable, the longest measuring approximately 0.5 μm. The lamellae of the endoplasmic reticulum are not abundant in the cytoplasm. Cisternae of endoplasmic reticulum are sometimes visible in the vicinity of the mitochondria. Some dictyosomes are also present.

Cytoplasmic inclusions accumulated during vitellogenesis are numerous and are varied in types. They occupy the larger part of the cytoplasm, differing in size, form, and density. By coupling ultrastructure study with cytochemical observations, the chemical nature of the inclusion was identified. Three types of inclusions were detected (Fig. 2: 1 to 8) and are described in the following three sections.

Type I, Lipid Inclusions

On semi-thin sections of the NE samples, the lipid inclusions (stained with Sudan black) occupy the larger part of the cytoplasm, and their distribution is homogeneous (Fig. 2: 1). At the ultrastructure level, comparison of the samples with or without lipid extraction (Fig. 2: 2 and 2: 3), shows that these compounds correspond to the largest inclusions, reaching a diameter of approximately 1 μm. Their contour is regular and, in most cases, they are enclosed by the granular endoplasmic reticulum. A higher electron density in the center than at the periphery characterizes these inclusions (Fig. 2: 2).

In several NE samples, the lipid globules were partially or completely absent (Fig. 2: 4 and 5).

Type II, Glycoprotein and Carbohydrate Inclusions

Round organelles, from 0.2 to 1 μm in diameter, are surrounded by a membrane. The homogeneous contents are visible in ultrathin sections. They may be dispersed in the cytoplasm, but they are mainly present at the periphery (Fig. 2: 5). The distribution and location of these reserves in ultrathin sections correspond to positive PAS reaction (Fig. 2: 6) and to the globules stained pink by Ponceau 2r (Fig. 2: 8) on the semi-thin sections. This suggests that type II inclusions are glycoproteinaceus in nature.

Glycogen detection by comparison between PAS staining in semi-thin sections (Fig. 2: 6) and the negative control (Fig. 2: 7) does not allow clear observation of this compound in the mature oocyte. However, we note a slightly more intense staining on oocytes untreated with amylase, which suggests the presence of glycogen.

Type III, Lysosome Inclusions

Distribution and occurrence of the lysosome inclusions detected by Ponceau 2R (Fig. 2: 8), are comparable way as type II inclusions. Certain differences were observed in MET. Type III inclusions are an irregular structure, and their location is unusual. They are provided with a single external membrane. They are heterogeneous in size, form, and electron density (Fig. 1: 2 and 1: 5) and always abundant, with a maximum size comparable to the lipid inclusions. Their heterogeneity contrasts with other inclusions of relatively homogeneous forms.

Ultrastructure Anomalies of the Oocytic Degeneration

Different degenerative alterations are observed (Fig. 3: 1 to 5). Degeneration in the female gamete can present a large increase of the perivitelline space (Fig. 3: 1 to 3) and a dilatation of the base of the microvilli. In some cases, the vitelline coat is detached and no microvilli are seen at the periphery (Fig. 3: 4). In the cytoplasm, mitochondria seem to be the first oocytic organelles involved in the degenerative processes (Fig. 3: 3). Other vitelline inclusions can also deteriorate, but lysosome bodies stay intact (Fig. 3: 4 and 5). The most severe damage observed in the cytoplasm include large vacuoles enclosing the vitelline bodies and cytoplasmic components, which are degraded to a lesser or greater level and forming dense globular masses. At this stage, intact lysosomal bodies are common (Fig. 3: 5).

Other Cytologic Alterotions

In some cases, mainly in free oocytes, the vitelline coat can be partially or completely detached from the plasmic membrane (Fig. 4: 1 and 2). In addition, the rupture of the plasmic membrane is sometimes seen (Fig. 4: 3), but the contents of the mature oocyte are not degraded.

DISCUSSION

Mature oocytes of *C. gigas* are comparable to those in other bivalve mollusc species, such as *Spisula solidissima* (Longo & Anderson 1970a, Longo & Anderson 1970b), *C. virginica* (Daniels et al. 1973), and *Pecten maximus* (Dorange & Le Pennec 1989, Devauchelle et al. 1997). In oocytes of *C. gigas*, the vitelline coat

structure seems different because of the tightness of the fibrillar net at the periphery. In this study, we did not detect modifications of the vitelline coat after fertilization, as observed in other bivalve molluscs: *Pecten maximus* (Dorange et al. 1989, Casse, 1995), *Mytilus edulis* (Humphreys 1962), other invertebrates, (Dohmen 1983, Epel et al. 1984, Pashchenko & Drozdov 1998), or in fish (Yemel'yanova 1980, Kjorsvik et al. 1990). In these species, cortical granules take part in the formation of the fertilization membrane. It is recognized that this membrane is a barrier that prevents polyspermy, but most molluscs apparently do not form a fertiliza-

tion membrane. The precise mechanism for preventing polyspermy is not clearly understood (Dohmen 1983). The formation of this membrane in oocytes of *C. gigas* could be explained as a specific reaction (Thierry & Rambourg 1974).

Three types of vitelline inclusions were identified in the mature oocytes of *C. gigas*. Lipid inclusions, type I are abundant and easily locatable globules in the cytoplasm because of their homogeneous form. We observed a partial or total vacuolization of the contents of these globules in some oocytes. Vacuolization is not the result of extraction from an extended period of dehydration in ethanol because, in the same batch of oocytes, one finds normal oocytes. If a technical problem is excluded, the assumption is that this is a variable state in the maturity of oocytes. Steele (1998) shows comparable modifications of these globules that coincide with other deteriorations in the cytoplasm. Dorange (1989) shows that the density of lipid inclusions can be correlated to the stage of

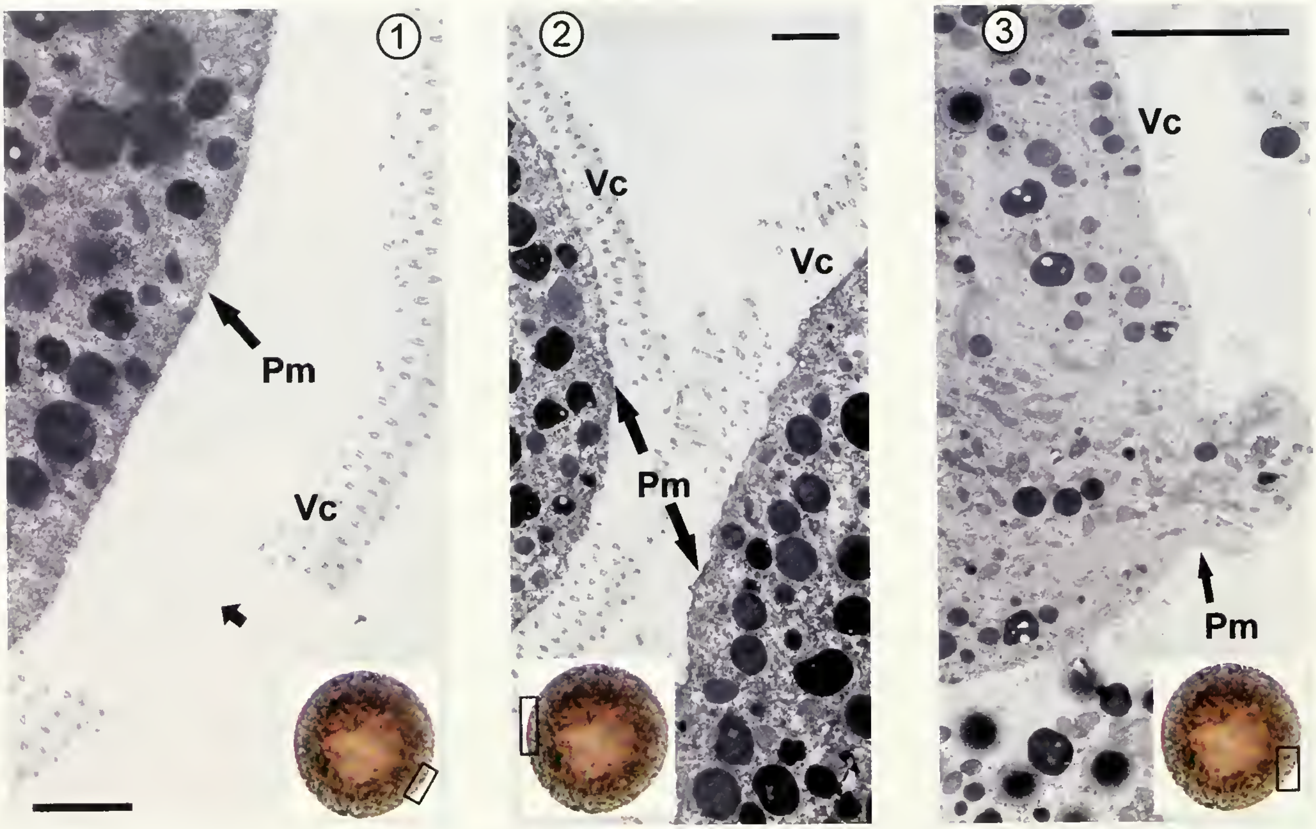

Figure 4. Other ultrastructural anomalies of the oocytes (1) Rupture of vitelline coat in mature oocytes. Plasmic membrane is not broken. Cytoplasm and vitelline inclusions are not modified its normal aspect. Scale: 1 µm. (2) Another example of the rupture of vitelline coat in mature *C. gigas* oocytes. Scale: 1 µm. (3) Rupture of the vitelline coat and plasmic membrane in mature *C. gigas* oocytes can take place at the gonad. In the cytoplasm, the organelles are intact. Cellular remains are observed between the oocytes. Scale: 5 µm. Legend: Vc, Vitelline coat; Pm, Plasmic membrane.

oocytic maturity in *P. maximus*. This also seems to be the case for *C. gigas*.

Lipid inclusions with a granular contour have been described in several species of bivalves such as *C. virginica* (Daniels et al. 1973), *C. gigas* (Steele 1998), and gastropods such as, *Ilyanassa* spp. (Gérin 1976) and *Acmaea* spp. (Kessel 1982). Daniels et al. (1973) and Steele (1998) suggest that it could be lipoprotein granules associated with the endoplasmic reticulum.

Glycoprotein was detected in type II inclusions that were stained by the protein and carbohydrate specific reaction in semi-thin sections. This type of inclusion has been noted in *C. virginica* (Daniels et al. 1973) and in the mussel *Mytilus edulis* (Albertini 1985). Positive staining by PAS in semi-thin sections seems to confirm the presence of glycogen. However, this must be checked at the ultrastructural level (reaction, Thierry & Rambourg 1974, for example). According to Tazawa et al. (1985) and Tazawa et al. (1986), these reserves represent the first source of energy during the first modifications in embryonic development of *C. gigas*.

Type III vitelline inclusions suggest lysosomal bodies. The presence of hydrolases (lysosomal enzymes) has been demonstrated in cytoplasmic globules oocytes of bivalves: *P. maximus* (Lubet et al. 1987, Dorange & Le Pennec 1989, Casse 1995), *Rangia cuneata* (Marsh et al. 1981), *Mytilus edulis* (Pipe & Moore 1985), and the gastropod *Littorina littorea* (Moore et al. 1982). Based on multiple observations, lysosomal bodies that are present during the degenerative stage of *P. maximus* oocytes were clearly identified by Lubet et al. (1987). Since its enzymatic activity is demonstrated, its presence in the oocytes of *C. gigas* must reveal different functions because it is always identifiable in the mature and degenerative stages.

The main causes of the poor viability of the gametes detected in the present study are related to the oocytic degenerative process. This is a phenomenon usually described in studies of the reproduction of fish, invertebrates in general, and the bivalve molluscs in particular (Lubet et al. 1987, Dorange et al. 1989, Paulet 1990, Ntiba et al. 1992, Sarojini et al. 1994, Widowati 1994, Steele 1998). Some serious alterations can be identified by direct examination of the samples using optical microscopy, but initial damage cannot be detected by means of morphologic observation. Ultrastructural techniques allow observation of different stages of degeneration. The first modifications involving the vitelline coat and plasmic membrane do not modify the form of the oocyte, which suggest that these gametes are not excluded during a morphologic examination. When degradation reaches the cytoplasm, oocyte shape is not modified in all cases. Therefore, damage may not be detected by simple microscopic observation.

It is important to mention that, according to our observations, this last stage does not seem to correspond to the same process of degeneration as the preceding one, but this cannot be confirmed now. First, damages may indiscriminately affect the periphery of gametes. Second, damage orients itself only to the content of the organelles, not to the periphery. These vacuolization already have been described in the typical oocytic degeneration process for bivalve molluscs *P. maximus* (Lubet et al. 1987, Dorange & Le

Pennec 1989), *Mytilus edulis* (Pipe 1987), and *Pinna nobilis* (De Gaulejac et al. 1995). In these species, modification coincide with degeneration of the vitelline membrane. This is not the general case observed. A study following oogenesis and oocytic lysis by ultrastructure techniques is required to explain this difference. The only morphologically identifiable degenerative stage corresponds to a severe degree of damage. In this stage, vitelline inclusions and organelles are grouped without order and they are degraded, forming masses of different density in cytoplasm. This causes important modification of the mass, density, and gamete form.

Another cytologic damage that obstructs larval development has been demonstrated in this study. It is the breaking of the vitelline membranes, without apparent alterations in cytoplasm. These damages are probably caused during the collection and handling of the gametes, but it is not possible to be certain that these damages are revealed in the oocyte morphology.

In conclusion, this study demonstrates that oocytes with normal external appearance can, in fact, display biochemical deficiencies or irreversible and lethal cytologic damages. These anomalies can explain the poor development of embryos and larvae. Although observation of these defects is difficult, its detection and quantification in light microscopy is possible by means of the Trypan blue exclusion test, as studied by Valdez–Ramirez et al. (1999) for oocytes of this species.

AN INTRINSIC MEMBRANE PROTEIN IN OYSTER SPERM STIMULATES SPAWNING BEHAVIORS IN *CRASSOSTREA VIRGINICA*: IMPLICATIONS FOR AQUACULTURE

PATRICK RICE,[1] SAMMY M. RAY,[1] SHERRY D. PAINTER,[2] AND GREGG T. NAGLE[2]*

ABSTRACT Pheromones are thought to play a critical role in triggering spawning in oysters, but none have been identified to date. Male and female oysters are stimulated to spawn by oyster sperm. Male oysters are also stimulated to spawn by oyster eggs, but females are not. Earlier studies suggest that the spawning activity associated with sperm may be membrane-bound. As a first step toward isolating and characterizing a spawning pheromone in sperm of the oyster *Crassostrea virginica*, we used: (1) an extraction and purification procedure for preparing oyster sperm membranes; (2) a method to selectively remove extrinsic sperm membrane-associated proteins; and (3) a bioassay to monitor the robust, repetitive adductor muscle contractions that occur concurrently with oyster spawning. This report presents evidence that the candidate oyster sperm pheromone is a heat- and trypsin-sensitive intrinsic membrane protein. A synthetic or recombinant fragment of the pheromone could be used in the aquaculture industry to induce spawning in oysters.

KEY WORDS: bivalve, *Crassostrea virginica*, mollusk, oyster, pheromone, sperm

INTRODUCTION

Spawning in the oyster, *Crassostrea virginica* Gmelin, has been known to be a group reaction for more than a century and involves the release of sperm and eggs by a number of oysters. Although spawning in *C. virginica* can be influenced by a seasonal rise in water temperature, male and female oysters are more readily stimulated to spawn by oyster sperm; male oysters are also rapidly stimulated to spawn by oyster eggs (Galtsoff 1938b). Sperm can induce spawning in oysters that do not respond to increased temperature stimulation. For example, approximately 55% of oysters that failed to react to increased temperature spawned immediately upon addition of sperm (Galtsoff 1938b). A minimum concentration of ~100–150 sperm per milliliter of seawater will induce an all-or-none spawning reaction that cannot be inhibited or stopped once it has begun. In physiologically ripe females, the presence of oyster sperm normally initiates ovulation and rhythmic contractions of the adductor muscle, and the latent period to spawning is relatively independent of the concentration of sperm (Galtsoff 1930, Galtsoff 1938b). In males, the latent period to spawning is usually shorter compared with females (Galtsoff 1940).

The active factor(s) that stimulates spawning in *C. virginica* is associated with the sperm and is not a soluble factor released with sperm (Galtsoff 1938b). As a first step toward characterizing the active factor in oyster sperm responsible for stimulating male and female oysters to spawn, we employed a simple extraction and purification procedure for preparing oyster sperm membranes, a method to selectively remove extrinsic sperm membrane-associated proteins, and a bioassay to monitor adductor muscle contractions that normally occur concurrently with oyster spawning.

A major obstacle to purifying and characterizing the factor(s) responsible for spawning in *C. virginica* is that spawning is restricted to a relatively brief reproductive season, and the year-round bioassay of sperm membrane fractions has not been possible. Therefore, a bioassay was used based on the observation that oysters initiate a series of strong, rhythmic contractions of the adductor muscle in response to sperm entering the mantle cavity via the incurrent siphon (Galtsoff 1938a, Galtsoff 1938b). In ripe females, this vigorous and repetitive clamping of the shells normally results in the ejection of a cloud of eggs to a distance of 30 cm or more. This activity is thought to result in a relatively wide and uniform distribution of eggs, improving their chances of fertilization by sperm. In this report, we present evidence that the oyster sperm factor(s) that stimulates the vigorous and repetitive adductor muscle contractions observed concurrently with spawning is a heat- and trypsin-sensitive intrinsic membrane protein.

MATERIALS AND METHODS

Animals

For tissue extractions, oysters (*Crassostrea virginica*) were collected from April to June 2000 and 2001 from Galveston Bay, Texas.

For bioassays, animals were collected from Galveston Bay year-round and temporarily kept on ice; the shell height ranged from approximately 38 to 52 mm. To avoid rapid increases in temperature that could induce spawning, oysters were first acclimated to room temperature (20–22°C) out of water and cleaned to remove external biofouling. Approximately 60 oysters were subsequently transferred to individually numbered clear glass, screw top beakers with lids (Qorpak; Fisher Scientific) containing 500 mL of artificial seawater (ASW; Instant Ocean®, Aquarium Systems, Mentor, OH) at 25 ppt (20–22°C), and acclimated for at least 12 h prior to bioassays. Containers were continuously aerated by an in-house air system using a pipette projecting through a hole in the beaker lid. Oysters that were used in bioassays in late summer and early fall were potentially ripe but may have spawned out, whereas those collected at later times were probably completely spawned out. The majority of bioassay animals used in these studies were presumed to be males since the largest oysters, which are typically females, do not fit into the beakers.

Tissue Extraction and Purification of Oyster Gonad Membranes

The entire visceral mass was removed from sexually mature *C. virginica*, and most of the associated mantle, gill, and palp tissue were excised; the sex was determined by microscopic observation of gametes, and male gonads were stored at −70°C until they were used. A flow diagram showing the extraction and purification

scheme is shown in Figure 1. The amount of visceral mass tissue used (range: 3.0–9.5 g) was sufficient to: (1) purify an excess amount of sperm membranes; and (2) obtain maximal responses in the bioassay. Visceral mass tissue was homogenized in 100 mL of ice-cold Buffer A (20 mM Tris-HCl, 2 mM ethylenediaminetetraacetic acid [EDTA], 1 mM phenylmethylsulfonyl fluoride, pH 7.4) using a Polytron homogenizer (Brinkmann), and centrifuged for 10 min at 5,000 × *g* (4°C). The resulting low-speed P1 pellets were resuspended by brief homogenization in 7.5 mL of Buffer A and centrifuged for 10 min at 5,000 × *g* (4°C). The combined low-speed S1 supernatants were subsequently centrifuged for 60 min at 100,000 × *g* (4°C) to generate high-speed P2 pellets (membrane fraction) and S2 supernatants.

Extraction of Extrinsic Membrane Proteins Using Sodium Carbonate

The standard procedure used to selectively remove extrinsic proteins from membranes using sodium carbonate (pH 11.5) was essentially that described by Fujiki et al. (1982). P2 pellets containing male gonad membranes were resuspended by brief homogenization in 30 mL of ice-cold 0.1 M sodium carbonate (pH 11.5) and incubated for 30 min on ice. Each sample was subsequently layered on a 3 mL cushion of 0.3 M sucrose, 10 mM Tris-HCl, pH 7.4 in an ultracentrifuge tube and the membranes were pelleted by centrifugation for 60 min at 150,000 × *g* to generate high-speed P3 pellets (containing intrinsic membrane proteins) and S3 supernatants (containing extrinsic membrane proteins) (Fig. 1). These were stored at 4°C. P3 pellets were resuspended by brief homogenization in ASW (25 ppt) immediately prior to bioassay.

In some experiments, P3 pellets were heated at either 68°C (30 min) or at 100°C (10 min) prior to bioassay.

Reduction, Alkylation, and Trypsin Digestion

To break the disulfide bonds in sperm intrinsic membrane proteins present in the P3 pellets, a procedure was used for denaturation, reduction and alkylation of proteins with 4-vinylpyridine (4-VP) that was essentially that described by Coligan et al. (1997).

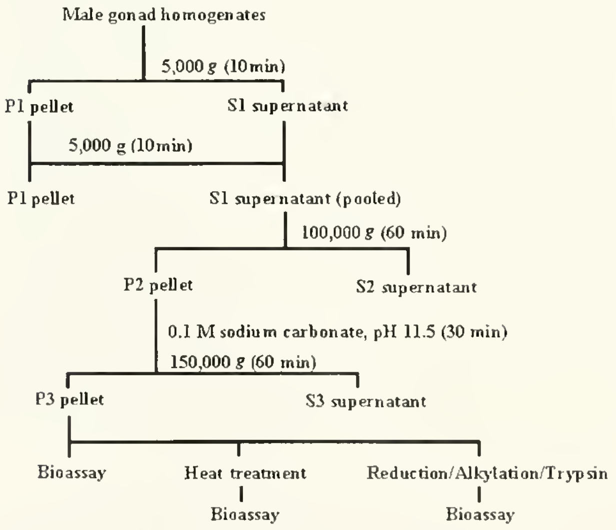

Figure 1. Flow diagram of the extraction and differential centrifugation procedures used to purify membrane fractions from male *Crassostrea virginica* gonads. The P3 pellets that were enriched in sperm membranes were either bioassayed directly or treated further and then bioassayed.

P3 pellets containing male gonad membranes were gently homogenized in 10 mL of ice-cold denaturing buffer (6 M guanidine-HCl, 0.5 M Tris-HCl, 2 mM EDTA, pH 8.2) to obtain a well-dispersed suspension, and the solution was bubbled with N_2 gas at room temperature (20–22°C) for 15 min. Following addition of 2-mercaptoethanol and incubation for an additional 30 min, 4-VP was added to the solution and incubated in the dark for 60 min. The reduced and alkylated samples were then dialyzed (Slide-A-Lyzer Dialysis Cassette; 10 kD MW cutoff; Pierce) against 0.5 M NaCl overnight at 4°C. The dialysate was subsequently digested with trypsin (Type III; Sigma; 37°C for 24 h) by established methods (Coligan et al. 1997) and bioassayed.

Bioassays

Due to the brevity of the reproductive season, most shell closure assays were performed when oysters were either partially or completely spawned out. Shell closure assays were performed on oysters whose valves were open and mantles were extruded, suggesting that filtration was occurring. Beaker lids were carefully removed to permit sample addition, and aeration was maintained throughout the assays. P3 pellets were resuspended by brief homogenization in 10 mL ASW (25 ppt), and 1.0-mL aliquots (i.e., one-tenth of one resuspended P3 pellet) were injected proximal to the incurrent siphon of oysters, and each vigorous closure of oyster valves was visually monitored during the subsequent assay period.

Additional experiments performed outside of the reproductive season specifically examined whether P3 pellets also stimulated at least minimal spawning in addition to shell closure. Oysters were initially observed for 5 min prior to injection of samples and the number of shell closures was recorded; oysters that exhibited large numbers of spontaneous shell closures prior to bioassays were not used. Following addition of sample (resuspended P3 pellet fractions), the number of shell closures was recorded, and material that was ejected during the 20-min period was examined microscopically for the presence of eggs or sperm. Since sperm are released through the excurrent siphon whereas eggs are released through the incurrent siphon, the direction of gamete release was noted. When spawning was detected visually and microscopically, oysters were subsequently sacrificed and the sex was confirmed by examining gonad smears for the presence of sperm or eggs.

Statistics

For each bioassay animal, the number of shell closures was determined, and the mean (± $S_{\bar{x}}$) for all replicates was calculated. The null hypothesis of equal means ($H_0 = \mu_1 = \mu_2 = \ldots \mu_5$) was tested using an F statistic generated during an analysis of variance (ANOVA) to determine whether a comparison of treatment sample means was valid. If the null hypothesis was rejected, then a multiple comparison of the treatment sample means was accomplished using a Fisher's protected least-square-difference (Fisher's PLSD) post-hoc analysis.

RESULTS

To confirm and extend previous observations by Galtsoff (1938b), freshly isolated sperm were diluted in ASW and found to stimulate a series of shell closures (shell clapping events; ≥4 in 5 min) in all cases (n = 3/3), as expected. Furthermore, when freshly isolated sperm were snap-frozen on dry ice, thawed, and assayed, the thawed sperm were still capable of stimulating a series of shell closures (range: 2–4 in 5 min) in all cases (n = 4/4).

Importantly, these observations suggest that the factor(s) that stimulate shell closure activity during spawning are resistant to at least one cycle of freezing and thawing. This suggests that male gonads could be dissected and stored at −70°C during the reproductive season and thawed for experiments at a later date. After selective removal of extrinsic membrane proteins from freshly isolated sperm, aliquots of resuspended high-speed P3 pellets containing intrinsic membrane proteins were assayed. The P3 material (1 mL = 10% of total sample) stimulated shell closure activity (range: 3–4 in 5 min) in 7 of 9 oysters (78%), whereas aliquots of high-speed S3 supernatants (10% of total volume) containing extrinsic membrane proteins stimulated shell closures in only 2 of 11 assays (18%). When male gonad tissue that had been frozen at −70°C for more than six months was subjected to the same purification procedure, that is, extraction and selective removal of extrinsic membrane proteins followed by differential centrifugation, similar results were obtained: resuspended P3 pellets (1 mL = 10% of total) stimulated vigorous, repetitive shell closures (range: 3–10 in 5 min) in 8 of 9 assays (89%). The data indicated that the activity was due to an intrinsic membrane factor(s) and not to extrinsic membrane proteins. In control experiments, the solution that was used to strip extrinsic proteins off of membranes (0.1 M sodium carbonate, pH 11.5) did not stimulate shell closure responses in any oysters ($n = 21$).

A 20-minute bioassay period was used in all subsequent shell closure bioassays. The number of shell closures in control assays using ASW was 1.2 ± 0.35 (mean ± $S_{\bar{x}}$; $n = 32$ oysters tested; Fig. 2A). After selective removal of extrinsic membrane proteins from male gonad membranes, 1-mL aliquots of resuspended P3 pellets (12 mg protein/mL; 10% of total sample) were found to stimulate an average of 10.8 ± 3.8 (mean ± $S_{\bar{x}}$; $n = 60$ oysters tested) shell closures within 20 min (Fig. 2B). After resuspended P3 pellets (12 mg protein/mL) were heated at 68°C for 30 min, the number of shell closures was not significantly different (11.4 ± 3.4; mean ± $S_{\bar{x}}$; $P = 0.82$; $n = 5$ oysters tested; Fig. 2B). However, when resuspended P3 pellets (12 mg protein/mL) were heated at 100°C for 10 min, the number of shell closures decreased by 41% (6.4 ± 1.7; mean ± $S_{\bar{x}}$; $P < 0.05$; $n = 10$ oysters tested; Fig. 2B). To test whether the active factor(s) was a protein, P3 pellets were resuspended in denaturation buffer, reduced and alkylated, dialyzed, and digested with trypsin; in this case, the number of shell closures decreased by 68% (3.5 ± 0.8; mean ± $S_{\bar{x}}$; $P < 0.0001$; $n = 58$ oysters tested) (Fig. 2B).

Additional experiments that were performed outside of the reproductive season, when the majority of animals had presumably already released most or all of their spawn, examined whether P3 pellets also stimulated detectable spawning in addition to shell closure. After selective removal of extrinsic membrane proteins from male gonad membranes, aliquots of resuspended P3 pellets were observed to stimulate spawning in three males ($n = 3$ of 80 experiments). In each case, sperm were released through the excurrent siphon and were visualized microscopically. These results suggested that an intrinsic sperm membrane protein(s) stimulated spawning as well as shell closure activity.

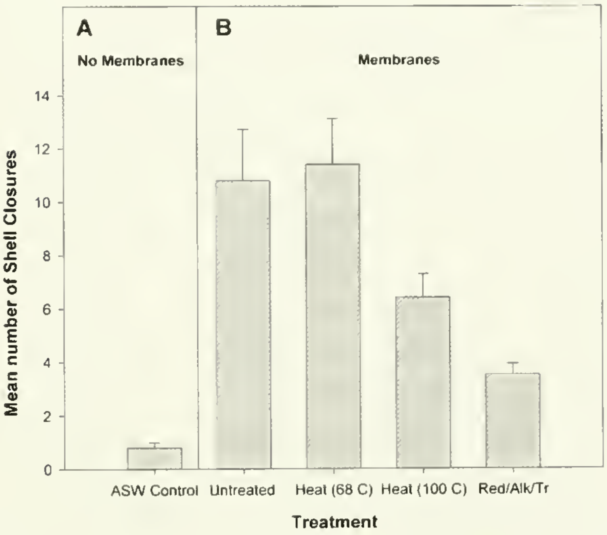

Figure 2. An intrinsic factor in sperm membrane stimulates spawning in *Crassostrea virginica*; spawning is accompanied by a series of shell closures (shell clapping) that have been used to assess the presence of the activity. The graph shows the average number of closures (± $S_{\bar{x}}$) in animals during a 20-min period following exposure to either: artificial seawater (ASW) alone; or ASW to which treated or untreated membrane fractions (resuspended P3 pellet) were added. (A) The average number of shell closures is low when oysters are incubated in ASW alone. (B) The average number was increased when untreated sperm membranes were added. Heating the membrane fraction before it was bioassayed reduced the average number. The effect was statistically significant at 100 C ($P < 0.05$), but not at 68°C ($P = 0.82$). Membranes were also reduced and alkylated to break disulfide bonds, dialyzed, and then digested with trypsin. The reduction in the mean number of closures is significant ($P < 0.0001$), supporting the suggestion that the factor is an intrinsic protein in the sperm membrane.

DISCUSSION

Mass spawning of oysters in an aquaculture setting requires at least one male in the tank to stimulate other male and female oysters to spawn. In some instances, the spawning operation is delayed for several hours or is not possible at all due to lack of a single spawning male to trigger general spawning of a tank of brood oysters. In the British Isles, there is a need for a synthetic or recombinant pheromone for routine 48-h exotoxicity tests that are in widespread use there. Presently, commercial hatcheries in the British Isles purify fresh sperm from *C. gigas* Thunberg to stimulate spawning for exotoxicity tests, but would prefer to avoid having sperm from another oyster in the water for the assays (S. Steele, Royal Holloway Univ. of London, pers. comm.). The availability of a synthetic or recombinant oyster spawning pheromone would: (1) avoid introducing sperm into the water during exotoxicity tests; (2) allow for a pathogen-free method for inducing spawning in oysters; (3) allow males and females to be induced to spawn separately, providing pure gametes for use in genetic manipulation for selective breeding of oysters with disease resistance, fast growth, etc.; and (4) simplify and standardize oyster hatchery operations.

As a first step toward characterizing the sperm-associated pheromone responsible for stimulating spawning in oysters, we used a method for selectively stripping extrinsic proteins off membranes that does not affect the disposition of integral components such as transmembrane and lipid-anchored proteins (Fujiki et al. 1982). It is the procedure most widely used to extract extrinsic (or adsorbed) proteins from organelle membranes, and has enabled investigators working on integral membrane proteins to efficiently remove soluble contaminating proteins, and to distinguish peripheral membrane proteins (those desorbed in the presence of sodium carbonate) from integral membrane proteins (those that remain membrane-associated following treatment) (Coligan et al. 1997).

Following sodium carbonate extraction (Fujiki et al. 1982) of freshly isolated oyster sperm membranes, the purified membranes (P3 pellet) enriched with intrinsic membrane proteins caused vigorous, repetitive shell closures in 78% of oysters tested; in contrast, the S3 supernatant, which was enriched with extrinsic membrane proteins, stimulated shell closures in only 18% of oysters tested. Similar results were obtained using male gonad tissue stored at −70°C for more than 6 mo. These initial data suggested that the sperm-associated pheromone was retained in sperm membranes, and that sodium carbonate treatment did not remove the shell closure-stimulating activity from sperm membranes.

More extensive experiments were conducted to test the heat and trypsin sensitivity of the candidate oyster sperm pheromone (Fig. 2). After removing extrinsic proteins from sperm membranes, vigorous and repetitive shell closure activity was still present in purified sperm membranes (P3 pellet fractions). Incubation of these P3 membranes at 100°C resulted in a significant reduction in this activity. Likewise, breaking disulfide bonds in intrinsic sperm membrane proteins followed by trypsin digestion resulted in a significant reduction of this activity, suggesting that the active factor(s) is a transmembrane or lipid-anchored membrane protein in the sperm membrane.

Little is known about the identity of any invertebrate or vertebrate water-borne peptide/protein pheromones or their receptors. Painter and colleagues (1998, 1999, 2000) were the first to determine the structure and biologic activity of a water-borne peptide pheromone in invertebrates; the 58-residue attractant ("attractin") in *Aplysia* has been cloned (Fan et al. 1997) and its 3-D structure predicted (Schein et al. 2001). Water-borne peptide pheromones (e.g., E*r*-1, E*r*-2) and their receptors have been best characterized in the protozoan *Euplotes raikovi*; the E*r* receptors, which probably arise by alternative splicing from the same gene for the E*r* pheromones, each contain a copy of a pheromone sequence secreted by the cell (reviewed in Luporini et al. 1996).

In contrast with soluble peptide/protein pheromones, oyster spawning presumably involves the direct binding of an intrinsic sperm membrane-associated protein(s) with membrane-associated receptors in neighboring oysters. This is based on the observation that oysters initiate a series of strong, rhythmic contractions of the adductor muscle in response to sperm entering the mantle cavity via the incurrent siphon (Galtsoff 1938a, Galtsoff 1938b). Detailed information regarding the nature of the sperm membrane protein(s) and its receptor are lacking, however. Therefore, a complete understanding of the molecular mechanisms underlying spawning activation will not be achieved until the sperm-associated membrane protein(s) and its receptor are structurally characterized and cloned.

A molecular mechanism for spawning has been proposed for other mollusks. It has been demonstrated in abalone that hydrogen peroxide causes gravid male and female abalones to spawn and that this effect may result from a direct activation of the enzyme-catalyzed synthesis of prostaglandin endoperoxide. The latter is a direct precursor of prostaglandins and thromboxanes; all three may be involved in regulating spawning in abalone (Morse et al. 1977). Hydrogen peroxide also induces synchronous spawning in male and female mussels (*Mytilus*) and in other molluscan species (Morse et al. 1977).

Lastly, regardless of the molecular mechanisms underlying sperm-induced spawning in oysters, the response of female oysters to sperm is not species-specific: sperm from *C. virginica*, *C. gigas*, or *C. angulata* Lamarck have been shown to stimulate spawning in females of all three species (Nelson 1931, Galtsoff 1932, Galtsoff & Smith 1932). This suggests that a synthetic or recombinant *C. virginica* spawning pheromone could be used in the aquaculture industry to induce spawning in several commercially important species.

FACTORS AFFECTING SPERM MOTILITY OF TETRAPLOID PACIFIC OYSTERS

QIAOXIANG DONG,[1] BENOIT EUDELINE,[2] STANDISH K. ALLEN, JR.,[3] AND TERRENCE R. TIERSCH[1]*

[1]*Aquaculture Research Station, Louisiana Agricultural Experiment Station, Louisiana State University Agricultural Center, Baton Rouge, Louisiana 70803;* [2]*Whiskey Creek Shellfish Hatchery, Tillamook, Oregon 97141;* [3]*Aquaculture Genetics and Breeding Technology Center, Virginia Institute of Marine Science, Gloucester Point, Virginia 23062*

ABSTRACT Factors such as osmotic pressure, extender solution, addition of caffeine, and pH have been shown to affect sperm motility in aquatic species. We evaluated the effects of 18 osmotic pressures, two extender solutions, seven caffeine concentrations, and a pH range of 3 to 14 on motility of sperm from tetraploid Pacific oysters, *Crassostrea gigas*. Motility was highest at 1000 mOsmol/kg (mean ± SD: 83 ± 14%). Calcium-free Hanks' balanced salt solution yielded significantly higher sperm motility than did artificial seawater. Sperm motility increased with caffeine concentrations to 20 mM (81 ± 12%) and decreased when concentrations were higher than 50 mM (55 ± 20%). Highest motility was obtained at a pH range of from 4 to 12; values outside this range yielded no motility. Addition of 10 mM caffeine to the different pH treatments also enhanced motility significantly. Overall, calcium-free Hanks' balanced salt solution at 1,000 mOsmol/kg, the addition of 10 mM caffeine, and a pH of around 10 could be used to enhance sperm motility of tetraploid Pacific oysters. Our findings would assist the use of motility assays to evaluate the effectiveness of various refrigeration or cryopreservation procedures, especially outside of the peak spawning season, when sperm motility can be low and variable.

KEY WORDS: *Crassostrea gigas*, sperm motility, pH, caffeine, osmotic pressure, tetraploid, cryopreservation

INTRODUCTION

Factors such as osmotic pressure (Bates et al. 1996), extender composition, pH, temperature (Lahnsteiner et al. 1997, Sunitha and Jayaprakas 1997), and additives such as caffeine (Scheerer and Thorgaard 1989, Tiersch et al. 1998) have been shown to affect sperm motility in aquatic species. Most studies have been conducted on teleosts (e.g., Morisawa et al. 1983a, Morisawa 1983b), and studies on invertebrates mainly focus on sea urchin (Morisawa et al. 1990), polychaetes (Pacey et al. 1994), and ascidians (Yoshida et al. 1992, Yoshida et al. 1994). Little is known about the effects of these factors on oyster sperm, especially on sperm from tetraploid oysters, which possess four sets of chromosomes instead of the normal diploid two sets.

Tetraploid oysters create opportunities for genetic improvement, including direct production of triploid (sterile) seedstocks by crossing with normal diploids. Refrigerated and frozen storage of tetraploid oyster sperm will be a critical tool for commercial-scale application of tetraploid stocks and for developing tetraploid breeding programs. Although subjective, motility estimation is the technique used most commonly to assess sperm quality of fish and shellfish (Piironen 1993, Tiersch et al. 1994, Koupal et al. 1995). Motility has been used to assess the sperm quality of oysters (Paniagua-Chavez et al. 1998), but its application with tetraploid oyster sperm is unexplored. The objective of this study was to develop procedures for evaluation of sperm quality to assist the overall goal of sperm storage for tetraploid Pacific oysters, *Crassostrea gigas*. Specifically, we evaluated the effects on sperm motility of: (1) osmotic pressure; (2) extender solution; (3) caffeine, and (4) pH. Our findings indicate that these factors can alter the motility of tetraploid oyster sperm collected late in the spawning season. To our knowledge, this is the first study to systematically characterize sperm motility of tetraploids of an aquatic species.

MATERIALS AND METHODS

Tetraploid oysters were obtained in September and October 2001 from Whiskey Creek Shellfish Hatchery (WCSH) (Tillamook, Oregon) and were shipped chilled by overnight delivery to the Louisiana State University Agricultural Center, Aquaculture Research Station (ARS). Water samples from WCSH had an osmolality of 873 mOsmol/kg as measured by vapor pressure osmometry (model 5500, Wescor Inc., Logan, UT) at the ARS. Sperm were collected by dry stripping of the gonad (Allen & Bushek 1992). Undiluted nonmotile sperm were equilibrated in 30 μL of test solutions at 23°C for 2 min before assessment of motility. Sperm motility was estimated at 200× magnification using darkfield microscopy (Optiphot 2, Nikon Inc., Garden City, NY) and was expressed as the percentage of cells actively moving in a forward direction.

Throughout the experiments, two extender solutions were used: artificial sea water (ASW) (Fritz Super Salt, Fritz Industries, Inc. Dallas, TX) and calcium-free Hanks' balanced salt solution (C-F HBSS) (Paniagua-Chavez et al. 1998). All chemicals (except ASW) were of reagent grade (Sigma Chemical Corporation., St. Louis, MO). Osmolality was measured with a vapor pressure osmometer.

In our first study, the effect on sperm motility of ASW of 18 different osmolalities ranging from 30 to 1400 mOsmol/kg was evaluated with a total of 20 oysters in four trials, for which oysters were received on August 24, August 30, September 19, and September 26. The second study compared ASW and C-F HBSS at 13 different osmolalities with five oysters, which were received on October 16. In the third study, the effect of caffeine was evaluated at seven concentrations (2 to 100 mM) with eight oysters from two shipments received on October 10 and October 16. In the fourth study, a pH range of from 3 to 14, with and without caffeine, was evaluated with three oysters that were received on October 10. Sperm from individual oysters was used for all studies (samples were not pooled). Within this manuscript, extender solutions at specific osmolalities such as ASW at 1,000 mOsmol/kg are abbreviated as ASW1000.

Data were analyzed using one-way or two-way analysis of variance. Tukey's honestly significant difference procedure was used to test for differences ($\alpha = 0.05$) among results for osmolalities, caffeine concentrations and pH levels (SAS Institute 1991).

RESULTS

Among the osmolalities tested, sperm from tetraploid Pacific oysters remained immotile when diluted with ASW below 500 mOsmol/kg (Fig. 1). Motility increased from 12 ± 12% (mean ± SD) in ASW500 to 50 ± 11% in ASW670. There was no significant difference among sperm motilities activated with ASW at 670, 700, 750, and 800 mOsmol/kg ($P > 0.05$). Although sperm motility was not significantly different among ASW at 900, 950, 1,000, and 1,100 mOsmol/kg, ASW1000 elicited the highest motility 83 ± 14% (Fig. 1). Motility decreased significantly when osmolality was greater than 1,100 mOsmol/kg.

Motility in C-F HBSS was significantly higher than that in ASW ($P < 0.0001$) (Fig. 2). Each extender showed the highest motility at 1,000 mOsmol/kg, which agreed with the results of the previous experiment. But motility in C-F HBSS1000 (81 ± 9%) was double that in ASW1000 (40 ± 22%). Other osmolalities of C-F HBSS also enhanced sperm motility. For example, motility in C-F HBSS670 (50 ± 10%) was six times greater than that in ASW670 (8 ± 13%) (Fig. 2). Because the oysters used in this experiment were received later in the spawning season than those used for the first study, lower motilities overall were observed for ASW.

Based on the results of the second experiment, C-F HBSS at 1,000 mOsmol/kg was used for caffeine assessments. Motility increased with caffeine concentrations of from 2 mM (60 ± 13%) to 20 mM (81 ± 12%) and decreased when concentrations were higher than 50 mM (55 ± 20%) (Fig. 3). The lowest motility (49 ± 10%) was in the control treatment: C-F HBSS1000 without the addition of caffeine, but additions of 2, 4, and 6 mM caffeine were not significantly different from the control ($P > 0.05$). Motilities in 10 and 20 mM caffeine were significantly higher than in other concentrations ($P < 0.05$), but they were not different from each other ($P > 0.05$) (Fig. 3).

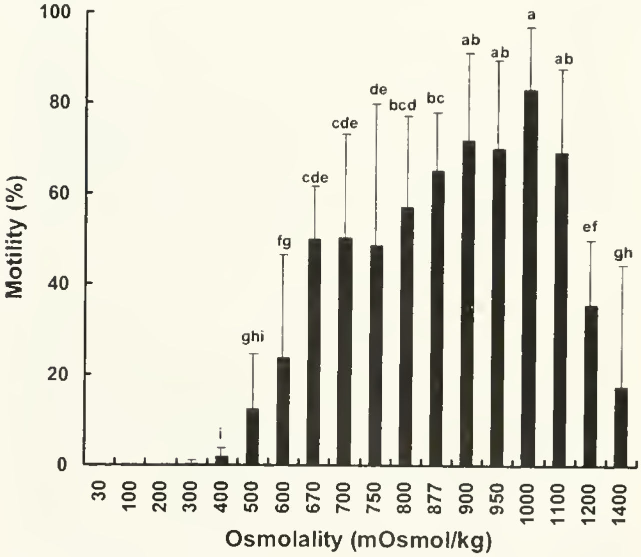

Figure 1. Percent motility (mean ± SD) of tetraploid Pacific oyster sperm activated in artificial seawater at 18 different osmotic pressures. Bars sharing a letter were not significantly different ($P > 0.05$).

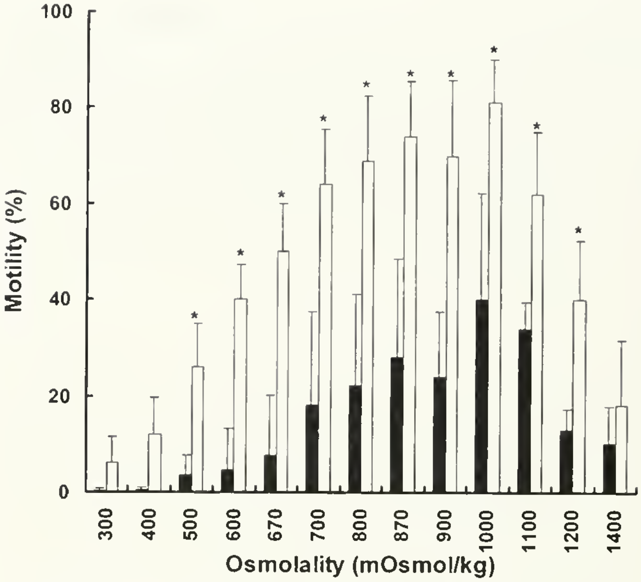

Figure 2. Percent motility (mean ± SD) of tetraploid Pacific oyster sperm activated in ASW (filled bars) and C-F HBSS (open bars). Bars with an asterisk indicate a significant difference ($P > 0.05$) between ASW and C-F HBSS.

Based on these results, C-F HBSS1000 with and without 10 mM caffeine were used for pH assessment. Motility was highest at a pH range of from 4 to 12; values outside this range yielded no motility (Fig. 4). The highest motility was in pH 10.5 (67 ± 6%), followed by pH 10 (63 ± 6%). The addition of 10 mM caffeine to these pH treatments enhanced motility significantly ($P < 0.001$)

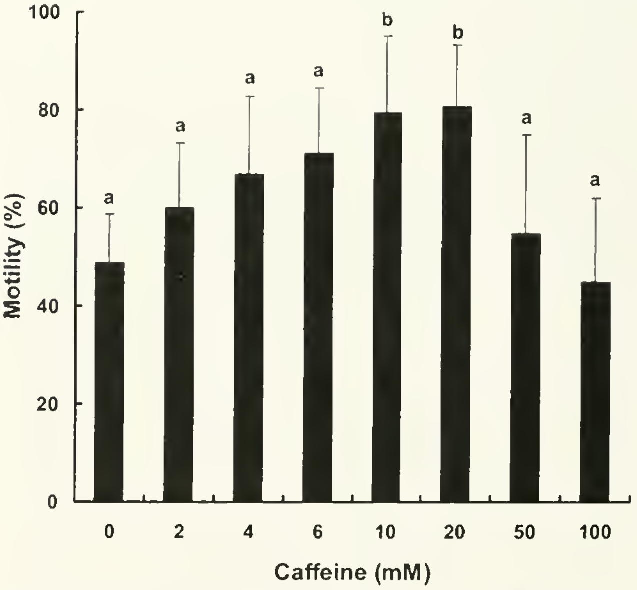

Figure 3. Percent motility (mean ± SD) of tetraploid Pacific oyster sperm activated with the addition of caffeine into C-F HBSS at 1,000 mOsmol/kg. Bars sharing a letter were not significantly different ($P > 0.05$).

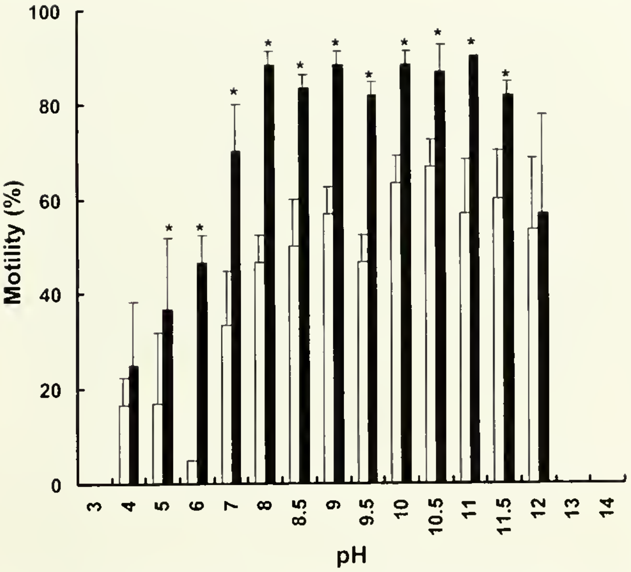

Figure 4. Percent motility (mean ± SD) of tetraploid Pacific oyster sperm in C-F HBSS at 1,000 mOsmol/kg with different pH treatments. Open bars, C-F HBSS without addition of caffeine; filled bars, C-F HBSS with 10 mM caffeine. Bars with an asterisk indicate a significant difference ($P > 0.05$) between presence and absence of caffeine.

(Fig. 4). Motility was 90 ± 0% in pH 11, 87 ± 6% in pH 10.5, and 88 ± 3% in pH 10. However, there was no significant difference in sperm motility across the pH range of from 7 to 12 ($P > 0.05$).

DISCUSSION

Sperm activation is a complex process in which roles are played by many factors, including osmotic pressure, extender composition, membrane structural changes, and extracellular and intracellular pH. Previous studies have suggested that different species have different sperm activation mechanisms. Basically, in fish there seem to be two major factors influencing sperm activation: changes of osmotic pressure and changes of ionic concentration. For instance, studies on muskellunge *Esox masquinongy* (Lin & Dabrwoski 1996), channel catfish *Ictalurus punctatus* (Bates et al. 1996), and Asian catfish *Clarias macrocephalus* (Tan-Fermin et al. 1999) suggested that sperm motility was initiated by a reduction of osmotic pressure. However, activation of sperm from salmonids and cyprinids was caused by changes in concentrations of ions such as potassium and calcium (Morisawa et al. 1983a, Billard & Cosson 1992). The mechanism of initiation of sperm motility has been most studied in salmonids although much remains unknown, especially at the intracellular level.

Motility studies in other taxa such as invertebrates are limited and the associated mechanisms remain largely unknown. There are less than 40 references addressing oyster sperm motility in any way since 1970. Most use motility as a criterion to evaluate fertilization or in toxicological assays to evaluate waste effluents or heavy metals. Factor that affect sperm motility such as osmolality, extender composition, pH, and temperature are briefly mentioned in these studies and others on sperm cryopreservation, and therefore the information is fragmented and dispersed. The present study was designed to address factors affecting the sperm motility of tetraploid Pacific oysters and provided a more detailed and systematic approach.

Osmolality, as mentioned above, plays an important role in the activation of fish sperm. Osmolalities of ~1000 mOsmol/kg (the full-strength salinity of sea water, 32 ppt) and 670 mOsmol/kg were previously used for sperm activation and extender solutions for *C. gigas* (Yankson & Moyse 1991, Kurokura et al. 1990). Other species were studied with sea water of ambient environmental salinity. The first investigation of sperm motility across a wide range of osmolalities was with the diploid eastern oyster, *C. virginica* (Paniagua-Chavez et al. 1998). High sperm motility (90%) was observed across a range of 600 to 1,500 mOsmol/kg (Paniagua-Chavez & Tiersch 2001). In the present study, sperm motility of tetraploid Pacific oysters was also observed across a wide range of osmotic pressures (500–1400 mOsmol/kg), but the highest motility was limited to 1,000 mOsmol/kg, although the oysters were conditioned in seawater at 873 mOsmol/kg. Whether osmotic pressure plays the major role in oyster sperm activation remains unknown; however, motility was suppressed in tetraploid sperm of *C. gigas* at osmolalities of lower than 500 mOsmol/kg. Suppression was reported to occur at less than 22 mOsmol/kg in *C. virginica* (Paniagua-Chavez et al. 1998). This might correspond to the habitat of these species in natural environments. *Crassostrea gigas* prefers higher and more stable salinities (15 to 33 ppt) (Kusuki 1991) than does *C. virginica*, which normally occurs from 5 to 40 ppt (Galtsoff 1964, Wallace 1966).

Natural seawater and ASW are most commonly used as extender solutions for sperm of marine organisms including estuarine organisms like oysters. Other extenders such as DCSB4 (Bougrier & Rabenomanana 1986), HBSS1990 (Zell et al. 1979), and C-F HBSS640 (Paniagua-Chavez et al. 1998) with specific ionic compositions have also been successfully used for oyster sperm. The removal of calcium from HBSS was found to enhance motility in sperm of diploid eastern oysters (Paniagua-Chavez et al. 1998) and tetraploid Pacific oysters (this study) and was also superior to ASW. Contrary to the situation in salmonids, in which sperm motility is initiated by a decrease in potassium concentration upon release into fresh water (Morisawa et al. 1983a), an increase of potassium concentration (200 mM) was found to have an activating effect on diploid Pacific oyster sperm (Faure et al. 1995). The same study showed no effect of the increase of potassium on sperm of the king scallop *Pecten maximus*, but an increase in motility was observed with media lacking sodium. These results may indicate a species-specific response for ionic effects on bivalve sperm motility. Also, changes in ion concentration, rather than absolute concentration, may act as the trigger of initiation of sperm motility.

Caffeine has been used as motility stimulant to optimize the recovery and quality of thawed spermatozoa in mammalian species (Correa & Zavos 1996, Park & Sirard 1996). Few studies have addressed use of this chemical in sperm of aquatic species and there are no reports for oysters. The present experiment showed a significant increase in sperm motility with the addition of 10 mM caffeine, while concentrations above 50 mM reduced motility. A previous study in the razorback sucker *Xyrauchen texanus* showed increased motility in refrigerated sperm after the addition of 5 mM caffeine, but not in thawed sperm (Tiersch et al. 1998). We did not evaluate the addition of caffeine with thawed sperm in this study, but fertilizing capacity of cryopreserved semen of rainbow trout *Oncorhynchus mykiss* was improved when eggs were fertilized in a buffered saline solution containing 5 mM theophylline, a chemical relative to caffeine used to prolong and intensify sperm motility (Scheerer & Thorgaard 1989).

Alkaline pH has been found to be conducive to sperm activation in aquatic species (Thorogood & Blackshaw 1992, Sunitha &

Jayaprakas 1997, Ciereszko et al. 2001), and pH values between 7 and 9 have been used in most studies for oyster sperm (e.g., Zell et al. 1979, Paniagua-Chavez et al. 1998). Study of the king scallop (Faure 1996) found that gonadal pH was more acidic than seawater pH and suggested that the acidity of the genital tract maintained the spermatozoa in a quiescent state. A reduction of sperm motility was reported in *P. maximus* and *C. gigas* upon decrease of pH in seawater (Faure 1996). In the present study, pH values below 7 induced a significant reduction in sperm motility although there was variation among individual oysters. The highest sperm motility was observed at a pH of 10, which agrees with findings for the Japanese pearl oyster *Pinctada fucata* (Yu et al. 1998), although that study found an interaction between salinity and pH. In that study, sperm motility could not be activated by seawater at a salinity of 30 ppt and a pH of 8.0, but motility was greater than 80% when pH ranged from 9.0 to 11.5. Sperm from tetraploid Pacific oysters showed motility over a wider pH range in the present study. It appears that relative influence of most factors affecting sperm motility of bivalves are species-specific.

Finally, the main practical interest in tetraploidy is for the production of triploids by mating with diploids. The induction of tetraploidy in oysters was first reported in 1994 (Guo and Allen, 1994). Studies of the factors affecting sperm motility of tetraploid oysters have only now begun as reported here. Our experiments indicate that use of C-F HBSS at 1,000 mOsmol/kg as an extender, the addition of 10 mM caffeine, and a pH of around 10 can be used to enhance sperm motility of tetraploid Pacific oysters. This would assist the use of motility assays to evaluate the effectiveness of various refrigeration or cryopreservation procedures, especially outside of the peak spawning season when sperm motility can be low and variable such as in this study. The effectiveness of these conditions in improving fertilization rates requires further study. Future research is required to evaluate differences between sperm of diploid and tetraploids within and among aquatic species.

ABSTRACT *Perkinsus marinus* infection intensity in *Crassostrea virginica* can be quantified without killing of oysters by determining parasite density in hemolymph samples incubated in fluid thioglycollate medium (FTM). The goal of this study was to improve existing protocols for counting of *P. marinus* in oyster hemolymph. Specifically, the objectives were to examine the effects on parasite number and diameter of: 1) adding supplements to FTM such as lipid and oyster extract; 2) incubating with various FTM preparations with and without agar or beef extract; 3) incubating with various hemocyte densities (10^5, 10^6, and 10^7 hemocytes/mL of FTM) in a constant FTM volume; 4) incubating with different volumes of FTM (0.2 mL, 1.0 mL, 5.0 mL, and 25.0 mL); and 5) sodium hydroxide digestion of cellular debris. From these results, an improved hemolymph protocol was developed. The diameters and numbers of enlarged parasites or hypnospores in hemolymph of 20 oysters measured by the improved protocol and the standard FTM hemolymph assay of Gauthier and Fisher were compared. Finally, the standard and improved protocols were compared with the FTM body burden assay. The diameter of hypnospores from samples processed with the improved protocol (26 ± 13 μm) was significantly greater than the diameters from samples processed with the standard protocol (10 ± 4 μm). The number of hypnospores in samples processed with the improved protocol ($8.6 \times 10^3 \pm 3.3 \times 10^3$) was significantly greater than the numbers in samples processed with the standard protocol ($1.9 \times 10^3 \pm 3.4 \times 10^3$). Results of the body burden assay were significantly correlated with results of the standard hemolymph assay and with results of the improved hemolymph assay. The coefficient of determination ($r^2 = 0.7602$) and slope (0.91189) of the regression of the FTM body burden assay against the improved FTM hemolymph assay was improved from the coefficient of determination (0.5543) and slope (0.61257) of the regression of the FTM body burden assay against of the standard FTM hemolymph assay.

KEY WORDS: dermo, *Perkinsus marinus*, FTM hemolymph diagnostic assay, *Crassostrea virginica*

INTRODUCTION

Use of a protocol to quantify the presence of the pathogenic protozoan *Perkinsus marinus* by determining the number of enlarged parasites, or hypnospores, in hemolymph samples of eastern oysters, *Crassostrea virginica*, allows estimation of infection intensity without killing oysters (Gauthier & Fisher 1990). Therefore, infection intensity in the same animal can be monitored over time. In the existing protocol, hemolymph from the adductor muscle sinus is removed, centrifuged, and the cell pellets containing oyster hemocytes and parasites are incubated in fluid thioglycollate medium (FTM) for 1 week. After incubation, cellular debris is digested with sodium hydroxide (NaOH). The hypnospores are stained with Lugol's solution and their numbers per mL determined. This FTM hemolymph assay has been useful to follow the progression of the disease in individual oysters under different environmental conditions (Fisher et al. 1992, Ragone Calvo & Burreson 1994).

Gauthier and Fisher (1990) proposed additional advantages of the FTM hemolymph assay, including the detection of early infections and the measurement of systemic infections rather than localized infections. In their initial study, the FTM hemolymph assay detected many infections misdiagnosed as negative by Ray's FTM tissue assay. In Ray's FTM tissue assay, a piece of oyster tissue (e.g., mantle tissue in Gauthier and Fisher's 1990 study) is incubated in FTM for about a week, the tissue is then smeared on a slide, and the parasites stained with Lugol's solution and the intensity of infection are estimated using a semi-quantitative scale (Ray et al. 1953, Ray 1954a, Ray 1954b). Bushek et al. (1994), however, found no evidence that the FTM hemolymph assay was more sensitive than the FTM tissue assay in detecting low *P. marinus* infections when both mantle and rectal tissues were used in the tissue assay. Moreover, correlations between FTM tissue and FTM body burden assays were always higher than correlations between FTM hemolymph and FTM body burden assays. The body burden assay measures the number of parasites in the whole oyster and is considered the most sensitive and accurate diagnostic assay for *P. marinus* (Bushek et al. 1994, Fisher & Oliver 1996, Oliver et al. 1998).

A quantitative competitive polymerase chain reaction (QCPCR) assay for *P. marinus* was recently shown to be more sensitive than the FTM hemolymph assay, detecting infections in 24 oysters compared with 22 infections with the FTM hemolymph assay (Yarnall et al. 2000). Diagnosis of *P. marinus* in oyster hemolymph by QCPCR detected as many infections as with the FTM body burden assay, suggesting that hemolymph is suitable for determining *P. marinus* infection in oysters. Whereas QCPCR is an effective assay and specific for *P. marinus*, it is also expensive and requires technical expertise and equipment in molecular biology to perform as indicated by Yarnall et al. (2000). The FTM hemolymph assay in contrast is easy and inexpensive to perform. There is thus a need to improve the sensitivity and accuracy of the FTM hemolymph assay.

Potential problems with FTM assays have been previously noted and include insufficient parasite enlargement, parasite clumping, and parasite adherence to the walls of centrifuge tubes, each of which can lower parasite counts (Bushek et al. 1994, Fisher & Oliver 1996). Poor parasite enlargement may be caused

by exhaustion of necessary nutrients in FTM or tissue (Ray 1954a, Bushek et al. 1994, Fisher & Oliver 1996). In addition, the protocols used in FTM hemolymph assay varied greatly among researchers in sample preparation (e.g., centrifugation speed), sample processing, and in parasite counting protocols (Gauthier & Fisher 1990, Ragone Calvo & Burreson 1994, Bushek et al. 1994, Oliver et al. 1998). It is likely that these recognized problems and differences in protocols account for the poor performance (i.e., sensitivity and accuracy) of the FTM hemolymph assay.

The goal of this study was to improve the protocol for counting of *P. marinus* in oyster hemolymph through systematic examination of components of the standard protocol described by Gauthier and Fisher (1990). The objectives were to examine the effects of: (1) adding supplements to FTM, including lipid and oyster extract; (2) adding various FTM preparations (with and without agar or beef extract); (3) incubating with various hemocyte densities (10^5, 10^6, and 10^7 hemocytes/mL of FTM) in a constant FTM volume; (4) incubation of hemocytes in different volumes of FTM (0.2 mL, 1.0 mL, 5.0 mL, and 25.0 mL); and (5) NaOH digestion of cellular debris on hypnospore diameter and number.

MATERIALS AND METHODS

Oysters

Eastern oysters were collected from Hackberry Bay (29°23′54″N, 90°28″W) in the spring of 1999, placed in 16 mm mesh shellfish cages (Aquatic Eco-Systems, Inc., Apopka, FL), and hung in the water from docks at the Louisiana Sea Grant Oyster Hatchery (29°12′30″N, 90°02′30″W) in Grand Isle, Louisiana, an area enzootic for *P. marinus*. In the summer and fall of 1999, oysters were transported to the Department of Veterinary Science at Louisiana State University, Baton Rouge, and were placed in an indoor recirculating system equipped with 1 μm and 10 μm cotton filters in polypropylene filter cartridges and an ultraviolet light. Water was maintained at 15 ppt with hw-Marinemix *Professional* sea salts (Hawaiian Marine Imports Inc., Houston, TX) and 25°C.

General Procedures

All chemicals were from Sigma Chemical Co. (St. Louis, MO) unless otherwise indicated. A notch was ground into the edge of oyster shells near the adductor muscle and 3 mL of hemolymph were withdrawn from the adductor muscle sinus. Hemolymph samples were transferred to 3 mL snap-cap tubes and immediately placed on ice to prevent hemocyte clumping. The number of hemocytes per mL of hemolymph was determined using a Neubauer Bright-Line hemocytometer (Reichert, Buffalo, NY). Hemolymph samples from each oyster, containing 10^6 hemocytes, were added to 1.5 mL microcentrifuge tubes, centrifuged at 800 × g for 10 min, and the supernatant was discarded. All samples were prepared in triplicate. Pellets were resuspended in 1 mL of alternative fluid thioglycollate medium (AFTM) (Sigma number A 0465) prepared according to the manufacturer's instructions and supplemented with 16 g/L of hw-Marine *Professional* sea salts and 50 μg/mL chloramphenicol. This solution, referred to as AFTM throughout this report, did not contain agar, unlike FTM (Sigma number T 9032), which contains 0.75 g/L of agar. Samples were layered with 10 μL of nystatin (5,000 Units/mL) to prevent fungal growth. Test tubes were stored in the dark at room temperature for seven days, allowing parasites within hemocytes to enlarge to hypnospores. After incubation, samples were centrifuged at 1500 × g for ten min and the AFTM supernatant was discarded. Pellets were resuspended in 1 mL of 2 N NaOH and incubated in a 60°C water bath for 1 to 2 h to digest hemocyte debris. Samples were centrifuged to remove NaOH and hypnospores were rinsed three times with 0.1 M phosphate-buffered saline (PBS) containing 0.5 mg/mL bovine serum albumin (BSA). In a previous study, it was found that BSA decreased parasite clumping and improved parasite recovery by reducing the number of parasite that adhered to the test tube walls (Coates et al. 1999). Samples were stored at 4°C in 1 mL of PBS supplemented with BSA and 2 mg/mL of sodium azide. At the time of counting, samples were centrifuged, and 900 μL of supernatant were removed. Each 100-μL sample was transferred to a separate well of a 96-well tissue culture plate. Fifty microliters of each sample was transferred to wells containing 50 μL of PBS with BSA to form a 1:1 dilution. Samples were serially diluted in this manner until a 1:64 dilution was reached. Lugol's solution (50 μL; 0.012 g/mL of potassium iodide and 0.008 g/mL of iodine in water) was added to each well to stain the samples. Tissue culture plates containing samples were centrifuged at 200 × g for 5 min to form a monolayer of hypnospores on the plate bottoms to facilitate counting. Numbers of hypnospores were recorded at 200-X magnification using an inverted microscope (Carl Zeiss, Inc., Thornwood, NY) from wells containing 100 to 400 hypnospores. Cells were counted at 400× when they were too small to identify at 200×. The diameter (μm) of 50 hypnospores from each sample was measured with an ocular micrometer, and the number of hypnospores per 10^6 hemocytes was calculated.

Experiments

Effects of Supplemented AFTM on Hypnospore Diameter and Number

Hemolymph was collected from five oysters as described above. AFTM, supplemented with 5% lipid concentrate (Gibco, Gaithersburg, MD), 5% oyster extract, or 5% oyster saline, was added to 10^6 hemocytes from each oyster. Oyster extract was prepared by homogenizing whole oyster tissue in oyster saline at a concentration of 0.2 g wet tissue per mL, centrifuging at 10,000 × g for 15 min, removing the oyster extract (supernatant), and storing it at −20°C. Oyster saline (0.95 g/L $CaCl_2{\cdot}2H_2O$, 1.46 g/L $MgSO_4$, 2.18 g/L $MgCl_2{\cdot}6H_2O$, 0.67 g/L KCl, 11.61 g/L NaCl, and 0.35 g/L $NaHCO_3$) was included as a control. Samples were incubated, processed, counted, and measured as described above. Lipid was found to increase hypnospore diameter and was added to FTM in all further experiments.

Effect of FTM Types on Hypnospore Diameter and Number

Hemolymph was collected from 15 oysters as described above and five formulations of FTM, supplemented with 16 g/L of hw-Marine *Professional* sea salts, 50 μg/mL chloramphenicol, and 5% lipid concentrate, were added to 10^6 hemocytes samples. The formulations compared were Bacto fluid thioglycollate medium (Becton Dickinson and Company, Franklin Lakes, NJ, Difco number 0256154), Bacto thioglycollate medium with K agar (Difco number 0607178), Bacto fluid thioglycollate medium with beef extract (Difco number 0697179), alternative fluid thioglycollate medium (Sigma number A 0465), and thioglycollate medium (Sigma num-her T 9032) (Table 1). Samples were incubated, processed, measured, and counted as described above.

Effect of Hemocyte Density on Hypnospore Diameter and Number

Hemolymph was collected from 15 oysters as described above and 10^5, 10^6, and 10^7 hemocytes from each oyster were incubated in 1 mL of AFTM supplemented with 5% lipid concentrate. For this experiment, the number of hypnospores per hemocyte was calculated, and hypnospore diameter was measured as described above.

Effect of AFTM Volume on Hypnospore Diameter and Number

Hemolymph was collected from 15 oysters as described above. Hemocytes (10^6) were incubated in 0.2, 1.0, 5.0, or 25.0 mL of AFTM supplemented with 5% lipid concentrate. Samples were processed, measured, and counted as described above.

Effect of NaOH Digestion of Samples on Hypnospore Diameter and Number

Hemolymph samples from 15 oysters were processed with and without NaOH digestion after incubation in AFTM supplemented with 5% lipid concentrate. Samples processed without NaOH digestion were centrifuged at 1500 × g for 10 min to remove the AFTM supernatant. Cell pellets were rinsed three times with sterile artificial seawater (hw-Marinemix *Professional*) at 15 ppt and containing 0.5 mg/mL BSA. Samples processed with NaOH digestion were treated as described in the General Procedures section.

Effect of Protocol on Hypnospore Diameter and Number

From the results of the above experiments, an improved protocol for counting of *P. marinus* in oyster hemolymph was developed and compared with the 'standard' protocol of Gauthier and Fisher (1990). Major differences between the standard and improved protocols are summarized in Table 2. Briefly, hemolymph samples were collected from 20 oysters infected with *P. marinus*. Hemolymph samples were divided into two equal aliquots, one aliquot to be processed with the standard protocol and the other to be processed with the improved protocol. Hemocytes (10^6) from samples processed with the standard protocol were incubated for seven days in 1 mL of FTM (Sigma number T 9032) supplemented with 16 g/L of hw-Marinemix *Professional* sea salts, 50 μg/mL of chloramphenicol, and layered with 10 μL of nystatin (5000 Units/ml). Hemocyte debris was digested with 1 mL of 2 N NaOH, and hypnospores were rinsed three times with 1 mL of distilled water. Samples were centrifuged, 900 μL of supernatant were removed, and each 100-μL sample was transferred to a separate well of a 96-well plate, where it was serially diluted in distilled water and stained with Lugol's solution. Standard protocol centrifugation speeds were increased to the centrifugation speeds of the improved protocol to exclude their effects on parasite recovery. Hemocytes (10^6) from samples processed with the improved protocol were incubated for seven days in 1 ml of AFTM (Sigma number A 0465) supplemented with 5% lipid, 16 g/L of hw-Marinemix *Professional* sea salts, 50 μg/mL of chloramphenicol, and layered with 10 μL of nystatin (5000 Units/mL). Hemocyte debris was digested with 1 mL of 2 N NaOH and hypnospores were rinsed once with 1 mL of distilled water supplemented with 0.5 mg/mL BSA and twice with 1 mL PBS supplemented with 0.5 mg/mL BSA. Samples were centrifuged, 900 μL of supernatant were removed, and each 100-μL sample was transferred to a separate well of a 96-well plate, where it was serially diluted in PBS supplemented with BSA and stained with Lugol's solution. After processing samples with both protocols, the number of hypnospores was counted 200× magnification in wells containing 100 to 400 hyp-

Comparison of Standard and Improved FTM Hemolymph Assay Against FTM Body Burden Assay

The standard and improved FTM protocols for counting *P. marinus* in oyster hemolymph (as described above) were compared with the FTM body burden assay for determining the number of parasites in whole oyster and a regression line was calculated for each comparison. The regression lines were compared with determine if infection intensities obtained from the improved hemolymph protocol were more closely correlated with infection intensities obtained from the body burden assay than those obtained from the standard hemolymph protocol.

The 20 oysters from which hemolymph was removed for comparison of the standard and improved hemolymph protocols, were processed using modification of the body burden assay of Fisher and Oliver (1996) (Coates et al. 1999). Briefly, each oyster was removed from the shell, blotted dry, and homogenized with a hand-held Biohomogenizer, a stainless-steel rotor/stator emulsifying instrument, (Biospec Products, Inc., Batlesville, OK, catalog number 1281) in 20 mL of sterile artificial seawater prepared at 15 ppt with hw-Marine *Professional* sea salts. One milliliter of homogenate was transferred to 9 mL of AFTM (Sigma number A 0465) supplemented with 16 g/L of hw-Marinemix *Professional* sea salts, 50 μg/mL of chloramphenicol 5% lipid, and layered with 100 μL of nystatin (5000 Units/mL), and incubated for seven days. Samples were centrifuged, the supernatant removed, and 10 mL of 2 N NaOH added for 4 to 5 h at 60°C to digest the oyster tissue. Hypnospores were rinsed once with 10 mL of distilled water supplemented with 0.5 mg/mL BSA and twice with 10 mL PBS supplemented with 0.5 mg/mL BSA. Samples were centrifuged, 5 mL of supernatant were removed, 50 μL of each sample were transferred to a separate well of a 96-well plate, where it was serially diluted in PBS supplemented with 0.5 mg/mL BSA and stained with Lugol's solution. The number of hypnospores was counted (200× magnification) in wells containing 100 to 400 hypnospores after dilutions. The number of hypnospores per gram of oyster tissue was calculated for each oyster and compared with the number of hypnospores per 10^6 hemocytes determined by the standard and improved hemolymph protocols using linear regression analysis.

Statistical Analysis

Statistical analysis was performed using SAS Version 8.0 software (SAS Institute, Inc. Cary, NC). Only hemolymph samples containing at least 50 hypnospores (per triplicate) were used data analysis. Data were log transformed and analyzed with a randomized block design (blocked by oyster). Tukey's post-ANOVA test was used to examine differences among treatments. Differences were considered significant at $P < 0.05$. All data were reported as mean ± standard deviation. To compare the standard and improved FTM hemolymph assays against the FTM body burden assay, two linear regressions were calculated using log-transformed data.

RESULTS

Effects of Supplemented AFTM on Hypnospore Diameter and Number

The diameter of hypnospores from samples incubated in AFTM supplemented with lipid concentrate (27.3 ± 11.5 μm) was significantly greater ($P < 0.0001$) than the diameter of hypnospores from samples incubated in AFTM supplemented with oyster extract (18.8 ± 9.4 μm) or with saline (16.5 ± 10.2 μm) (Fig. 1). No significant difference in hypnospore diameter was found between samples incubated in AFTM supplemented with oyster extract or with saline. No significant difference was found in the hypnospore numbers between samples incubated in AFTM supplemented with lipid concentrate ($1.9 \times 10^5 \pm 7.1 \times 10^4$), oyster extract ($1.8 \times 10^5 \pm 4.7 \times 10^4$) or the saline control ($2.2 \times 10^5 \pm 6.6 \times 10^4$).

Effect of FTM Types on Hypnospore Diameter and Number

No significant differences were found for hypnospore diameter or hypnospore number among samples incubated in different formulations of FTM (Table 3). The absence of agar in the Sigma alternative fluid thioglycollate medium facilitated sample processing because the viscous layer that generally collected over hypnospore pellets after centrifugation when samples were incubated in FTM with agar was eliminated.

Effect of Hemocyte Density on Hypnospore Diameter and Number

The diameter of hypnospores from samples that received 10^5 hemocytes per ml of AFTM (19.9 ± 8.8 μm) was significantly greater ($P < 0.001$) than the diameter of hypnospores from samples that received 10^6 hemocytes per ml (15.3 ± 8.7 μm) and 10^7 hemocytes per ml (15.2 ± 12.1 μm) (Fig. 2). No significant difference was found in hypnospore diameters between samples that received 10^6 hemocytes per ml and 10^7 hemocytes per ml. No significant difference was found in the number of hypnospores per hemocyte among samples that received 10^5 hemocytes per ml (0.06 ± 0.15 hypnospores/hemocyte), 10^6 hemocytes per ml (0.67 ± 2.26 hypnospores/hemocyte) and 10^7 hemocytes per ml (0.03 ± 0.07 hypnospores/hemocyte).

Effect of AFTM Volume on Hypnospore Diameter and Number

The diameter of hypnospores from samples that were incubated in 5.0 mL (24 ± 12 μm) and 25.0 mL (28 ± 13 μm) of AFTM was significantly greater ($P < 0.0001$) than the diameter of hypnospores from samples incubated in 0.2 mL (13 ± 6 μm) and 1.0 mL (16 ± 8 μm) of AFTM (Fig. 3A). However, the number of hypnospores in samples incubated in 25.0 mL of AFTM ($4.5 \times 10^4 \pm 6.9 \times 10^4$) was significantly lower ($P < 0.0002$) than the number of hypnospores in samples incubated in 0.2 mL ($9.3 \times 10^4 \pm 1.1 \times 10^5$), 1.0

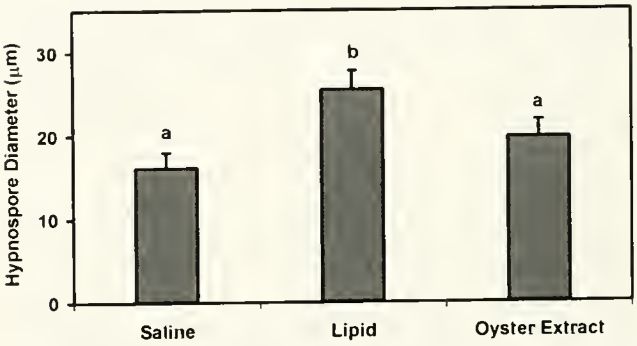

Figure 1. Hypnospore diameter (mean ± SD, $n = 5$) after incubation in AFTM supplemented with lipid concentrate, oyster extract, and saline (control). Hemocytes (10^6) were incubated for 7 days in 1 mL of supplemented AFTM. Treatments sharing a letter were not significantly different.

TABLE 3.

Average values (mean ± SD, $n = 9$) of hypnospore diameter and number of hypnospores per 10^6 hemocytes after incubation in different types of FTM.

Type of FTM	Hypnospore Diameter (μm)	Number of Hypnospores
Difco Bacto FTM	21 ± 11	$8.3 \times 10^4 \pm 1.1 \times 10^5$
Difco Bacto FTM with K agar	20 ± 12	$1.8 \times 10^5 \pm 3.3 \times 10^5$
Difco Bacto FTM with beef extract	19 ± 11	$1.2 \times 10^5 \pm 1.7 \times 10^5$
Sigma alternative FTM	18 ± 11	$2.0 \times 10^5 \pm 4.0 \times 10^5$
Sigma FTM	22 ± 13	$1.8 \times 10^5 \pm 3.1 \times 10^5$

mL ($1.8 \times 10^5 \pm 2.7 \times 10^5$), and 5.0 mL ($1.2 \times 10^5 \pm 1.5 \times 10^5$) of AFTM (Fig. 3B). No significant difference was found in the number of hypnospores among samples incubated in 0.2, 1.0, and 5.0 mL of AFTM.

Effect of NaOH Digestion of Samples on Hypnospore Diameter and Number

No significant difference was found in hypnospore diameter between samples processed with NaOH digestion (24 ± 17 μm) or without it (19 ± 9 μm). No significant difference was found in the number of hypnospores between samples processed with NaOH digestion ($1.8 \times 10^4 \pm 2.6 \times 10^4$) or without it ($2.6 \times 10^4 \pm 3.8 \times 10^4$). Sodium hydroxide facilitated counting by reducing cellular debris.

Effect of Protocol on Hypnospore Diameter and Number

Hypnospore diameter from samples processed with the improved protocol (26 ± 13 μm) was significantly greater ($P < 0.0001$; $n = 20$) than the diameter of hypnospores from samples processed with the standard protocol (10 ± 4 μm). Hypnospore numbers in samples processed with the improved protocol ($8.6 \times 10^3 \pm 3.3 \times 10^3$) were significantly greater ($P < 0.0001$) than the number of hypnospores in samples processed with the standard protocol ($1.9 \times 10^3 \pm 3.4 \times 10^3$). Hypnospores from hemocytes processed with the improved protocol readily settled to the plate bottom and could be easily counted. Hypnospores processed with the standard protocol were difficult to count because they remained suspended in the wells and the media column had to be scanned vertically as a consequence (Fig. 4).

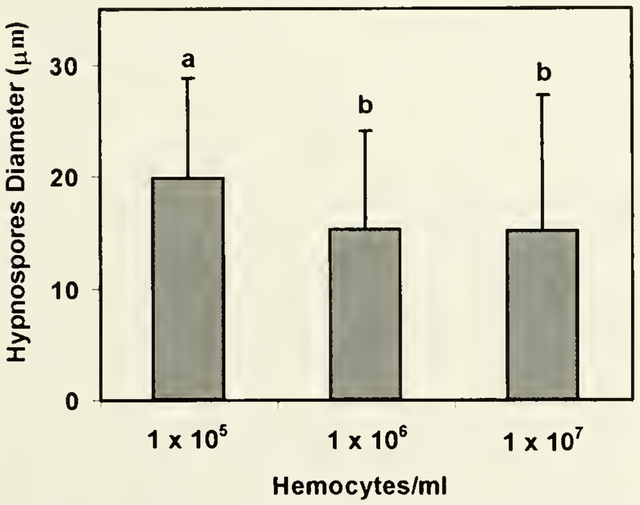

Figure 2. Effect of hemocyte density (10^5, 10^6, or 10^7 hemocytes per ml of AFTM) on hypnospore diameter (mean ± SD, $n = 13$). Hemocytes were incubated in 1 mL of AFTM supplemented with 5% lipid for seven days. Means sharing a letter were not significantly different.

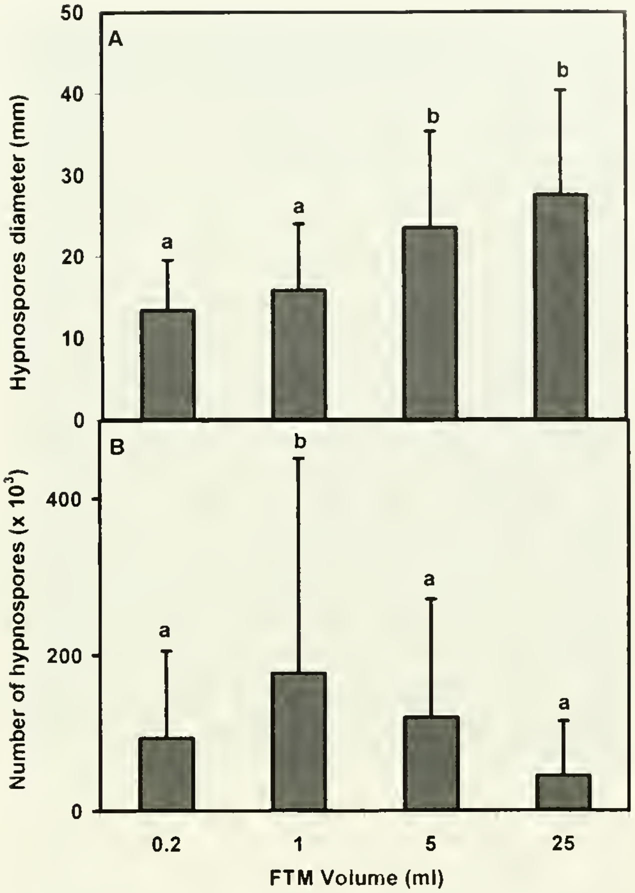

Figure 3. Hypnospore diameter (A) and number (B) (mean ± SD, $n = 10$) after incubation in 0.2, 1.0, 5.0, and 25.0 mL of AFTM. Hemocytes (10^6) were incubated for seven days in 1 mL of AFTM supplemented with 5% lipid. Means sharing a letter in each panel were not significantly different.

Comparison of Standard and Improved FTM Hemolymph Assays with FTM Body Burden Assay

Using linear regression, comparison of the infection intensity determined by the body burden assay (log of hypnospores per gram of oyster tissue) and the infection intensity determined by the standard hemolymph assay (log of hypnospores per 10^6 hemocytes) showed that the correlation was highly significant ($P < 0.0001$) with a coefficient of determination (r^2) of 0.5543 and a slope for the regression line of 0.6126 (Fig. 5A). Using linear regression, comparison of the infection intensity determined by the body burden assay and the infection intensity determined by the improved hemolymph assay showed a highly significant correlation ($P < 0.0001$) with an improved coefficient of determination ($r^2 = 0.7602$) and slope (0.9119) (Fig. 5B). This increased coefficient of determination indicated a reduction in variance with the improved FTM hemolymph assay.

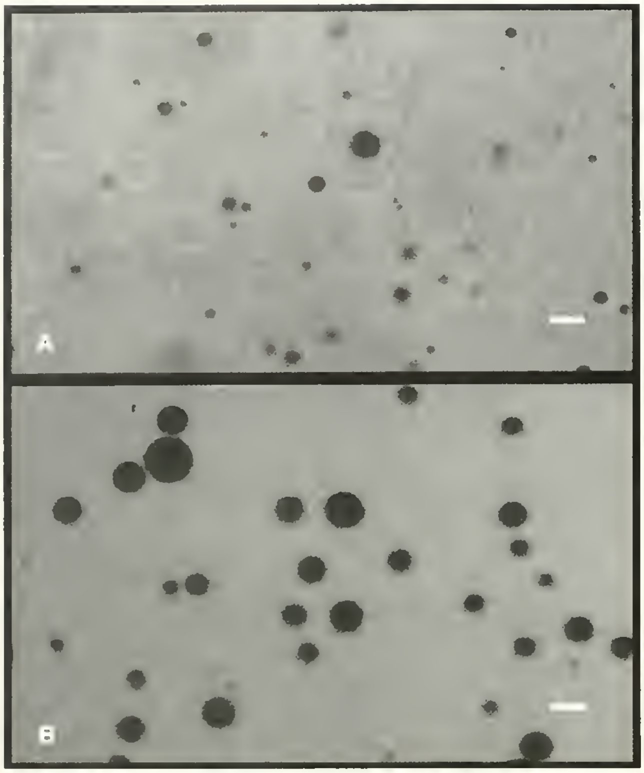

Figure 4. Light micrographs of *Perkinsus marinus* hypnospores after incubation and processing with the standard and improved protocols at 200× magnification. Bar represents 30 μm. A, Hypnospores were small (7–13 μm) and not clearly visible after incubation and processing with the standard protocol. B, Hypnospores were larger (15–44 μm) and more visible after incubation and processing with the improved protocol.

DISCUSSION

Use of the improved protocol to count *P. marinus* in hemolymph resulted in a 167% increase in hypnospore diameter and a 358% increase in hypnospore number over the standard protocol. The improved protocol also facilitated sample processing and counting. These improvements were caused by modifications of the standard hemolymph protocol, such as the addition of lipid concentrate to AFTM, the use of FTM without agar, and the addition of BSA to rinsing solutions. These modifications resulted in larger hypnospores, decreased sample viscosity, increased hypnospore recovery, and reduced cellular debris. Because processing, identification, and counting of hypnospores were facilitated, the improved protocol was simpler and more accurate than the standard protocol for counting of hypnospores in hemolymph. As a result, the coefficient of determination (r^2) of the linear regression between *P. marinus* $\log_{10}$ numbers in oyster body and *P. marinus* $\log_{10}$ numbers in hemolymph increased from 0.554 to 0.760 when the improved hemolymph protocol instead of the standard hemolymph protocol was used to count *P. marinus* in hemolymph.

Results from previous studies have suggested that nutrients from FTM and oyster tissues are used by enlarging parasites and that the ratio of FTM to oyster tissue may be critical for optimal hypnospore enlargement (Ray 1954a, Bushek et al. 1994, Fisher & Oliver 1996). The failure of parasites in highly infected oyster tissue to fully enlarge in FTM was proposed to be a result of exhaustion of necessary substances in medium or tissue (Ray 1954a). Hypnospore enlargement was also reported to be greatest in the FTM tissue assay, intermediate in the FTM hemolymph assay and least in the FTM body burden assays and therefore related to the volume of oysters sampled per ml of FTM (Bushek et al. 1994). Moreover, parasite enlargement was inversely related to infection intensity. Using *P. marinus* cultured *in vitro*, parasite enlargement in FTM can be significantly increased by addition of various nutrients including lipids (Wagner et al. 2001). Despite these observations, the effects of supplementing FTM with nutrients such as lipid or oyster extract and the effects of the ratio of FTM to oyster nutrients (e.g., from hemocytes) on parasite enlargement and numbers had not been studied and therefore needed to be investigated to improve the FTM hemolymph assay.

Addition of lipids to AFTM significantly increased hypnospore diameter by 66% over the saline control, and facilitated sample processing and counting because larger hypnospores were more easily pelleted during centrifugation. Lipids were added because the accumulation of numerous lipid droplets in hypnospores is characteristic of this life stage and may be critical to enlargement (Perkins & Menzel 1966, Perkins 1996). It was recently confirmed that lipids are taken up and stored in hypnospores (Soudant et al. 2000). This study found that fluorescent lipid analogs were primarily stored in cytoplasmic lipid droplet after 24 h of incubation but that after 24 h, fluorescence appeared in the membrane and cytosol of hypnospores.

The mean diameter of hypnospores in AFTM supplemented with 5% oyster extract was only 14% greater than the diameter of hypnospores in AFTM supplemented with oyster saline. It was surprising that the addition of oyster extract did not induce significant cell enlargement over saline as oyster extract would be expected to contain high concentrations of nutrients. Although the components of the oyster extract were not examined, it is likely that the water-soluble extract contained only small amounts of oyster lipids, which may account for the minimal enlargement of hypnospores.

Determining the effects of the ratio of infected hemocyte number to AFTM volume on hypnospore formation helped formulate the optimal combination of nutrients, from oyster and AFTM, to promote maximal parasite enlargement. In this study the number of infected hemocytes incubated in a constant volume of AFTM was adjusted, as was the volume of AFTM that had a constant number of infected hemocytes. Hypnospores from the lowest hemocyte density (10^5 cells per ml of AFTM) had the greatest enlargement indicating hypnospores in this treatment had more nutrients available from AFTM. Unfortunately, this low density may not provide an adequate sample size for determining parasite infection intensity. Using a higher number of hemocytes while maintaining hemocyte density (e.g., 10^6 per 10 mL) requires a larger volume of FTM, which in turn may affect the assay. To address this potential effect of volume on the assay, 10^6 hemocytes were incubated in various volumes of AFTM. Hypnospores from 10^6 hemocytes incubated in the largest AFTM volumes (5 and 25 mL) had the greatest enlargement, but there was also a significant decrease in the number of hypnospores from samples incubated in 25 mL of AFTM, indicating that smaller cells may be lost during processing of these volumes. Moreover, large volumes of AFTM requires the purchase of larger amounts of media and antibiotics, which increases cost. The most practical and optimal ratio was set at 10^6 hemocytes to 1 mL of AFTM. At this ratio of infected hemocytes to AFTM volume, parasites had adequate nutrients available for

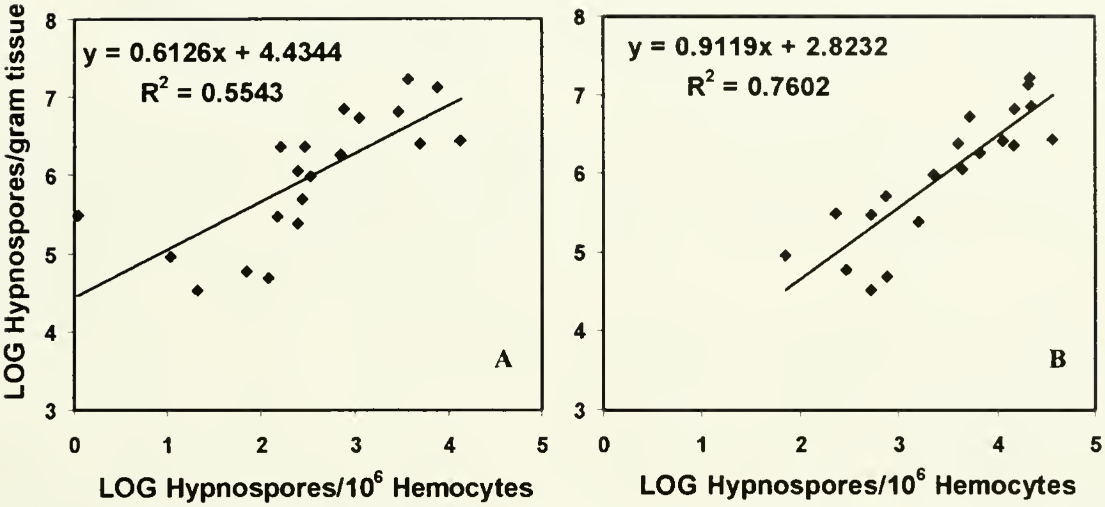

Figure 5. Linear regression lines, formulas, and coefficient of determinations for the comparison of the log of the number of hypnospores per 10^6 hemocytes determined by the standard FTM hemolymph protocol and the log of the number of hypnospores per gram of oyster tissue determined by the body burden assay (A), and for the comparison of the log of the number of hypnospores per 10^6 hemocytes determined by the improved FTM hemolymph protocol and the log of the number of hypnospores per gram of oyster tissue determined by the body burden assay (B).

enlargement in a small AFTM volume while minimizing protocol cost and hypnospore loss.

Perkinsus marinus in hemolymph has exclusively been reported in numbers of parasite per ml of hemolymph (Gauthier & Fisher 1990, Bushek et al. 1994, Oliver et al. 1998, Yarnall et al. 2000). The volume of hemolymph collected per oyster for use in the assay in these past studies varied by as much as a factor of 10, affecting the assay performance. Most parasites, however, are found within the phagosomes of hemocytes (Ray 1954a, Perkins 1996) and the density of hemocytes in hemolymph of bivalves can vary considerably with factors such as temperature, disease and feeding (Feng et al. 1977, Ford & Tripp 1996). *Perkinsus* may, therefore, be better expressed in number of parasites per number of hemocytes (e.g., per 10^6 hemocytes).

The coefficient of determination (r^2) of the linear regression of *P. marinus* $\log_{10}$ numbers in oyster body on *P. marinus* $\log_{10}$ numbers expressed per 10^6 hemocytes was 0.760 (n = 20). When the numbers of *P. marinus* for the same hemolymph samples were expressed per ml of hemolymph instead of 10^6 hemocytes, the coefficient of determination was 0.776 (n = 20) and higher than all, except for one previously reported r^2. An r^2 of 0.53 (n = 12) for Texas oysters sacrificed 24 h after collection and an r^2 of 0.89 (n = 12) for animals held for ten days at high temperature and salinity before sampling were reported by Gauthier and Fisher (1990). An r^2 of 0.675 (n = 25) was reported by Yarnall et al. (2000). An r^2 of 0.241 (n = 100) for oysters from Apalachicola Bay, Florida and an r^2 of 0.771 (n = 100) and 0.738 (n = 100) for oysters from Virginia and New York were reported by Oliver et al. (1998).

The use of FTM hemolymph assay is not recommended for predicting the number of parasites in whole oyster with light *P. marinus* infections (<1,000 parasite/g tissue) (Bushek et al. 1994, Oliver et al. 1998). In our study, the intersects (i.e., y when x = 0) of the linear regression for the number of parasites in whole oyster was 665 ($\log_{10}$ 665 = 2.823) or 1834 ($\log_{10}$ 1834 = 3.2635) depending on whether hemolymph parasite number was expressed per hemocyte or per ml. Hence, parasite numbers per g tissue in whole oyster would need to be greater than these numbers for the hemolymph FTM assay to be able to detect any parasite. This is in agreement with a Bushek et al. (1994) study in which a high percentage of oysters with parasite numbers below 1,000 *P. marinus* per g (wet) tissue were diagnosed as negative with the FTM hemolymph assay. The limitation in sensitivity of the FTM hemolymph assay is less of a concern for Gulf coast oysters than for oysters from the Northeast and central Atlantic coast because *P. marinus* prevalence in Gulf oysters in most sites is close to 100% as determined by the FTM tissue assay. This assay typically detects infection intensities when they are greater than 1,000 parasite/g wet tissue (Bushek et al. 1994, Soniat 1996, Fisher et al. 1996).

No statistical differences in hypnospore diameters or numbers were found among the FTM formulations tested, indicating that none of the FTM formulations provided more nutrients for parasite uptake than others. After incubation of parasites in media composed of individual FTM components, Ray (1954a) found that yeast extract combined with dextrose or casitone were the nutrients responsible for parasite enlargement. All FTM formulations tested in the present study contained approximately equal concentrations of yeast extract (5.0 g/L), dextrose (5.5 g/L), and casitone (15.0 g/L), which explains why no increase in hypnospore diameter or number was found among the FTM formulations tested. Incubation of hemocytes in FTM without agar, or AFTM, did simplify the processing and counting of samples. A viscous layer often forms over the cell pellets during rinsing steps before and after NaOH digestion when FTM with agar is used to enlarge *P. marinus* cells (La Peyre, personal observation, Oliver et al. 1998). This layer is made of indigestible agar because the use of AFTM eliminated this layer, thereby simplifying sample processing and reducing the risk of losing hypnospores in the discarded layer. Sample counting was also greatly simplified because 1) debris including indigestible agar that can interfere with hypnospore counting was eliminated, and 2) hypnospores readily settled on the bottom of wells of tissue culture plates forming monolayers and could be easily counted. In contrast to earlier studies, the need to scan for parasites vertically through the column was eliminated (Choi et al.1989, Gauthier & Fisher 1990, Bushek et al. 1994). Moreover, parasite suspensions could be serially diluted in 96-well plates and counted at the appropriate dilution faster than they could be prepared at the appropriate dilution and counted on filter paper by the technique of Oliver and Fisher (1996) or counted with hemacytometers as used by Choi et al. (1989). Although agar is traditionally used in the microbiological medium FTM to preserve anaerobic conditions and keep bacteria suspended throughout the media for maximizing the use of nutrients (Hitchens 1921), it was clear from our study that the conditions produced by this viscosity are not necessary to enlarge *P. marinus* parasites. AFTM was therefore selected for parasite enlargement in the improved FTM hemolymph protocol.

In an evaluation of methods to diagnose *P. marinus*, NaOH digestion was used to process hemolymph and oyster tissue. It was found that NaOH digestion facilitated the counting of hypnospores from oyster tissues and from hemolymph, but it was noted that NaOH may not be needed for the hemolymph technique because it adds time and labor to the assay (Bushek et al. 1994, Fisher & Oliver 1996). In our study, NaOH digestion of hemolymph samples simplified and reduced the time spent counting. By eliminating debris, cells formed a monolayer on cell culture plate bottoms eliminating the need to scan vertically for hypnospores caught in debris. In past studies, it was noted that hypnospores became sticky forming clumps and adhering to the sides of test tubes after NaOH digestion and upon rinsing (Choi et al. 1989, Bushek et al. 1994, Fisher & Oliver 1996). In our study, the loss of hypnospores as a result of clumping and adherence to the side of test tubes was alleviated by adding BSA to rinsing solutions as recommended by Coates et al. (1999).

In conclusion, simple modifications to the standard protocol for counting of *P. marinus* in oyster hemolymph improved the technique. The addition of lipid to AFTM, the use of FTM without agar, and the use of BSA in rinsing solution facilitated sample processing and counting. The availability of an improved protocol to count *P. marinus* in hemolymph will be useful in monitoring the dynamic change of parasites in hemolymph in infected individual oysters under various conditions. The role of hemocytes in the infection process or in the elimination of the parasites (e.g., hemocyte killing assay) can also be investigated more accurately with this assay.

ABSTRACT We applied time series of fishery-dependent and fishery-independent data to develop indices of relative biomass and estimates of absolute abundance and biomass for the Maryland oyster population. The principal objectives for this work were to specify a baseline and determine trends relative to the Chesapeake Bay Program's goal to achieve a 10-fold increase in the standing stock of oysters in the Bay from a 1994 baseline. Population biomass varied by 3-fold from 1986–2001, with most of the variation caused by changes in the stock of market-sized oysters. There were also important spatial differences in population structure and trends over a gradient of salinity. Lagged correlations between small oyster biomass and either market-sized oyster biomass or landings were not statistically significant but suggested that most of the market-sized oysters and those harvested were four to five years old. The index of relative biomass for market-sized oysters proved to be a useful predictor of annual harvests in Maryland. We used this relationship to estimate absolute abundance and biomass of oysters for the time series. The latter estimates may be biased negatively with respect to true abundance and biomass because of biases in both the fishery and the fishery-independent monitoring program. The index of relative biomass will be a suitable measure of population status relative to the oyster restoration goal only so long as the population remains at relatively low levels. Because the index has a theoretical maximum of about 75% of the 10-fold goal, a quantitative estimator will be required for higher population levels.

KEY WORDS: oysters, *Crassostrea virginica*, stock assessment, biomass, Chesapeake Bay

INTRODUCTION

Oysters once supplied the most valuable fishery in Chesapeake Bay (Christmas & Jordan 1991), but after the mid-1980s, a declining oyster stock could no longer support historical levels of harvest. The principal reasons for reduced harvests from 1987 to 2001 were (1) high mortality rates of oysters caused by the parasitic diseases MSX (*Haplosporidium nelsoni*) and Dermo (*Perkinsus marinus*) and (2) low rates of spat settlement throughout most of this period (Krantz undated, Maryland DNR 2001). In addition to economic losses to the fishery, the depletion of oyster standing stocks has been thought to (1) reduce the quantity and quality of shell-bar habitats for oysters and associated epifauna (MacKenzie 1996) and (2) impair water quality by loss of the oyster population's capacity to filter particulate matter (Jordan 1987, Newell 1988, MacKenzie 1996).

In June 2000, the interjurisdictional Chesapeake Bay Program established a goal to increase oyster populations 10-fold by 2010, from a 1994 baseline. Our objectives for the work presented here were to (1) quantify the 1994 baseline, (2) compare the current population with recent and historical populations, (3) develop methods to measure consistently the status of populations with respect to the goal, and (4) examine relationships between long-term fishery-independent surveys and annual harvests. In addition to meeting these objectives, we have developed methods for estimating absolute abundance, biomass and fishing mortality from these data. Only data from the Maryland portion of Chesapeake Bay were used in our analysis. We are working with scientists in Virginia on a combined, bay-wide assessment of the oyster population.

MATERIALS AND METHODS

Oyster Surveys

Size frequency, disease, mortality, and spat density data were collected from oyster dredge samples at 43 sites (Fig. 1) in October to November from 1990 to 2000 (in a few cases, 42 or 44 sites were sampled). The standard dredge has an opening 80 cm wide and a capacity of approximately 2.5 bushels (the volume of a Maryland oyster bushel is ≈46 L, or about 475 oysters at the minimum market size of 76 mm). Dredge tows were taken from areas of the oyster bars with relatively high concentrations of shell, as determined by the sampling crew with a sounding pole. Our observations indicated that tow times and boat speed (hence the area swept) tended to be consistent, but these variables were not formally controlled. From 1990 to 1996, five replicate dredge tows were made at each site; data were collected from a 0.2 bushel subsample of all material in each dredge sample. From 1997 to 2000, two tows were made at each site, with a 0.5 bushel subsample taken from each tow. All live oysters in the subsamples were counted and measured, with measurements recorded in 5 mm size classes. Boxes (articulated oyster shells without tissue remaining) also were counted and measured. All spat were counted in each sample. Sample data were standardized to a fixed volume (one bushel, as defined above) of all material retained by the dredge. A complete description of this survey, known as the Modified Fall Survey (MFS) can be found in Smith and Jordan (1993).

A more extensive survey of 300 to 400 sites has been conducted in the fall of each year since the 1970s. In this survey, typically only one dredge tow is made; all live oysters, spat, and boxes from 0.5 bushel of material are counted. The oysters are not measured individually but are classified as markets (>76 mm), smalls (age 1+ and older oysters <76 mm), or spat. Means and ranges of shell heights for each class are estimated visually by an experienced technician and recorded (Homer et al. 1996).

Length-Weight Analysis

A relationship between dry tissue weight and shell height was developed to convert size-frequency data to biomass. During the 1999 fall survey, 10 oysters were collected from each of 42 sites (one of the 43 survey sites did not have sufficient live oysters) and returned to the laboratory for processing. The oysters were selected to be representative of the size range encountered at each site. In the laboratory, the oysters were measured (bill to umbo curved shell height in mm), then shucked carefully, retaining all meat and shell liquor. Each oyster was put into a tared aluminum weighing boat, weighed, dried to constant weight at 85°C, and then reweighed. Wet and dry tissue weights were recorded in g, to the nearest mg.

The relationship between dry tissue weight and shell height was quantified by linear regression of the $\log_{10}$-transformed variables. Indices of relative biomass were calculated by applying the length-weight regression equation to each 5 mm size class of live oysters (excluding spat), then multiplying the number of oysters in that size class by the predicted weight. The midpoint in mm of the size class was used as the nominal shell height for the estimated weight. The weights were summed over all size classes within each replicate subsample, resulting in 1629 individual observations of the index over 43 sites and ten years. Indices of relative abundance were calculated similarly using total counts of oysters (excluding spat) within each subsample. Indices of biomass and abundance were calculated separately for small (<72 mm) and market (≥72 mm) oysters, and for all oysters combined. The legal minimum size for harvested oysters in Maryland is 3 inches (76 mm), but the nearest size class in which survey data are recorded is 72 to 77 mm. We examined the underlying variation in the indices by two-way analysis of variance, accounting for the fixed effects of site, year, and site-by-year interaction.

Relationships Between Fishery-Dependent and Fishery-Independent Data

We used linear regression to determine whether the fishery-independent data could predict commercial harvests. Harvest data were obtained from the Maryland Department of Natural Resources. Because the oyster season is open from October to March, landings are reported for the year the season closes, whereas the MFS data applicable to the annual harvest are collected in October through November of the previous year. For this reason, the analyses reported here are indexed to the harvest year, that is, the 1985 MFS corresponds to the 1986 harvest, and the biomass index for 1986 is derived from data collected in the fall of 1985. However, when referring to the fishery-independent data per se, we use the year in which the data were collected. Annual harvest totals, recorded in bushels, were regressed against the annual mean biomass index for market oysters and the annual abundance index for market oysters. Nine years of data, from harvest years 1991–1999, made up the initial calibration data set. We then used dredge survey data from 1985–1989 for the bars sampled by the MFS to calculate the biomass indices and perform a hindcast test of the harvest prediction model. The 1985–1986 harvest was 1.56 million bushels, nearly 20 times greater than the 1993–1994 harvest. Also, the index previous to 1990 was based on mean sizes for market oysters rather than individual measurements. Prediction of the 1985–1986 and subsequent harvests, therefore, would provide a stringent test of the robustness of this simple model. Once the model was calibrated and validated by hindcasting, we recalibrated over the entire time series, and forecast landings for the 1999–2000 and 2000–2001 harvest seasons.

Quantitative Estimation of Standing Stocks

The success of the market oyster biomass index in predicting annual landings suggested that we could use this relationship to quantify the oyster population. We made the key assumption that differences between predicted and reported landings were entirely caused by differences in rates of fishing mortality. Smith and Jordan (1993) estimated a mean exploitation rate of 0.53 (53% of the market stock harvested) for Maryland oysters for the 1990 to 1991 season. They projected size-frequency data from the 1990 MFS to 1991, assuming a mean growth rate of 20 mm per year and subtracting 1991 observed natural mortality, estimated from box counts as [boxes/(boxes + live oysters)], from each size class. The exploitation rate then was estimated by difference between the projected relative abundance (without exploitation) and that observed from the 1991 survey. Because the ratio of reported to predicted harvest for that year was approximately unity, we computed the instantaneous rate of fishing mortality (F) for the time series as

$$F = -\log e\left[1 - 0.53\left(\frac{H}{\hat{H}}\right)\right],$$

where H = reported harvest and $\hat{H}$ = predicted harvest. Estimates of harvestable stock size (S) for each year were computed as $S = H \cdot e^{F}$ (in units of bushels). Estimates of total population abundance (N, excluding spat) were computed as

$$N_t = N_m + N_m\left(\frac{R_s}{R_m}\right),$$

where the subscripts t, m, and s indicate total, market, and small oysters, respectively, R refers to the relative abundance estimates from the fishery-independent survey, and

$$N_m = \sum_{1}^{i}\left[a_i S\left(\frac{R_i}{R_t}\right)\right],$$

where $a_i = 10^{3.5-0.0113(L_i)}$, R_i is the relative abundance of market oysters in each size class, R_t is the total relative abundance of market oysters, and L_i is the nominal length for each size class of market oysters. The last equation estimates the number of oysters of a given size per bushel, derived by linear regression from tabulated counts (unpublished data, Maryland Department of Natural Resources). Absolute population biomass was estimated by multiplying the proportion of oysters in each size class from fishery-independent size frequency distributions by total absolute abundance (N_t, calculated as above) and the nominal weight for each size class:

$$B_t = \sum_{1}^{i}\left[N_t W_i\left(\frac{R_i}{R_t}\right)\right],$$

where B_t is total population biomass, W_i is the nominal weight in g for each 5 mm size class, R_i is the relative abundance in each size class, and R_t is the total relative abundance over all size classes.

Recruitment

Spat (young of the year oysters) are counted in each sample taken during fall oyster surveys. Although annual mean spat counts have been used for many years as an indicator of year class strength (Meritt 1977, Homer et al. 1996, Krantz undated), they are not always reliable indicators of subsequent recruitment to the population because of high, variable rates of early juvenile mortality (Newell et al. 2000) and the impacts of diseases on submarket oysters. Counts of small oysters (>1 y old and <76 mm in shell height) may be better indicators of recruitment to adult and exploitable stocks than spat counts. Therefore, we examined the potential of small oyster counts and biomass to predict landings, as well as biomass of market oysters in subsequent years, by regressing landings and market oyster biomass against 1- to 5-y lags of the small oyster indices.

Influence of Salinity

Recruitment of oysters to the population and disease-related mortality are positively correlated with salinity in northern Chesapeake Bay (Jordan 1995, Calvo et al. 1996). To examine the effects of salinity on the biomass index, we assigned each of the MFS sites to one of three salinity zones based on 1990 to 2000 mean salinity measured during the fall at the time oyster samples were taken (Fig. 1). These zones were defined as low (mean salinity <12 ppt), medium (12–14 ppt), and high (>14 ppt). At salinity <12 ppt, *H. nelsoni* infections occur rarely, if ever; *Perkinsus marinus* infections, although chronic in this zone, are associated with low to moderate mortality rates; and recruitment rates of both small and market oysters are typically very low, except in areas where natural recruitment has been supplemented by transplanted seed oysters. In the medium salinity zone, *H. nelsoni* epizootics are sporadic, occurring only in drought years, mortality associated with *P. marinus* is moderate to high, and recruitment is variable. In the high-salinity zone, *H. nelsoni* infections tend to be enzootic, mortality rates associated with *P. marinus* infections are consistently high, and recruitment, although variable, tends to be higher than in the lower salinity zones.

RESULTS

Length-Weight Relationship

The linear relationship between the log of dry tissue weight and the log of shell height was quantified as $\log_{10}$(dry tissue weight) = 2.06[$\log_{10}$(shell height)] − 3.76, with tissue weight in g and shell height in mm; n = 410, r^2 = 0.50, $P < 0.0001$ (Fig. 2). Removal of a few outlying observations or weighting the regression for uneven distribution of the dependent variable on the independent variable made only trivial differences in the parameter estimates and the coefficient of determination. Therefore, population-scale estimates of biomass should be accurate, even though the relationship does not have satisfactory precision for estimates at smaller scales (individuals or small samples).

Variability of Biomass Indices

In the two-way analysis of variance models, sites, years, and site-by-year interactions explained 85 to 91% of the variation in index values for small oysters, market oysters, and the total population; all effects were significant (Table 1). The residual 9 to 15% of overall variation was caused by differences between replicate samples.

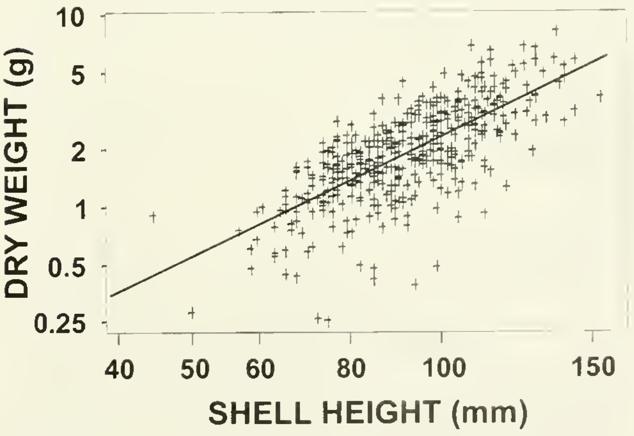

Figure 2. Relationship of oyster dry tissue weight to shell height.

TABLE 1.

Analysis of variance results for examining sources of variability in biomass indices of total, market, and small oysters, 1990 to 1999.

Source of Variation	Degrees of Freedom	F	P Value
Total Biomass			
(Mean = 114.4 g dry weight per bushel, r^2 = 0.91, n = 1629)			
Site	43	85.96	<0.0001
Year	9	89.10	<0.0001
Site × year	378	18.73	<0.0001

Year	9	94.46	<0.0001
Site × year	378	8.88	<0.0001
Total	1630	16.24	<0.0001
Small Oyster Biomass			
(Mean = 49.8 g dry weight per bushel, r^2 = 0.89, n = 1631)			
Site	43	64.60	<0.0001
Year	9	23.31	<0.0001
Site × year	378	15.81	<0.0001
Total	1630	22.74	<0.0001

Relationships Between Fishery-Dependent and Fishery-Independent Indicators

There was a significant linear relationship between the mean relative biomass of market oysters sampled in October through November of each year and the quantity of oysters harvested during the commercial season (generally October 1 through March 31, with minor variations). The resulting regression equation was $\log_{10}(y) = 1.64(\log_{10}x) + 2.39$, where y = predicted annual harvest in bushels and x = mean relative biomass of market oysters (r^2 = 0.89; Fig. 3). This regression was developed from 10 y (harvest years 1991–2000) for which we had replicate samples and size frequency data. A hindcast of this model for 1986 to 1990 landings, using only counts and mean sizes of market oysters, yielded reasonable estimates. Over the 15 harvest years from 1986 to 2000, the mean absolute difference between predicted and reported landings was 18.5% (minimum 3.7%, maximum 57.6%, standard deviation 17%). The poorest prediction was for 1987, a period of sharply declining relative biomass associated with an epizootic of MSX disease. An earlier validation of the model used a regression of nine years of data along with biomass from the 1999 Fall Survey to predict 1999 to 2000 oyster landings at 379,000 bushels; reported landings were less than 1% greater (380,000 bushels). The prediction for 2000 to 2001 landings was 331,000 bushels, about 5% less than reported (348,000 bushels). With the model validated by hindcasts and forecasts, it was appropriate to use the entire time series to estimate model parameters (Fig. 4).

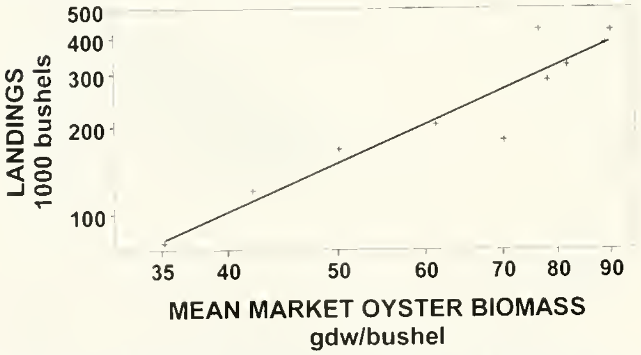

Figure 3. Relationship between annual reported oyster landings and annual mean market oyster biomass index (g dry weight of oyster tissue per bushel of dredged material). Both axes are logarithmic. r^2 = 0.89.

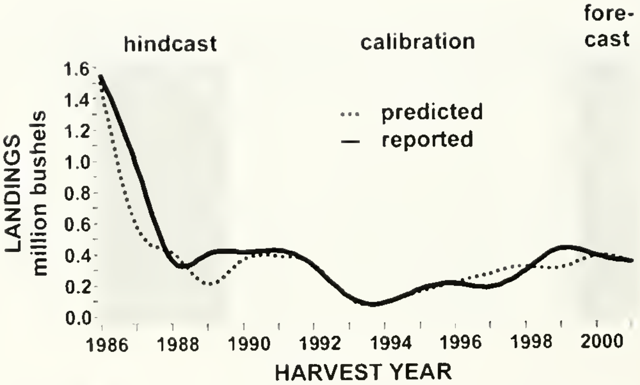

Figure 4. Predicted and reported oyster landings, 1986 to 2001.

Biomass as an Indicator of Population Size

The biomass index for the total population showed more than 3-fold variation over a 15-y period (Fig. 5). Most of this variation was caused by changes in the market oyster index, which varied by more than 6-fold. Small oyster biomass was more stable, varying by a factor of 2.4. The 1994 baseline index for the total population

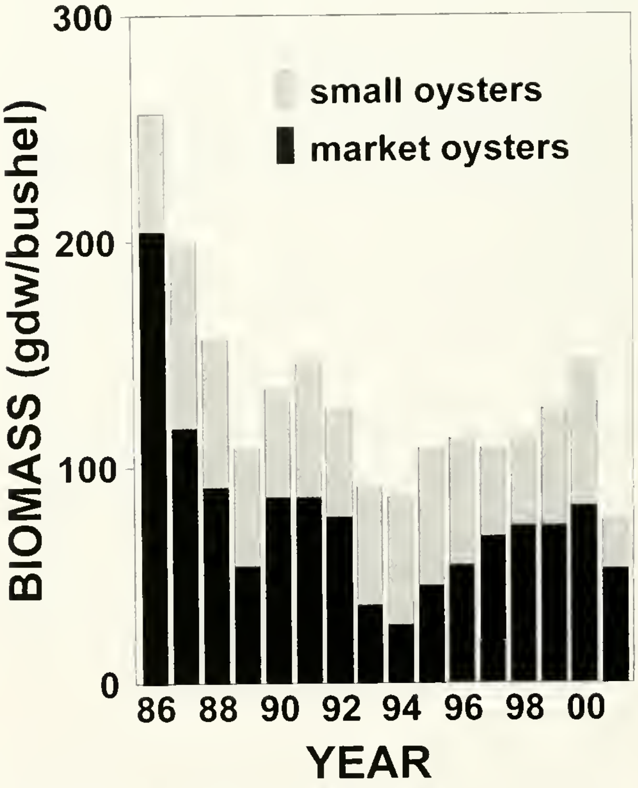

Figure 5. Biomass indices (g dry weight of oyster tissue per bushel of dredged material) for small, market, and total oysters, 1986 to 2001.

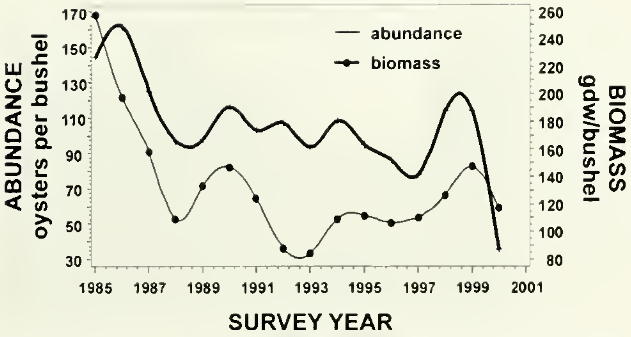

Figure 6. Annual means of relative biomass and relative abundance, 1985 to 2001.

(84.4 g dry weight of oyster tissue per bushel of dredged material) was the lowest in the time series, largely because of a very low index of market oysters (34.8), yet small oyster biomass in 1994 (49.6) was close to the 15-y mean (51.4).

Although there were similarities between trends in relative biomass and relative abundance from 1986 to 2001, there were important divergences (Fig. 6). The sharp rise in abundance from 1997 to 1998, for example, reflects the large spat set observed in 1997, followed by a sharp increase in the abundance of small oysters in 1998. The biomass also increased from 1997 to 1999, but more slowly. Sharp declines in biomass from 1985 to 1989 and from 1990 to 1992 were associated closely with disease epizootics.

Trends in biomass varied considerably over three salinity zones (Fig. 7). In the low-salinity zone, population biomass was moderate and relatively stable, whereas in the midsalinity zone, biomass declined almost steadily for nine years, followed by partial recovery from 1995 to 1999. In the high-salinity zone, biomass decreased sharply from 1986 to 1989 and did not show sustained recovery. Differences between the zones were even more evident when expressed as mean biomass per individual over the full time series (Fig. 8).

Estimates of Fishing Mortality, Total Mortality, Absolute Abundance, and Absolute Biomass

Estimated instantaneous annual rates of fishing mortality varied from 0.23 in harvest year 1997 to 1.29 in 1989. Instantaneous annual total mortality for the market oyster stock ranged from 0.57 in 1997 to 1.67 in 1989 (Table 2, Fig. 9). These ranges corresponded to annual exploitation rates of 21 to 72% and annual total mortality rates of 43 to 92% for the market stock.

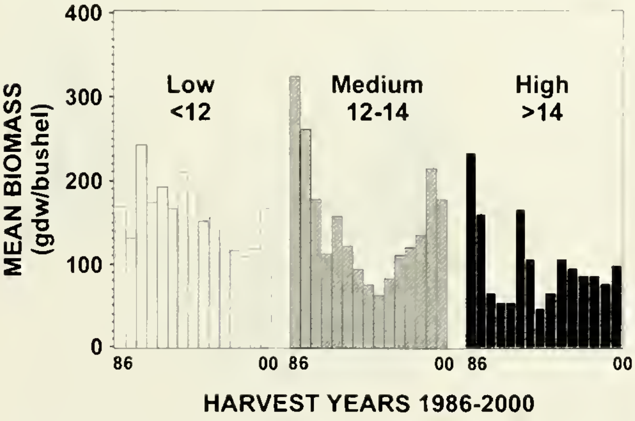

Figure 7. Mean relative biomass by salinity zone, 1986 to 2001.

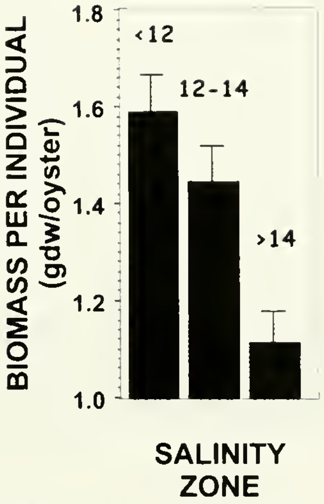

Figure 8. Mean relative biomass per individual oyster by salinity zone. Error bars are standard errors.

Our estimates of total oyster abundance from harvest years 1991 to 2001, for which size-frequency data were available, ranged from 2.66 to 6.29 × 10^8 individuals, with a mean of 4.78 × 10^8. Total population biomass over the same time period ranged from 2.41 to 8.64 × 10^8 g dry tissue weight, with a mean of 5.74 × 10^8 g (Fig. 10). Mean biomass per individual oyster (biomass divided by abundance) was 1.18 g, ranging from 0.82 to 1.42 g over the time series (Fig. 11). For reference, the predicted dry weight of a minimum-sized market oyster (76.2 mm) is 1.31 g.

Recruitment

Lags of small oyster biomass (0–5 y) were not significantly correlated (Spearman r, $P > 0.05$) with market oyster biomass or annual oyster harvests from 1986 to 2001. The strongest positive correlation ($r = 0.58$, $P = 0.06$) was between harvest and a 4-y lag of small oyster biomass (Fig. 12).

DISCUSSION

We estimated total oyster population abundance and biomass for Maryland's portion of Chesapeake Bay from 1986 to 2001. Although these estimates appear to represent population trends accurately, there are several sources of uncertainty and potential bias, which are discussed below. Until these uncertainties can be reduced by further assessment and analysis, we recommend use of the indices of relative biomass reported here as more reliable mea-

TABLE 2.

Summary statistics for instantaneous rates of fishing mortality (F), natural mortality (M), and total mortality (Z) for harvest years 1986 to 2001 ($n = 16$).

Variable	Minimum	Maximum	Mean	Standard Deviation
F	0.23	1.29	0.71	0.25
M	0.11	0.91	0.39	0.22
Z	0.57	1.67	1.11	0.32

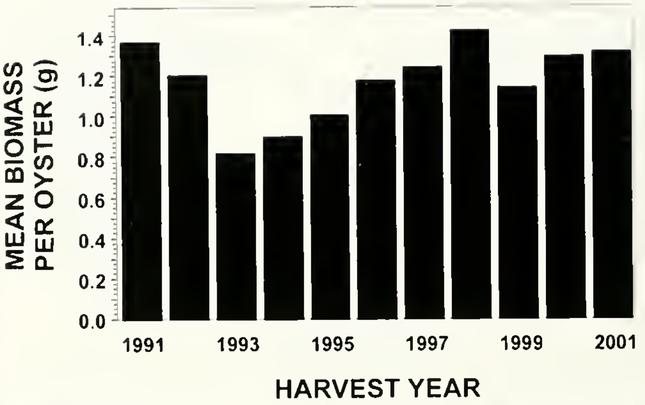

Figure 11. Estimated annual means of absolute biomass per individual oyster, 1981 to 2002.

sures of changes in the oyster population than our estimates of absolute abundance and biomass.

Indices of relative biomass and abundance rely on the principal assumption that the fishery-independent monitoring program accurately represents trends in the oyster population as a whole. The MFS, the source of data for index calibration, was designed specifically for consistent assessment of trends in oyster relative abundance, population structure, mortality and disease status (Smith & Jordan 1993). For these purposes, fixed sites, sampled consistently over time, are appropriate. The monitoring sites are widely distributed throughout the oyster-producing areas of Maryland, and evidence presented here suggests they provide data representative of real trends in the population.

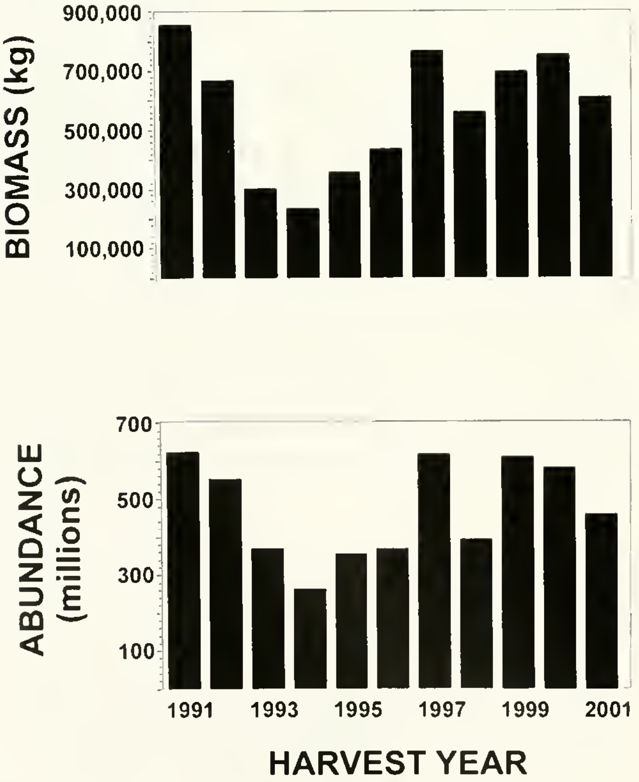

Figure 10. Estimates of absolute biomass and abundance, 1991 to 2002.

Unbiased, quantitative estimates of population size generally require spatially randomized sampling, a condition not satisfied by the data used in our assessment. Our estimates of absolute biomass and abundance also depend on the untested assumption that differences between predicted and reported oyster landings are caused solely by variations in fishing mortality. Both of these considerations introduce biases and inaccuracies of unknown magnitude to the quantitative assessment. Preliminary estimates of population abundance we derived entirely from fishery-independent data sources resulted in higher estimates of population abundance than those derived from fishery-dependent estimates. The fishery-independent estimates ranged from 1.1 to 1.7 × 10^9 oysters in 2000 to 2001, compared with 0.6×10^9 oysters estimated for the same period by the methods reported here. We conjecture that neither the fixed-station monitoring program nor the fishery landings data adequately represent potentially large numbers of oysters scattered at low densities in marginal habitat areas. Areas with low densities of oysters would not be targeted by the fishery because the catch per unit of effort would be very low. Similarly, the fixed monitoring sites were selected to represent typically productive areas of high quality habitat. We plan to collect quantitative data from a variety of habitat types during 2002 to get better

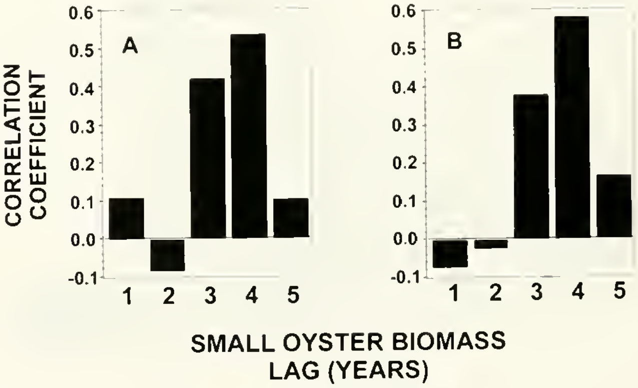

Figure 12. Correlations between lags of small oyster biomass and (A) reported landings and (B) market oyster biomass.

estimates of oyster densities, especially in areas of marginal habitat. Until further refinements can be made to the quantitative assessment, we view it as yielding minimal estimates of oyster abundance and biomass.

The equation relating shell height to dry tissue weight used to compute the biomass index explained 50% of the variation between individual oysters. Morphology, growth, and physiologic conditions can vary greatly in *C. virginica*, depending on specific habitat conditions, health, and other factors (Carriker 1996, Ford & Tripp 1996). The condition of each oyster weighed and measured for this study was assessed both by visual inspection (scored 1–8, "watery" to "fat," according to standard procedures used in our laboratory) and by calculating the percentage of water in the tissues from the difference between wet tissue weight and dry tissue weight. Inclusion of either of these condition indicators as a covariate in the length-weight regression improved the total r^2 to > 0.70. Because oyster condition is not measured routinely in population surveys, we could not account for this source of variation in biomass indices. We conclude that the length-weight equation has low precision for predicting the biomass of individuals or small groups of oysters, but has sufficient accuracy for estimating biomass at population or sub-population scales.

Harvest Predictions, Fishing Mortality, and Recruitment

The close relationship between reported annual landings and the biomass index for market oysters has provided a method for predicting total annual harvest early (mid-November) during each oyster season (October–March). This capability is helpful to managers of the oyster fishery, who are often asked by the press and other interested parties to make these predictions. This relationship also has provided a quantitative link between relative and absolute abundance and biomass of oysters, and a way to estimate fishing mortality rates. Because natural mortality (the ratio boxes:live oysters plus boxes) is observed directly during the annual monitoring program, we now have estimates of total mortality for market-sized oysters. These relationships are being used, along with other parameters, to calibrate a population dynamics model for Maryland oysters.

Ulanowicz et al. (1980) developed a multiple regression model to predict Maryland oyster harvests four years into the future from data on spat settlement and management effort (transplantation of seed oysters) in previous years. The time series of data used in their model was from the 1960s and 1970s, a period when parasitic diseases were not major influences on oyster population dynamics. During the period of the present study, variations in annual landings have depended strongly on oyster mortality rates, which in turn have depended primarily on variations in disease intensity (Gieseker 2001).

Instantaneous annual rates of fishing mortality (F) varied from 0.23 to 1.29 from 1986 to 2001, corresponding to exploitation rates of 21 to 72% of the market oyster stock harvested each year. The mean exploitation rate of market-sized oysters over 16 y was 51% ($F = 0.71$). This value of F contrasts with that estimated by Rothschild et. al. (1994) at 1.3 (73% exploitation rate) for 1990; our estimate of F for that year was 0.76 (53%). Their estimate of F apparently included some natural mortality (M) because their estimated value of M was 0.15, compared with our measured value of $M = 0.22$ for 1990. The resulting total mortality of the market stock for 1990 was 0.94 (61%) in this study, compared with 1.45 (77%) reported by Rothschild et al. (1994). Besides underestimating natural mortality, Rothschild et al. (1994) estimated mean age at first capture at 2.6 y (legal minimum length 76 mm), and the mean age of the harvest (85 mm mean length) at 3.0 y. Growth curves we derived from size-frequency data for thousands of Maryland oysters collected during surveys from 1990 to 2000 predicted that the average 76 mm oyster was 4.0 y old, and the average 85 mm oyster was 4.5 y old. This disparity in age-at-length determinations could explain the higher rates of total mortality and fishing mortality estimated by Rothschild et al. (1994) using a modified Beverton-Holt formulation (Ehrhardt & Ault 1992), because overestimation of the growth coefficient would yield a higher rate of total mortality. Our recruitment analysis suggested that oysters are most likely to be harvested at ages of four to five years in Maryland, consistent with our growth-based predictions of age at first capture and mean age of capture, and with findings by Ulanowicz et al. (1980).

Our estimates of total mortality assume that instantaneous rates of fishing mortality and natural mortality are additive, that is, these sources of mortality do not occur simultaneously within a harvest year. This assumption cannot be strictly true, but mortalities associated with *P. marinus* and *H. nelsoni* dominate the natural mortality term and generally occur from May to October (Ford & Tripp 1996). Because the fishery operates from October to March, interaction between the two mortality terms should not be a major source of error, but probably is a source of positive bias in the total mortality estimates. We plan to test this assumption more rigorously in our continuing stock assessments. Among the uncertainties in estimating mortality, we note the questionable accuracy of determining annual rates of natural mortality from box counts. For example, experimental data presented by Christmas et al. (1997) indicated that roughly 50% of boxes remained intact for more than two years in northern Chesapeake Bay, suggesting that our surveys overestimated annual mortality. Counteracting biases might involve (1) mechanical disarticulation of boxes by the dredge used for sampling, or (2) pre-mortem deterioration of the hinge ligament in diseased and dying oysters, which could hasten disarticulation compared with the chemically-killed oysters used in the Christmas et al. (1997) study.

Effects of Salinity on Population Structure and Biomass

The sharp differences between trends in oyster biomass in high-, medium-, and low-salinity zones partially reflect different rates of recruitment and natural mortality. In high salinity areas, infections with *H. nelsoni* and *P. marinus* are enzootic, with chronically high rates of mortality. Relatively few oysters survive to market size in this zone, but higher rates of spat settlement and recruitment to the sub-market stock tend to maintain populations of small oysters. Populations in the medium salinity zone undergo epizootics of *H. nelsoni* and attendant mortality episodes during extended dry periods, when salinity rises to within the tolerance range for the parasite (13–15 ppt; Paraso et al. 1999). Infections with *P. marinus* are enzootic in this zone except during very wet periods; mortality can be high even in the absence of *H. nelsoni*, but oysters generally survive to larger sizes than in the high-salinity zone. Spat settlement is moderate and episodic in these mid-salinity areas. In the low-salinity zone, *H. nelsoni* is absent or very rare, and although *P. marinus* can reach high prevalence in these populations, oyster mortality rates are lower than in high- and mid-salinity zones. Spat settlement and natural recruitment are sporadic and must be supplemented by transplants from other regions of the Bay or from hatcheries to sustain these harvested subpopulations. Occasionally, freshets cause significant oyster mortality in the areas of lowest salinity. The net long-term results of these dynamics are as follows: (1) relatively stable subpopulations of larger oysters in the low-salinity zone; (2) subpopulations that fluctuate in size and abundance in the mid-salinity zone; and (3) subpopulations in the high-salinity zone that are typically comprised mostly of submarket oysters, which can reach high abundance in some areas. Jordan (1995) used multivariate analysis to classify Maryland oyster bars into six groups based on several population attributes; salinity was the most important independent variable associated with population structure in that analysis.

Oyster Biomass and Abundance Relative to the Chesapeake Bay Restoration Goal

In terms of the relative biomass index, the 1994 baseline Maryland oyster population (from which a 10-fold increase is to be gained by 2010) was 84.4 g dry tissue weight per bushel of dredged bottom material. An index of 844, therefore, would indicate achievement of the goal. In 2001, the index was 117, about 1.4 times the baseline, or 14% of the goal. By combining the length-weight equation and the equation for estimating the number of oysters per bushel, we estimate that a Maryland bushel cannot contain more than about 640 g dry weight of oyster tissue. For this reason, the index of relative biomass cannot realize the desired value of 844 with current sampling methods. Although the biomass index is a satisfactory indicator of trends as long as the oyster population remains at low levels, quantitative assessment will be essential for determining attainment of the goal. Working with Virginia scientists, we expect to establish a bay-wide baseline and annual assessments of absolute abundance and biomass by the end of 2002.

These analyses would not have been possible without relatively long time series of consistent monitoring data. Earlier publications based on MFS data (Smith & Jordan 1993, Jordan 1995) characterized the first 2-4 y of the data set (1990—1993), but relationships such as those depicted in Figures 3, 4 and 12, along with our estimates of absolute oyster abundance and biomass, would be difficult to elicit without data spanning many years. Significant temporal trends in ecosystems as large and variable as Chesapeake Bay can be difficult to detect without decades of consistent data (Vaas & Jordan 1991, Jordan & Vaas 2000), an important consideration in the design and maintenance of large-scale monitoring programs. In turn, such monitoring programs, including the resources to manage, analyze and interpret the data, are essential wherever society has established specific goals for rehabilitation of natural resources and ecosystems.

ACKNOWLEDGMENTS

This work was supported in part by a grant from the NOAA Chesapeake Bay Stock Assessment Committee (NA07FU0539), and by the Maryland Department of Natural Resources (DNR). Many people from DNR's Shellfish Division, especially Roy Scott, John Hess, Mickey Astarb, Mitchell Tarnowski, and Captains John Collier and Lee Daniels contributed to field data collection. Connie Lewis of DNR provided oyster landings data. Jim Uphoff's thoughtful review of a draft of this article was most helpful. The authors thank our colleagues from Virginia, Roger Mann and Jim Wesson, for their enthusiastic collaboration in our stock assessment efforts, and Kennedy Paynter from the University of Maryland for his support and encouragement. Copies of the following literature are available from the first author of this article: Christmas and Jordan (1991), Gieseker (2001), Homer et al. (1996), Krantz (undated), Maryland DNR (2001), and Smith and Jordan (1993).

EXPERIMENTAL EFFECTS OF WATER TEMPERATURE ON THE GAMETOGENIC DEVELOPMENT OF BROODSTOCK IN THE OYSTER, *OSTREA CHILENSIS*

ANDREW G. JEFFS,[1,2] B. J. DUNPHY,[2] AND R. M. G. WELLS[2]

ABSTRACT A protocol for reliably conditioning broodstock of the Chilean oyster, *Ostrea chilensis*, is required because the commercial aquaculture of this species has been constrained by the low and variable number of naturally spawning adults. Therefore, the gametogenic response of hatchery conditioned *O. chilensis* broodstock under differing temperature regimes (10°C, 15°C, and 20°C) was investigated, and compared with changes in a wild population over the same time. The overall loss of gametes, particularly ova, through spawning and phagocytosis was significantly higher in oysters held at 20°C and these oysters tended to increase early oogenesis and decrease early spermatogenesis. There was also greater variability in the abundance of reproductive products, particularly female products, among oysters at the higher experimental temperature. At 10°C and 15°C, oysters had similar levels of gametogenic products to wild oysters. Over the experimental period when natural water temperatures remained low the wild oysters also increased early spermatogenesis and oogenesis, but there was little loss of gametes or phagocytosis. The results indicate that warmer water temperatures may be involved in synchronizing and initiating oogenesis, and could be a useful tool for resetting the gametogenic cycle in broodstock. Unlike many other species of cultured oysters, it appears that conditioning broodstock of *O. chilensis* may best be undertaken at low water temperatures.

KEY WORDS: Chilean oyster, *Ostrea chilensis*, conditioning, gametogenesis, reproductive cycle, New Zealand

INTRODUCTION

The lack of a large and reliable supply of larvae is a major impediment to commercial aquaculture of the Chilean oyster, *Ostrea chilensis* (Philippi 1845), in a number of countries including South America and New Zealand (Lépez 1983, Utting 1987, Valencia Camp 1990, Hickman 1992, Jeffs 1995). The development of hatchery techniques for artificially conditioning and inducing larval production in broodstock at any time of the year would overcome this obstacle. However, the factors influencing the reproductive cycle of the Chilean oyster are poorly understood and consequently the development of effective hatchery techniques remains in their infancy (Jeffs & Creese 1996). There are only three published reports of preliminary attempts in Chile to condition broodstock of this oyster, all of which have produced mixed results (Ramorino 1970, Chaparro 1990, Wilson et al. 1996). The first unsuccessful attempts to condition and spawn Chilean oysters in a laboratory were made with minimal control over water temperature and feeding (Ramorino 1970). A preliminary study by DiSalvo et al. (1983a), DiSalvo et al. (1983b) induced some oysters to spawn earlier than in the wild by using artificially raised temperatures. Similar results were obtained with control over both water temperatures and feeding by Chaparro (1990). He found that some broodstock held at 17°C and 20°C matured and spawned spermatozoa and eggs, however, oysters held at 14°C matured and spawned spermatozoa, but did not spawn eggs. Broodstock held at 14°C and given a higher feeding allocation was the only experimental treatment in which oysters maintained their reproductive condition.

Field research in New Zealand has suggested that low winter water temperatures (<12°C) play an important role in increasing adult gonad condition and subsequent larval production (Westerskov 1980, Jeffs et al. 1996, Jeffs & Hickman 2000). The aim of this research is to experimentally assess the role of water temperature on the gametogenic cycle of the Chilean oyster while attempting to control other variables, such as food availability, that may also affect reproductive activity. The broodstock for the research came from a wild population of oysters in the Manukau Harbour, in northwestern New Zealand that has previously been identified as having high natural fertility (Jeffs et al. 1996).

MATERIAL AND METHODS

Experimental Setup

On June 20, 1993, 216 oysters of a size known to be capable of brooding larvae (≥50 mm shell height; Jeffs et al. 1996, Jeffs et al. 1997a) were randomly collected from a natural bed of oysters in the Manukau Harbour (see Fig. 1) and transported to the laboratory. The oysters were scrubbed to remove debris and then randomly assigned to six 300-l rectangular plastic conditioning tanks. Oysters were suspended in the tanks in plastic trays and each tank was filled with 5 μm filtered seawater at the ambient temperature of the Manukau Harbour that was 13.1°C. Over the next 48 h the water temperature of three sets of two tanks was adjusted slowly to each of the three experimental temperatures of 10°C, 15°C, and 20°C. Every 24 h the seawater in the tanks was changed with 5 μm filtered seawater at the experimental temperature. The water temperatures in the tanks were monitored using maximum to minimum mercury thermometers that were reset at each water change. Tanks were aerated continuously via an airstone. With each water change, the tanks of oysters were all fed an equal quantity of mixed monoalgal cultures of *Chaetoceros gracilis*, *Isochrysis galbana*, *Pavlova lutheri*, and *Thalassiosira pseudonana* that were in excess of daily requirements. This was judged by the presence of remaining food in the water at the end of the 24-h period. If the water was cleared prior to this time additional food was added to all of the tanks. On five occasions when live algal cultures were insufficient Celsys™ Algal 161 microfeed consisting of dried *Tetraselmis suecica* resuspended in seawater was also fed. All of these microalgal species are known to be nutritious to *Ostrea chilensis* or bivalves generally (Walne 1970, Brown et al. 1989, Laing 1991). After 50 days the broodstock from each tank were harvested and processed for histology.

Wild Population Samples

Oysters were collected from the population in the Manukau Harbour to provide a comparison with the results for the experi-

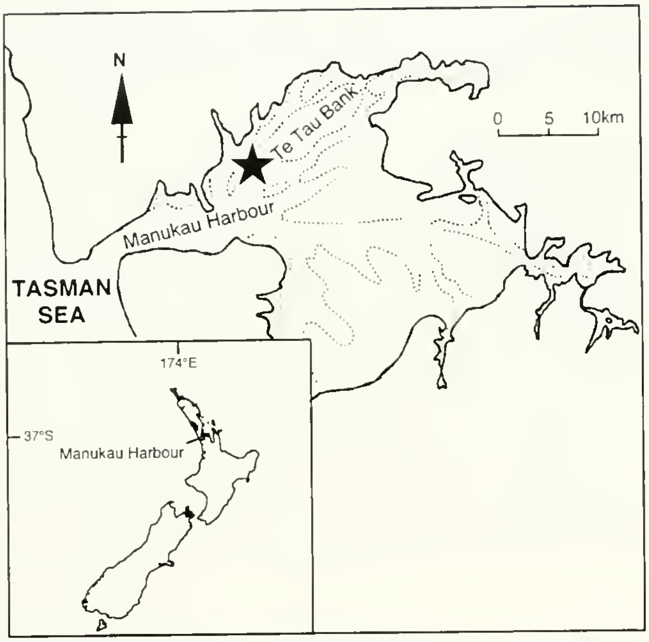

Figure 1. Map showing location of Chilean oyster population used for this study.

mental broodstock. At the start (day 1), mid-point (day 28) and conclusion (day 50) of the experiment about 70 oysters (≥50 mm shell height) were collected randomly from the Manukau Harbour and processed for histology. Ambient water temperature in the harbor was recorded at each sampling time.

Histologic Processing

Each oyster was carefully opened and a note made of the presence of larvae in the brood chamber. A 5-mm thick section of tissue was excised from each oyster parallel to the anterior-posterior axis between the labial palps and the posterior adductor muscle and then fixed in Bouin's solution. Tissue sections taken in this manner for this species are known to contain gametes representative of the whole gonad (Jeffs 1998). Permanent microscope slide mounts were made of the gonad material once it had been stained with haemotoxylin and eosin to differentiate the reproductive tissues.

Histologic Analysis

Each slide was examined under a compound microscope at up to ×100 magnification and the presence of different types of reproductive products were analyzed by a semi-quantitative method developed and verified specifically for this oyster (Jeffs 1998, Jeffs 1999). The method relies on assigning a score of 0–3 (0 = absent, 3 = abundant) to the abundance of reproductive features found that are associated with different aspects of the gametogenic cycle. Five stages of spermatogenesis (spermatogonia, primary and secondary spermatocytes, spermatids, and spermatozoa) and three stages of oogenesis (oogonia, oocytes, and ova) were scored. Additionally, the release of ova and spermatozoa from the lumen of the follicles (= gamete loss or spawning) and the abundance of reabsorption of unspawned ova and spermatozoa (= phagocytosis or reabsorption) were scored in the same manner that has previously been verified (Jeffs 1998, Jeffs 1999). The amount of connective tissue surrounding the follicles was also scored, providing an inverse measure of the overall quantity of reproductive material present in the follicles (Jeffs 1998, Jeffs 1999). Finally, a visual estimate was made of the percentage of male reproductive products over the entire gonad section.

Statistical Analyses

Statistical comparisons were made for the scores of the gametogenic attributes of oysters among the three wild sampling events, the three temperature treatments and between the replicate pairs of treatment tanks using Kruskal-Wallis tests (Sokal & Rohlf 1995). The 12 response variables consisted of those reproductive attributes measured under the microscope. Bonferroni corrected significance levels were used for the tests to control for inflated type 1 errors caused by multiple significance testing.

RESULTS

Water Temperatures

Recorded water temperatures in Manukau Harbour were 13.1°C at the initial collection of broodstock, 11.6°C at the day 28 of the experiment, and 11.9°C at the completion of the experiment. After the initial water temperature change over 48 h the water temperatures in the experimental tanks did not fluctuate more than ±1°C from the treatment temperatures for the remaining duration of the experiment.

Brooding

At the completion of the experiment five oysters (6.9%) were brooding larvae in the 10°C treatment (3 in one tank and 2 in the other). Three oysters (4.2%) were brooding in the 15°C treatment (3 in one tank and none in the other). No oysters were brooding in the 20°C treatment.

Samples of oysters taken from the wild population found 5 out of 70 oysters (7.1%) were brooding larvae at the outset of the experiment, 5 out of 73 oysters (6.8%) were brooding at day 28 and 6 out of 73 oysters (8.2%) were brooding at the end of the experiment.

Statistical Analyses

Analyses showed that there was no difference in the reproductive attributes of oysters held in the two tanks used in each experimental treatment. Therefore, the results for the two tanks were pooled for each experimental treatment. Statistical comparisons were made of the scores for the reproductive attributes of oysters among the three experimental temperature treatments, and among those sampled from the wild over the duration of the experiment (Fig. 2 and Fig. 3). For the experiment, significant differences were found among the scores for connective tissue ($P < 0.000001$) and phagocytosis ($P < 0.000005$). For oysters sampled from the wild, significant differences were found among the scores for percentage male ($P < 0.001$), spermatogonia ($P < 0.0005$), primary spermatocytes ($P < 0.0001$) and oocytes ($P < 0.0001$). The overall trends in the data were explored by plotting mean values for the variables with their standard errors (Figs. 2 and 3).

Spermatogenesis

Over all of the oysters examined the male reproductive products were generally more abundant than female reproductive prod-

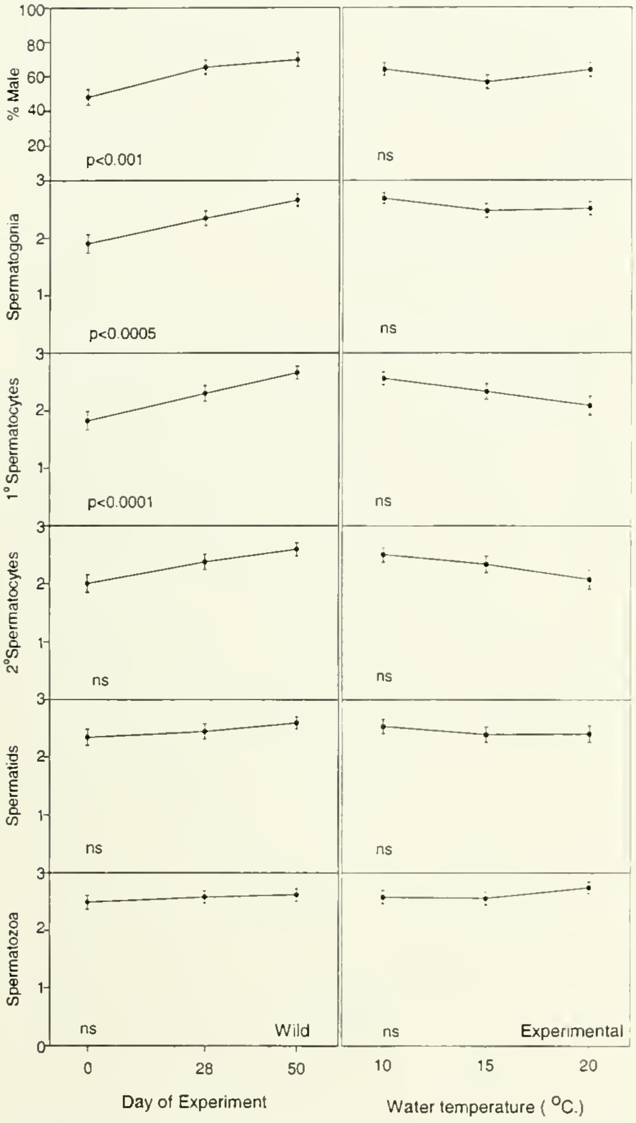

Figure 2. Mean scores (± standard error) of male gametogenic characteristics and percent male of Chilean oysters plotted against either time of sampling (wild population), or experimental water temperature (experimental population). Significant differences between scores as identified by Kruskal–Wallis tests are indicated (ns = not significant).

ucts. In the wild population of Chilean oysters there was a significant increase in the proportion of male reproductive material accumulating in the gonad ($P < 0.001$). This was associated with a trend for male reproductive attributes, especially for the early spermatogenesis stages (spermatogonia ($P < 0.0005$), primary spermatocytes ($P < 0.0001$) and secondary spermatocytes) to increase in abundance over the 50-day experimental period as the natural water temperatures decreased. At the end of the experimental period oysters in the three temperature treatments contained a similar abundance of male reproductive products as oysters in the wild population. However, there was a general trend for the abundance of male reproductive products, especially the early spermatogenesis stages, to decrease slightly and for the variability in the abundance of reproductive products to increase with increasing experimental temperature.

Oogenesis

On average ova were more abundant among all of the experimental and wild oysters than oogonia or oocytes. These earlier stages of oogenesis tended to increase in the wild population of Chilean oysters over the study period. For example there was a significant increase in oocytes among wild oysters over the period ($P < 0.0001$). At the end of the experiment the oysters in three temperature treatments contained a similar abundance of female reproductive products as oysters in the wild population. The abundance of the early stages of oogenesis (oogonia and oocytes) in oysters tended to increase with higher experimental water temperature. The abundance of ova in the 20°C treatment, however, tended to be lower than for the other temperatures, and for the wild population. The variability in abundance of female reproductive products was also greatest in the 20°C treatment.

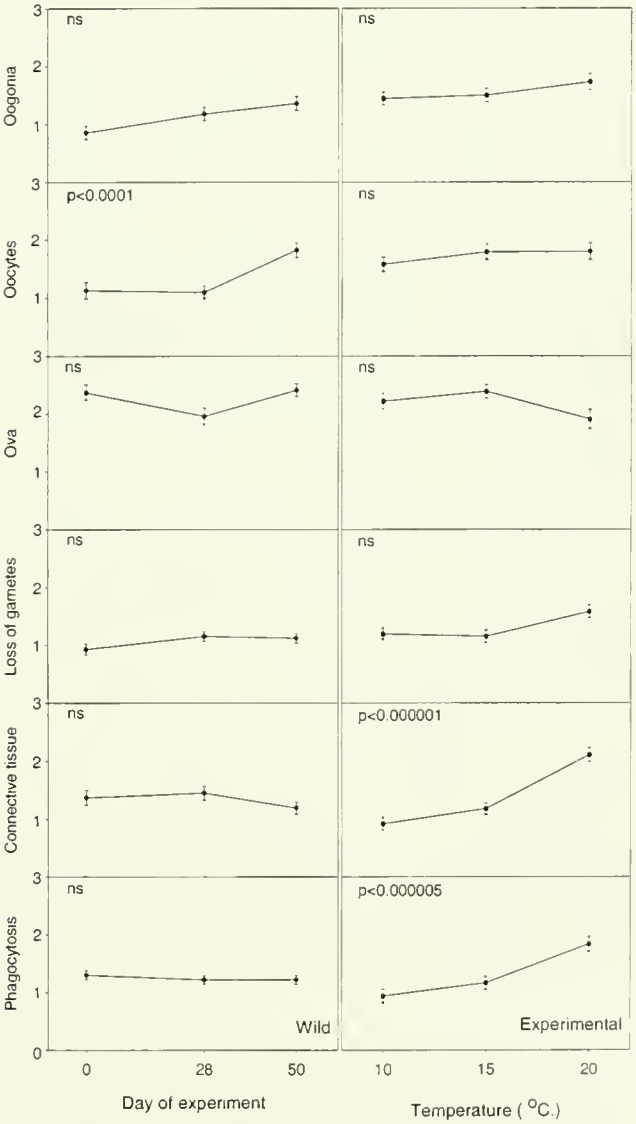

Figure 3. Mean scores (± standard error) of female gametogenic of Chilean oysters plotted against either time of sampling (wild population), or experimental water temperature (experimental population). Significant differences between scores as identified by Kruskal–Wallis tests are indicated (ns = not significant).

Gamete Loss and Phagocytosis

The recent loss of gametes, the amount of connective tissue and phagocytosis of reproductive products was at similar low levels among the three wild samples of oysters suggesting that gamete materials were accumulating in the gonads over this period. However, for the experimental oysters the recent loss of gametes, and especially the amount of connective tissue and the amount of phagocytosis of reproductive products all tended to increase with increasing temperature and especially at 20°C.

DISCUSSION

Low water temperatures have been widely implicated in controlling the production of female gametes in *Ostrea chilensis* (Westerskov 1980, Winter et al. 1984, Jeffs et al. 1997a, Jeffs et al.1997c, Jeffs 1999). Field studies within New Zealand surmised that water temperatures of <12°C acted to increase the gonad condition and the development of ova in local Chilean oyster populations (Westerskov 1980, Jeffs et al. 1997b, Jeffs 1999, Jeffs & Hickman 2000). The results of our laboratory study revealed that the effect of temperature on gonad development was consistent with the patterns observed in wild populations of this oyster (Jeffs & Creese 1996, Jeffs et al. 1997a). However, a considerable amount of variability remained in the gametogenic response of individual oysters to experimental temperatures, a pattern that appears to be a feature of this species (Jeffs et al. 1997b).

In this study male and female gametes were accumulated in the gonads of wild oysters experiencing cold winter water temperatures and there was little overall loss or phagocytosis of gametes. The accumulation of reproductive products in winter/spring preceding a minor spring/summer peak in spawning has been observed in other wild populations of this oyster (Jeffs et al. 1996, Jeffs 1999, Jeffs & Hickman 2000). The experimental oysters exhibited a similar response to lower water temperatures, with oysters held at 10°C and 15°C also accumulating similar amounts of developing reproductive material to wild oysters. In both the wild and experimental oysters at 10°C and 15°C early spermatogenesis had increased. In wild oysters there were signs that early oogenesis also increased. A similar pattern has also been observed in the Olympia oyster, *Ostrea lurida*, where experimental broodstock held at 12°C increased their gonad condition, while those at 18°C and 21°C lost condition through the gonad cycle being rapidly advanced (Santos et al. 1993). Similar results have also been found for Chilean populations of *O. chilensis* maintained in hatcheries over a range of temperatures (Chaparro 1990, Toro & Morande 1998). Such a response is common to many other species of bivalves held at elevated temperatures (Utting & Spencer 1991, Utting & Millican 1997). This rapid advance of the gonad cycle would also explain the absence of brooding oysters among the broodstock oysters held at 20°C in our study because these oysters would have already spawned or reabsorbed their gametes, whilst those at lower temperature were still developing. This was evidenced by the increases in the loss of gametes, connective tissue and phagocytosis observed amongst our experimental oysters at 20°C, and previously identified amongst oysters taken from wild populations during periods of similar warm water conditions (Jeffs et al. 1996, Jeffs et al. 1997a, Jeffs et al. 1997c, Jeffs et al. Jeffs 1998, Jeffs et al. 1999).

The results for these two *Ostrea* species are in contrast to the widely cultivated Pacific oyster, *Crassostrea gigas*, the European oyster, *O. edulis*, and the American oyster, *C. virginica*, which are known to undergo gonad development at warmer water temperatures, (e.g., 18°C to 24°C) and commercial broodstock conditioning relies on using these warmer temperatures (Aboul–Ela 1960, Quayle 1969, Mann 1979, Muranaka & Lannan 1984, Dinamani 1991, Santos et al. 1993, Castagna et al. 1996). Within this temperature range the experimental *O. chilensis* in this study lost condition through increased gamete loss and phagocytosis and decreased early spermatogenesis. There was also a trend for early oogenesis to increase, but this has previously been associated with rapid initiation of early gametogenesis after the extensive loss of gametes and subsequent rapid phagocytosis of remaining gamete material at warm water temperatures (Jeffs 1998, Jeffs 1999, Jeffs & Hickman 2000). All of these patterns of gonad change observed in our study are consistent with those previously observed in populations of wild oysters in warm water temperatures during summer-autumn (Jeffs 1998, Jeffs & Hickman 2000).

The results of this study suggest that manipulating water temperatures has the potential to be an effective method of controlling broodstock development in *O. chilensis*. Unlike other species of commercial oysters, cold-water temperatures appear to be important in stimulating early spermatogenesis and oogenesis and the accumulation of developing gametes much needed for effective conditioning of broodstock. Warm water temperatures appear to rapidly advance the development and loss of developing gametes (through spawning and phagocytosis) already held in the gonads, and this is followed by the rapid increase in oogenesis. Therefore, warm water temperatures have the potential to be used for advancing the development of gametes in broodstock conditioned at cold temperatures toward spawning and for restarting the gametogenic cycle from early gametogenesis in broodstock in attempt to create greater synchrony among individual broodstock.

ACKNOWLEDGMENTS

The authors thank Geoff McAlpine for sagely oyster advice, Jo Evans and Simon Hooker for helping to establish the algal cultures, and Beryl Davy for the histologic preparations. Logistic support from Bob Creese and the Leigh Marine Laboratory made this research possible. Martin von Randow undertook the statistical analyses. This work was supported by the New Zealand Foundation for Science, Research and Technology.

HISTORICAL CHANGES IN INTERTIDAL OYSTER (*CRASSOSTREA VIRGINICA*) REEFS IN A FLORIDA LAGOON POTENTIALLY RELATED TO BOATING ACTIVITIES

RAYMOND E. GRIZZLE,[1]* JAMIE R. ADAMS,[1] AND LINDA J. WALTERS[2]

ABSTRACT Research in the late 1990s showed that some intertidal eastern oyster (*Crassostrea virginica*, Gmelin) reefs in Mosquito Lagoon within the Canaveral National Seashore, Florida had dead margins consisting of mounded up, disarticulated shells. It was hypothesized that boating activities were the cause of the damage because all the reefs were adjacent to major navigation channels. To investigate this, we characterized the history of the appearance of dead margins and other reef changes using aerial photographs taken between 1943 and 2000. Imagery analyzed included prints (black & white, color, or color IR) from 1943, 1951, 1963, 1975, 1988, and 1995, and digital imagery from 2000 (USGS 1:12,000 digital ortho-quarterquads), at scales from 1:6,000 to 1:24,000. Prints were scanned at a resolution sufficient to yield 1-m pixels. After scanning, each set of images was georeferenced to the year 2000 imagery using ArcView and ArcInfo GIS software. All reefs found to have dead margins based on 1995 and 2000 aerials were visited in 2001 and 2002 to confirm the presence and extent of dead areas. This provided ground-truthing for the "signature" (a highly reflective, light-colored area adjacent to darker-colored live reef) to be used to detect the appearance of dead margins in the historical aerials. The earliest appearance of dead margins was in the 1943 aerials on one reef adjacent to the Intracoastal Waterway (ICW), a major navigation channel. The total number of reefs affected and areal extent of dead margins steadily increased from 1943 through 2000. In 2000, 60 reefs (of a total of ~400 in the Park) had dead margins, representing 9.1% of the total areal coverage by oyster reefs in the Park. Along the ICW, some reefs migrated away from the channel as much as 50 m and in 2000 consisted mainly of empty shells mounded up a meter above the high water mark. In contrast, many reefs in areas away from navigation channels showed little change over the 57-year period. This historical analysis provides strong (although correlative) evidence that boating activity has had dramatically detrimental effects on some oyster reefs in the study area. Ongoing studies are aimed at further testing this hypothesis and elucidating the causal mechanisms involved.

KEY WORDS: eastern oyster, *Crassostrea virginica*, reefs, aerial photographs, remote sensing, boating activities

INTRODUCTION

The eastern oyster, *Crassostrea virginica*, forms extensive reefs subtidally and intertidally along the eastern US coast (Bahr & Lanier 1981, Burrell 1986). Intertidal reefs make up the dominant form from North Carolina to the northern end of the Mosquito Lagoon in east central Florida. Most of Mosquito Lagoon in this area is within the boundaries of Canaveral National Seashore (CANA), the present study area. Here, the intertidal oyster reef constitutes a major habitat type (Grizzle 1990). Within CANA, reefs are managed for their ecological importance and are harvested commercially and recreationally (Walters et al. 2001).

Previous research within CANA characterized reef distribution and abundance patterns (Grizzle 1990) and focused on management issues (Grizzle & Castagna 1995). Based on an analysis of 1995 aerial imagery and subsequent field surveys, it was discovered that numerous reefs had dead margins consisting of disarticulated shells mounded up several decimeters above the adjacent living reef (Grizzle, pers. obs.). This pattern differed from the well-documented, long-term growth pattern of a dead middle area surrounded by living oysters (the "senescent stage" of Bahr & Lanier 1981) because the dead zones were along the margins of the reefs. Also, the dead margins consisted mainly of well-packed shells instead of a shell/sand/mud mixture as typically found in the dead middle area of senescent reefs. Further analysis showed that all reefs with dead margins occurred adjacent to channel areas that were heavily used by boats, including the federally maintained Intracoastal Waterway (ICW) that runs along the western edge of CANA. It was hypothesized that boating activities may be responsible, at least in part, for the dead margins.

This study was initiated as part of a larger project aimed at assessing the potential impacts of boating activities on oysters. Emphasis in the present report is on historical changes in oyster reefs based on aerial imagery, and the results of associated studies will be reported in future publications. The major objectives of this report are: (1) describe the present (2000) distribution of oyster reefs in CANA; (2) characterize historical (1943 to 2000) changes in the CANA reefs based on aerial photographic imagery, with an emphasis on those reefs with dead margins in 2000; and (3) relate historical reef changes to environmental factors, with an emphasis on boating activities.

METHODS

Study Area

The study area was in northern Mosquito Lagoon in east-central Florida (Fig. 1) and restricted to the Canaveral National Seashore (CANA), a National Park unit that is an example of a relatively stable barrier beach/lagoonal ecosystem (Grizzle 1990, Walters et al. 2001). Most of the Lagoon within CANA is a complex system of shallow open water areas and nearly 100 mangrove (*Rhizophora mangle* and *Avicennia germinans*)-dominated islands. Oyster reefs occur in intertidal areas, often adjacent to seagrass (mainly *Halodule wrightii*) beds that are extensive in some areas (Morris et al. 2000). Water depths are <1 m in most areas and the annual salinity range is typically between 25 and 35 psu, occasionally increasing to 40 psu (Grizzle 1990). Mosquito Lagoon is the northernmost body of water in the Indian River Lagoon system (IRL) that has been described as the richest and most diverse estuary in the continental United States (see references in 1995 special issue of *Bulletin of Marine Science*, Vol. 57; also see Walters et al. 2001). The ecological importance of this area has

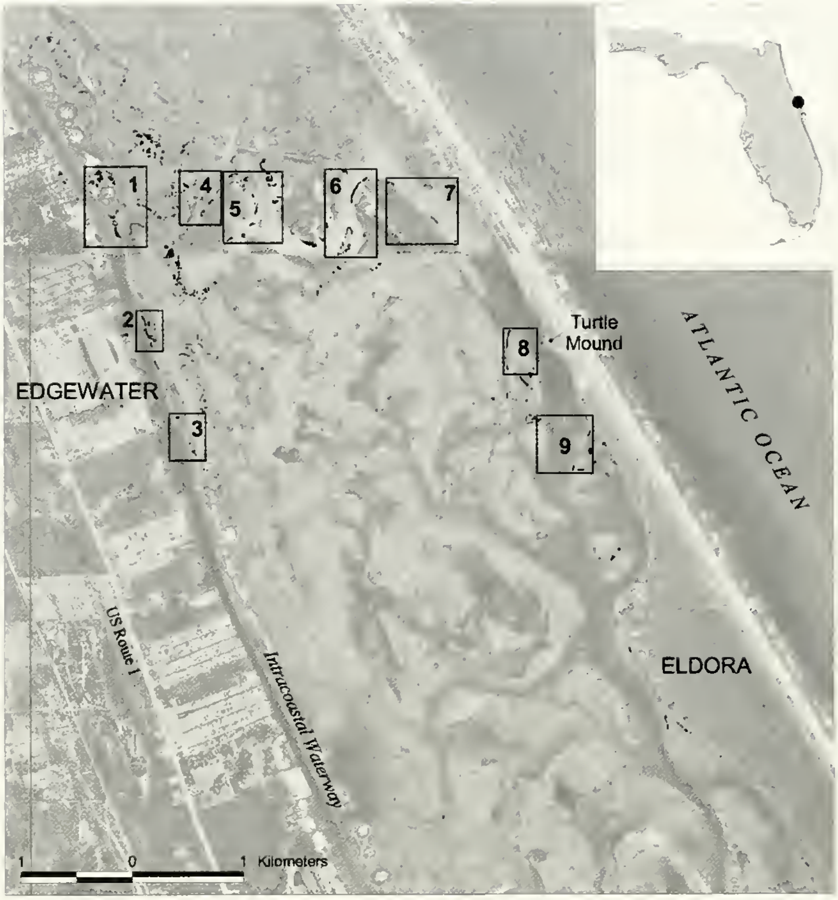

Figure 1. Northern portion of Canaveral National Seashore, showing most of ~400 mapped oyster reefs (each shown as a black polygon exaggerated 2× horizontally) based on year 2000 imagery. Nine study groups used in historical (1943–2000) assessment are indicated. Note that "live reefs" and "dead margins" are combined in this figure.

been demonstrated by the US Environmental Protection Agency in listing the entire IRL as an Estuary of National Significance, and by the State of Florida in classifying it as a Florida Outstanding Waterway and Aquatic Preserve, the highest level of State protection.

Aerial imagery of the types and sources indicated in Table 1 were used in this analysis. Prints were converted to digital format following the "soft-copy photogrammetry" methods outlined in Finkbeiner et al. (2001). Each print was scanned at a resolution sufficient to yield 1-m pixels. After scanning, each set of images was referenced to the year 2000 orthorectified digital imagery using sufficient reference points to remove distortion from the photographs. Year 2000 imagery provided enough detail so that link points could easily be established to all historical photos. The link files were created in ArcView by doing a side-by-side comparison of photos and creating points on each to reference corresponding locations. This method created "from" and "to" points that were used in ArcInfo to warp the historical photos and register them to a UTM coordinate plane. On average, 35 to 40 points were established for each photo pair. This allowed the polynomial order of transformation to be varied enough to compare different levels of warping in ArcInfo. The higher the order of the polynomial, the more distortion can be removed. Warping results from order 1 to 6 were compared and it was determined that third order transformations were sufficient to match these images to their year 2000 counterparts. Such results were anticipated due to the low vertical relief of the target area. Vertical relief is one of the primary sources of distortion in aerial photography.

TABLE 1.

Aerial imagery used in present study.

Year	Type	Source	Scale
1943	Black & white prints	St. Johns River Water Management District	1:16,000
1951	Black & white prints	Volusia County	1:16,000
1963	Black & white prints	Volusia County	1:24,000
1975	Color prints	Volusia County	1:24,000
1988	Color prints	Volusia County	1:24,000
1995	Color infrared prints	University of New Hampshire	1:6,000
2000	Digital	US Geological Survey	1:24,000

Live reefs initially were identified based on the following criteria (i.e., "signature"): dark margins with a lighter middle area, round to irregular in shape, and with a smooth texture (Fig. 2). These criteria were applicable regardless of imagery type. In color and color IR photos, the darker zone of the reef was typically olive to olive-gray in color. As an example of the overall image, round reefs resembled a donut with the center being lighter in color than the outer ring. In stark contrast to the live reef signature, dead

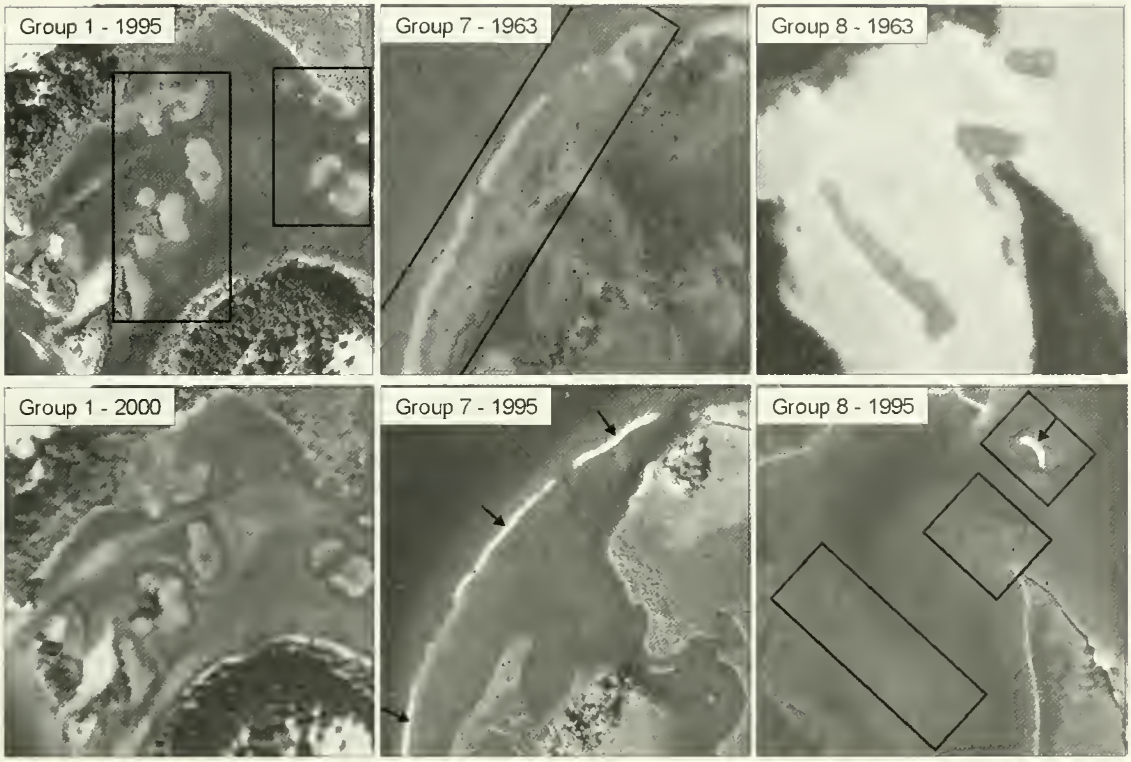

Figure 2. Examples of signatures for live reef (LR; reefs enclosed in boxes for one year only of each pair of aerials) and dead margins (DM; indicated by arrows) from different kinds and qualities of imagery. Group 1—1995: LR signature with dark margin not evident; Group 1—2000: typical LR signature of dark margin surrounding lighter central region, but low quality imagery. Group 7—1963: 100% LR; Group 7—1995: LR with extensive DM (bright white) along outer edge of reef. Group 8—1963: three LR reefs in low quality imagery caused by poor sun angle and surface reflectance; Group 8—1995: three LR reefs as in 1963, but outer reef with extensive DM in 1995.

margins appeared in all types of imagery as a high reflective, light-colored (typically bright white) area adjacent to the darker-colored live reef (Figs. 2 and 3).

Using these interpretation criteria, eight preliminary maps were produced: a basemap showing all oyster reefs (minimum size ~10 m^2) in CANA based on 2000 aerials, and one map for each of the seven aerials from previous years showing only those reefs that had dead margins in 2000. It should be noted that only a subset of all reefs in CANA was mapped using the pre-2000 imagery. This is because emphasis with respect to historical changes was on those reefs that had dead margins in 2000. To make assessment of historical changes more manageable, reefs with dead margins in 2000 were arranged into nine groups based on location (Fig. 1). All nine groups were quantitatively analyzed but only representative aerial imagery is shown here. Due to variations in size of the reefs, a constant map scale could not be used across all nine groups. Each group boundary was positioned to emphasize changes from year to year on an individual group basis and to show sufficient detail. Special care was also taken to include any partial reefs so that area calculations would remain consistent.

Field surveys were conducted in November 2001 and March 2002 to ground-truth the reef maps produced using the 2000 aerials. Ground-truthing included assessment of initial reef signature criteria and mapping accuracy. In November 2001, all reefs initially mapped with dead margins were visited to determine the accuracy of the interpretations of live reef and dead margins. Based on this survey, a revised set of reef maps was produced. A second field survey was conducted in March 2002, to assess the revised maps with an emphasis on mapping accuracy. Following the general recommendations of Congalton and Green (1999) and Finkbeiner et al. (2001), multiple points on several individual reefs were chosen for field inspection. At each point, latitude and longitude (using a differential geographic positioning system, DGPS) were recorded, and bottom type (dead margin, live reef, or non-reef) identified. Each logged point was plotted on the revised maps to determine locational and interpretational accuracy.

RESULTS AND DISCUSSION

Reef Signature and Ground-Truthing

A field survey in November 2001 indicated that the initial reef signature criteria were sufficient for correct identification of nearly all of the reefs based on 2000 aerials. Live reefs surrounded by bottom features (e.g., light-colored sand, dark mud) that contrasted with the reef signature were accurately mapped. Interpretation of reef boundaries was difficult only when bottom features (e.g., some seagrass beds, gray sands and muds) that resembled live reefs occurred adjacent to the reef. It should also be noted that in some areas on some aerials, reefs appeared a uniform gray, either darker or lighter than surrounding areas (e.g., see "Group 1—1995" and "Group 8—1963" reefs in Fig. 2). These departures from the typical signature were apparently a result of the photo being taken during low tide when the reefs were exposed. In some cases, these aerials were also of poor quality caused by excessive glare off the water surface and thus poor light penetration of the water column (e.g., "Group 8—1963" reefs in Fig. 2). Dead margins were dramatically visible in all but the poorest quality aerials because of high reflectivity of the mounded up and sun-bleached

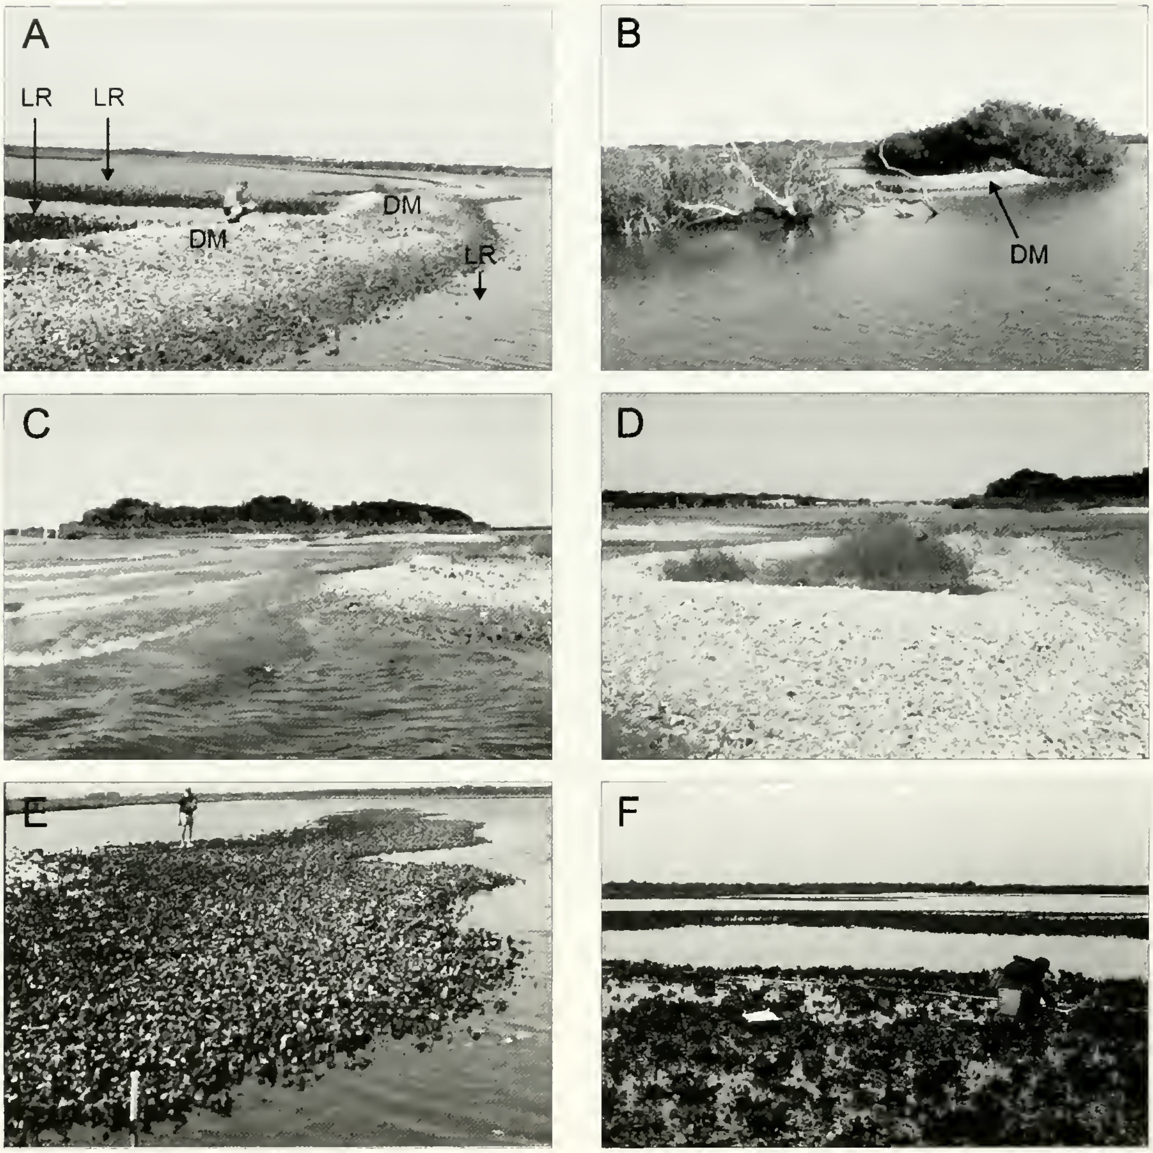

Figure 3. Dead margins (DM) in 2002 showing typical relation to live reef (LR). A) Long, arching reef from Group 6; note presence of LR on both sides of DM. B) Small reef from Group 4 with DM and scattered LR behind it. C) Large cluster of DM in Group 1 resulting from long-term migration away from ICW from 1943–2000. D) DM being colonized in middle by macrophytes; mound of dead shells extended nearly 1 m above the high water line and was adjacent to navigation channels on two sides, resulting in the rounded shape. E) and F) Typical live reefs with no DM.

shells (Fig. 2). Dead margins were only difficult to interpret when they occurred adjacent to light-colored sand or sand/shell mixtures. Hence, the initial reef signature criteria described above were found to be valid.

Remote sensing of various types of coastal benthic habitats using aerial photography is becoming an important tool for detecting environmental change (Finkbeiner et al. 2001). Much of this work has been on seagrasses (e.g., Ferguson et al. 1993, Morris et al. 2000, Virnstein 2000) but research on other habitat types, including oysters, has been published. One of the earliest published studies mapped the reefs in this study area using aerial photographs taken in 1984 (Grizzle 1990). A similar survey was conducted in Georgia in the late 1970s (Harris 1980). There are also ongoing studies involving aerial photography of oyster reefs in other areas of Florida and South Carolina, but we are aware of no published literature on this work. Hence, although aerial imagery has been used in previous oyster reef research, the published literature is meager. Finkbeiner et al. (2001) suggest a general protocol for mapping coastal habitats, but to our knowledge no published description of an interpretive signature for intertidal oyster reefs exists. Such a description is essential for further development of a standard protocol for mapping oyster reefs.

It should be noted that the suggested signature for live reefs includes potential "dead centers" (see Introduction section) as part of the live reef. This study did not discriminate between different densities of live oysters. However, there were discernable differences between dead centers and areas of different densities of live oysters, suggesting that useful information on oyster abundance may be obtained using aerial imagery. The overall pattern of a darker outer region surrounding a lighter-colored middle derives at least in part from the fact that higher densities of live oysters typically occurred at the margins of CANA reefs compared with middle areas (Grizzle & Castagna 1995). This pattern should be expected in general for older reefs in the "senescent stage" described by Bahr and Lanier (1981) but it may also be the pattern for most large reefs. Increased growth at the margins also has been reported for reef-forming blue mussels, *Mytilus edulis* (e.g., Newell 1990; Svane & Ompi 1993). In the only relevant study on oysters we are aware of, Powell et al. (1987) characterized small-scale differences in distributions of oysters on reefs but did not report an "edge effect." Further work is needed on small spatial scale patterns detectable by aerial photographs so that remote sensing techniques can be developed to monitor characteristics reflecting overall reef "health" in addition to just total areal coverage of "live" reef.

To further assess interpretational accuracy as well as locational accuracy, 405 individual points on 56 reefs were logged and plotted in March 2002; the second field visit to the study site. Overall, this assessment again (as did the November 2001 field survey) verified that interpretation accuracy was nearly 100%. It also showed that location accuracy was within expected ranges. Of the 405 points visited, identified and plotted, 94% were within 5 m of the actual DGPS-determined location (Table 2). DGPS is generally considered to have an accuracy of about 5 m with 95% confidence.

Oyster Reef Distribution Within CANA in 2000

Approximately 400 live reefs ranging in size from 10 m^2 to 4180 m^2 were mapped using year 2000 aerials, and nearly all reefs occurred in the northern half of the study area (Fig. 1). Although not quantified, there was a strong decreasing trend in areal coverage by live oyster reefs from north to south, reflecting the amount of tidal influence in the area (see Grizzle 1990 for further discussion). The total bottom area within CANA covered by live reefs in 2000 was 12.3 ha. Live reefs showed a wide range of overall morphologies and spatial orientations, including all three types described by Kennedy and Sanford 1999 (based on Stenzel 1971): string (perpendicular to shore), fringe (parallel to shore), and patch (small, compact form). String reefs and fringe reefs occurred along the edges of many of the major tidal channels. Patch reefs typically occurred away from the channels, sometimes in groups that resulted in dendritic patterns, with reefs separated by winding open water areas only a few meters wide.

In 2000, dead margins occurred on about 60 reefs covering 1.12 ha and representing 9.1% of the total oyster reef areal coverage in the Park (Fig. 1, Table 3). All reefs with dead margins occurred adjacent to major channel areas, including narrower channels probably not affected by wind waves and broader expanses with sufficient fetch for development of waves. On an individual reef basis, the dead margins ranged from <10% to ~100% of each reef's total areal coverage. Hence, some reefs only suffered minor losses while others appear to have been completely killed.

TABLE 2.

Locational accuracy data showing percent of individual plotted points within the indicated (1 m, 2 m, etc.) accuracy level.

Reef type	# points plotted	Accuracy level			
		0 m	1 m	2 m	5 m
live	137	100	110	116	125
dead	161	119	140	145	154
live + dead	298	219	250	261	279
Percent accuracy:		73.4	83.9	87.6	93.6

TABLE 3.

Total coverage in hectares for dead margins and live reef in all nine groups by year, and Park-wide in year 2000 only. See Figure 4 for bar charts of data by group by year.

Year	1943	1951	1963	1975	1988	1995	2000	All of CANA
TOTAL Dead	0.02	0.10	0.26	0.29	0.55	0.85	1.12	1.12
TOTAL Live	6.55	5.28	4.71	5.73	5.39	3.60	4.06	12.28

% Dead	0.3	2.0	5.5	5.1	10.3	23.7	27.6	9.1

Historical Changes in CANA Oyster Reefs

There was a consistent increase in areal coverage by dead margins from their first appearance on a reef near the ICW in 1943 through 2000, when about 60 reefs were affected throughout the study area (Fig. 4, Table 3). In 1951, dead margins covered only 0.10 ha of bottom area, and all but one (Group 5) were located along the ICW. In most other areas away from the ICW, dead margins first appeared in 1975 or 1988 and showed a steady increase in areal coverage over time. As already noted, by 2000, dead margins occupied 1.12 ha of bottom area representing 9.1% of the total oyster reef areal coverage in the Park.

Some reefs were remarkably dynamic over the 57-year study period, with the most dramatic changes occurring in nearly all reefs adjacent to the ICW (e.g., Group 1 in Fig. 5). In these areas, there was a general movement away from the ICW and an increase in areal coverage by dead margins over time. For example, some reefs in Group 1 moved a distance of approximately 50 m away from the ICW between 1943 and 2000. In contrast, none of the reefs in groups located away from the ICW moved by more than a few meters over the 57-year period, including those with dead margins. Also, the general shape, areal coverage, and location remained relatively stable for many reefs over the period (e.g., most reefs in Group 5, Fig. 5).

An obvious and probably the most serious limitation on use of historical imagery is that ground-truthing is limited. For this study, the 2000 aerials were ground-truthed with respect to interpretation and mapping accuracy. Information from this effort was used to infer the level of confidence placed on historical mapping. There was a wide range of overall quality of the historical aerials caused by differences in sun angle, water clarity, tidal stage, and other factors. This variability affected the mapping process but there is no way to quantitatively assess the effect. A technique that seemed to make the mapping process more accurate for the historical imagery was to analyze a single reef or group of reefs beginning with the ground-truthed 2000 maps and proceeding backwards in time. It was also found that for a year with poor quality imagery, examination of the previous and subsequent years made identification of the reefs easier on that imagery. Thus, while there is no way to rigorously assess accuracy of historical imagery there may be ways to improve the process.

Based on 1986 imagery, Grizzle (1990) presented a distribution map of oyster reefs in this study area. This map was revised based on 1995 imagery by Grizzle and Castagna (1995). The maps pro-

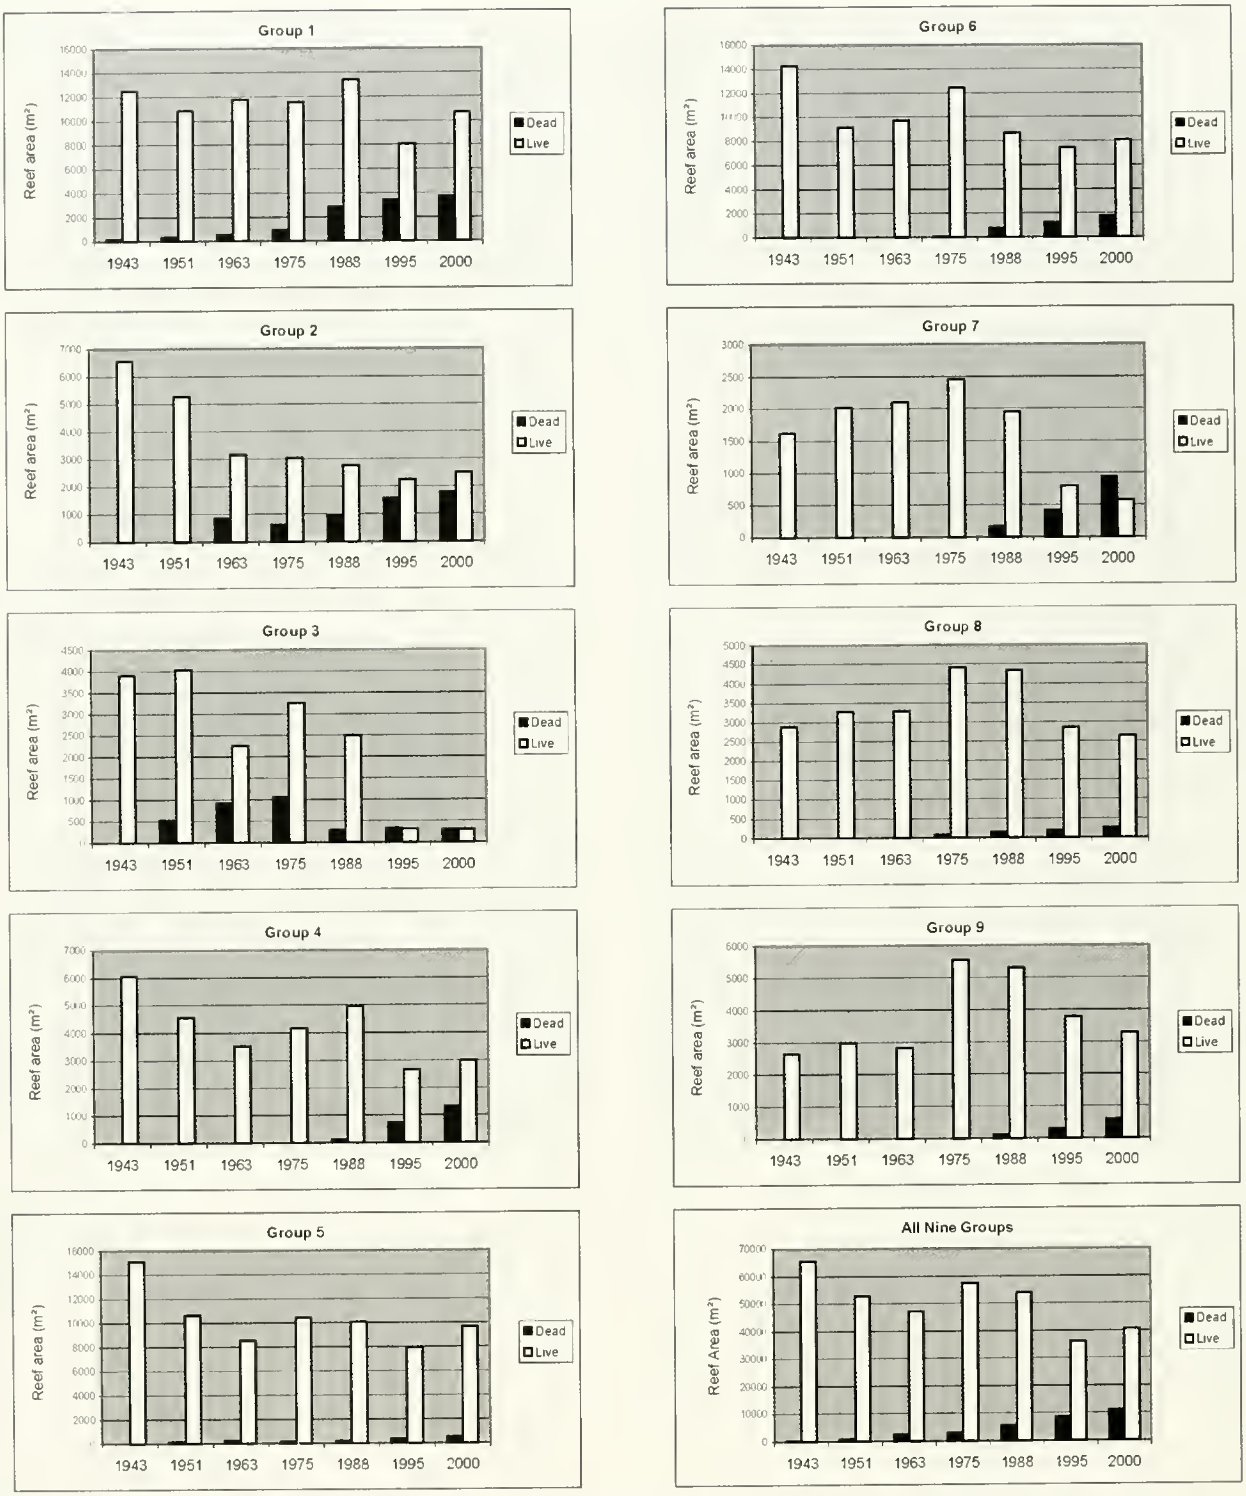

Figure 4. Areal coverage by live reef and dead margins from nine study groups over 57-year period, and all groups combined in last graph.

duced for both studies were very similar with respect to total number of reefs (~400) and overall reef distribution pattern. However, Grizzle and Castagna (1995) noted a wide disparity in reported total areal coverage by oyster reefs: 31.7 ha in 1986/1990, and 14.0 ha in 1995. They further noted that the higher figure was incorrect, and was an artifact of the low-resolution GIS program used in 1990 that assigned all mapped reefs a minimum size of 0.05 ha. Inspection of the 1983 aerials used in this study corroborates this conclusion, and suggests that other than an increase in dead margins there was probably little change in total oyster reef coverage in the Park between 1986 and 1995.

Potential Causes of Historical Reef Changes

This historical assessment was designed to provide a partial test of the hypothesis that boating activities have been a causal factor

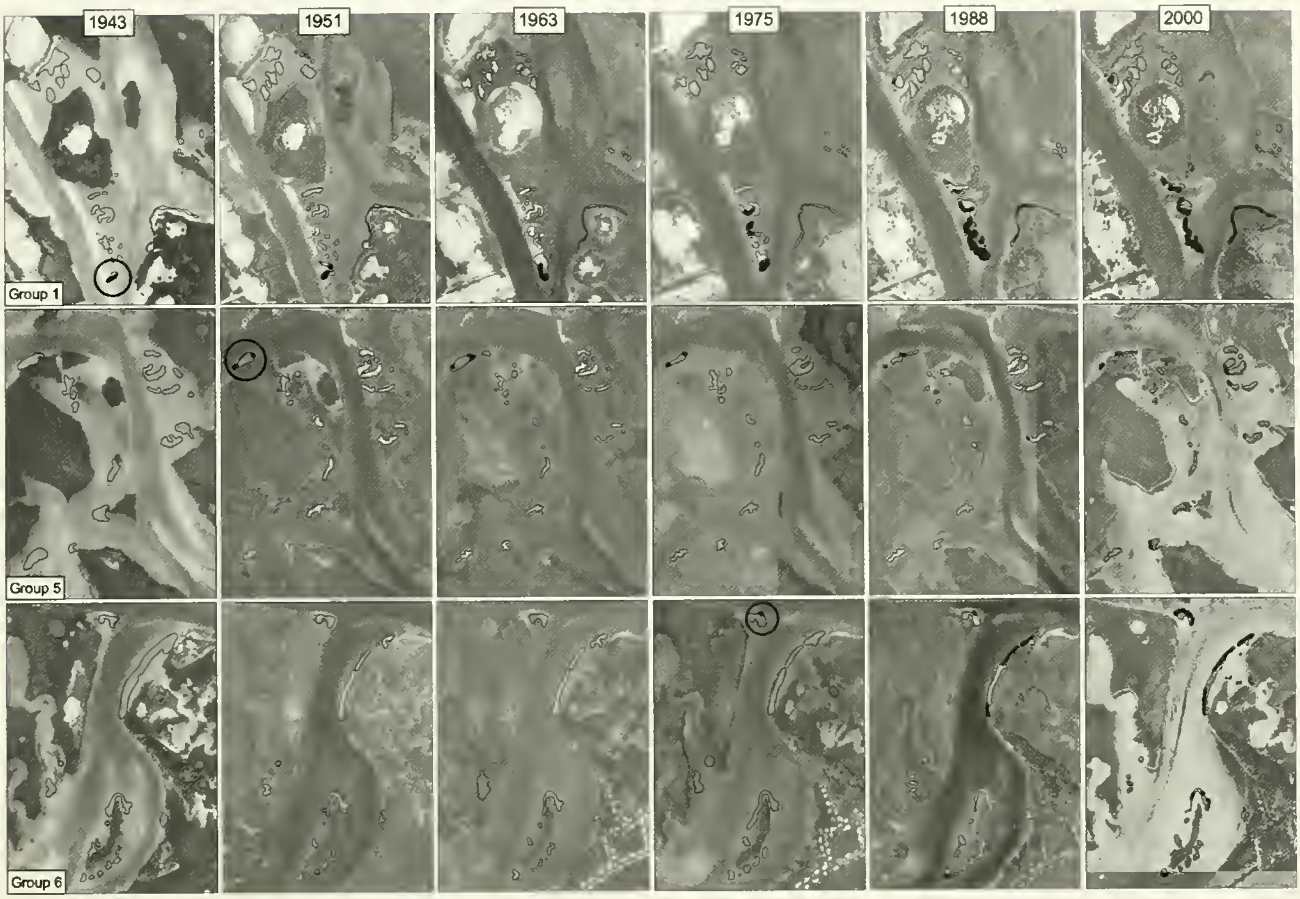

Figure 5. Three of nine reef groups showing differences in reef dynamics over the 57-year study period. Live reefs outlined with narrow black line; dead margins (DM) filled in. Circles show first occurrence of DM for that group (1943 for Group 1, 1951 for Group 5, 1975 for Group 6.

in the occurrence of dead margins on some oyster reefs in the study area. Data presented here support this hypothesis in several ways, and yield no information for rejection of it. Moreover, the present analysis indicates that for some reefs the existing (2000 to 2002) dead margins represent only a vestige of the areal extent of those reefs historically.

The major findings that implicate boating activities are associated with the fact that all of the approximately 60 reefs with dead margins identified for the 57-year study record (1943 to 2000) occurred immediately adjacent to major navigation channels. Data available since 1986 show an average annual increase of about 10% in the number of boats registered in the two counties (Volusia and Brevard) that border the Mosquito Lagoon (Hart et al. 1994), coinciding with an average annual increase of about 9% in bottom area covered by dead margins from 1988 to 1995 (Table 2). There were over 51,000 registered boats in Volusia and Brevard counties in 1998, nearly twice the state average (J. Stewart, pers. com.). The extent of dead margins increased by 16.4% from 1995 to 2000. Such a correlation between registered boats, and thus potential boating activity, and dead margins does not of course require a cause-and-effect relation. However, if boating activities were involved in the observed increases in dead margins, such a correlation would be expected. Assuming boating activities were involved, what might be the actual mechanisms causing the dieoffs at the margins?

The importance of water movement (including tidal currents and waves) to oyster reefs was recognized by Grave (1905), and subsequent research has provided several hypothetical cause-and-effect relations but no quantification of them (see reviews by Bahr & Lanier 1981, and Kennedy & Sanford 1999; see additional discussion later). Bahr and Lanier (1981) suggested that vertical growth rate and morphologic form of intertidal reefs were strongly affected by wave action. Waves (and currents) transport sediment to and from the reef, and in some cases eventually result in sediment buildup and loss of oysters in the central region (see more discussion in the Introduction section). Bahr and Lanier also noted (p. 57) that ". . . a water current or wave energy regimen above a certain threshold level will prevent the development . . ." of a reef. And they showed (p. 34) a photograph of "shell debris characteristic of high energy beach shores . . ." that resembled the mounded up dead margins observed in the present study. Wave energies of some magnitude are clearly capable of destroying an existing reef. However, we are not aware of research that quantifies the relationships involved, nor the actual mechanisms involved.

Hypothesized inhibitory mechanisms for reef development include: vertical accretion of the reef surface to an elevation too high in the intertidal caused by waves (Churchill 1920; Bahr & Lanier 1981), smothering and substrate instability caused by excessive sediment transport (Marshall 1954), and inhibited larval settlement caused by sediment ("grit") movement (Gunter 1979). Analysis of historical aerials for reefs along the ICW in this study also suggest that a reef can be physically moved by wave energies, resulting in a range of responses from slow migration to total destruction, much in the fashion that barrier islands migrate shoreward (termed "transgression") under increased wave energies (Davis 1996). As already discussed, this study was not designed to test particular causal mechanisms for observed reef declines. They are the topic of ongoing studies by Linda Walters and colleagues (e.g., Wall et al. 2002, Walters et al. 2002) and will be reported elsewhere. This study, however, does provide strong (although correlative) evidence that boating activity has had dramatically detrimental effects on some oyster reefs in the study area.

ABSTRACT The monthly variation of the biochemical composition was studied for one year in relation to the reproductive cycle in a population of *Spondylus leucacanthus*, a commercially important species in the Gulf of California. Carbohydrate, lipid, and protein concentrations were determined in the adductor muscle, gonad, and digestive gland. Protein was the main constituent in the gonad, digestive gland, and adductor muscle. Lipids were important in the digestive gland, whereas in the gonad they were moderately represented and in the muscle they showed low and virtually invariable concentrations during the study period. Carbohydrates were found largely in the adductor muscle and the digestive gland, whereas the gonad showed lower concentrations. *S. leucacanthus* has a seasonal reproductive cycle with a reproductive inactivity period at the end of the autumn and throughout the winter. Gametogenesis starts at the end of the winter, continuing during springtime, and ending in the summer, where 90% of organisms are ripe, coinciding with the highest lipid concentration in the gonad. Spawning takes place in early autumn. It is concluded that this species has a conservative reproductive strategy because it largely uses energy reserves for gamete development, in addition to energy obtained from food, to supplement its energetic expenditure.

KEY WORDS: *Spondylus leucacanthus*, reproductive cycle, biochemical composition, Gulf of California

INTRODUCTION

In the Gulf of California, *Spondylus leucacanthus* and other bivalve species, including *Megapitaria aurantiaca, Argopecten ventricosus, Lyropecten nodosus*, and *Spondylus calcifer* are of great importance because of the high commercial value of soft parts, adductor muscle, and shell. (Villalejo-Fuerte & Muñetón-Gómez 1995, Skoglund & Mulliner 1996, Villalejo-Fuerte & García-Domínguez 1998, Muñetón-Gómez et al. 2001). The exploitation of commercially important bivalve populations in the Gulf of California has fostered a number of studies focused on reproductive and feeding aspects (Baqueiro et al. 1982, Villalejo-Fuerte & Ochoa-Báez 1993, Villalejo-Fuerte & Ceballos-Vázquez 1996, Félix-Pico et al. 1997, Villalejo-Fuerte & García Domínguez 1998, Villalejo-Fuerte et al. 2002).

In general, reproduction in marine bivalves is associated with food availability and nutrient reserve storage in specialized organs (Gabbott 1975, Bayne 1976, Barber & Blake 1981, Boadas et al. 1997, Claereboudt & Himmelman 1997). When organisms reach reproductive maturity, growth slows down as a result of the reproductive effort, and the biochemical composition may change according to the reproductive requirements (Lodeiros et al. 2001). Those species where energy storage and gamete production cycles overlap temporally are considered "opportunistic"; in contrast, those in which both cycles are clearly separated in time because of the use of previously stored energy reserves for gonad development are known as "conservative species" (Bayne 1976).

Gonad development implies an intense metabolic activity, including the storage of large amounts of lipids in the developing eggs, either at the expense of glycogen reserves previously accumulated in storing tissues, at the expense of food supply, or from both sources (Gabbott 1975). A decrease in glycogen and protein contents coupled with a rise in lipid content during gonad development has been described for the pectinids *Chlamys septemradiata* (Ansell 1974), *Pecten maximus* (Comely 1974), *Argopecten irradians* (Hickey 1978, Barber & Blake 1981), *Chlamys opercularis* (Taylor & Venn 1979), *Placopecten magellanicus* (Robinson et al. 1981), and *Hinnites giganteus* (Lauren 1982). The influence of temperature on nutrient-transfer regulation from reserve-storing organs to the gonad has also been described for *A. irradians* and *Patinopecten caurinus* (Sastry & Blake 1971, Barber & Blake 1981, MacDonald & Bourne 1987). The potential relationship between morphophysiologic indices and the storage and use of nutrient reserves during reproduction was described for wild populations of *A. circularis* (Villalejo-Fuerte & Ceballos-Vázquez 1996) and *S. calcifer* (Villalejo-Fuerte et al. 2002).

In the Gulf of California, *S. leucacanthus* banks have been overexploited at depths of less than 15 m (Baqueiro et al. 1982), but beyond 40 m there are banks that have not been affected by commercial fisheries. Studies of this population focused on the reproductive cycle (Villalejo-Fuerte & García-Domínguez, 1998) and gut content have been conducted in relation to reproduction and phytoplankton abundance (Muñetón-Gómez et al. 2001). The lack of information on protein, lipid, and carbohydrate content in storage organs and its potential association with the reproductive period in this species, analyzed from a seasonal perspective, were the reasons for the development of this research.

MATERIALS AND METHODS

An average of 36 specimens of *S. leucacanthus* with a range in shell height from 40 to 94 mm (mean of 60 mm) were collected each month, from June 1996 to May 1997, south of Isla Danzante (26°55′–26°30′N and 112°–111°40′W) in the Gulf of California (Fig. 1), using a net at 40 m of depth.

For the biochemical analysis, 16 specimens were used each month. In the laboratory, specimens were cleaned, eliminating water from the pallial cavity, and were washed with distilled water. Then, soft parts were separated from the shell and weighed, followed by the dissection of the adductor muscle, gonad, and digestive gland. Each organ was weighed separately and oven-dried at 100°C for 24 h. The dry tissue was pooled and homogenized and

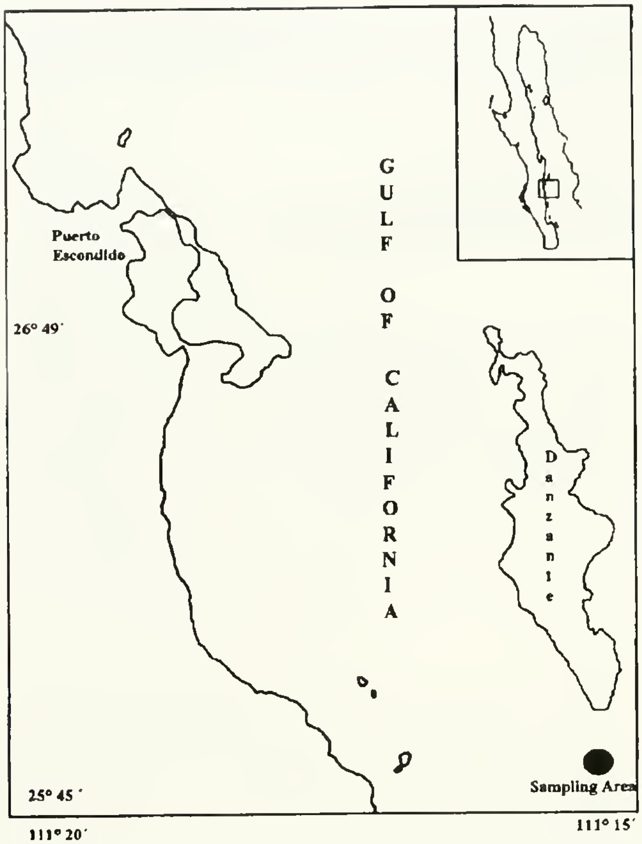

Figure 1. Location of the sampling area in the vicinity of Danzante island, Gulf of California.

then was ground into a powder. Subsamples of this homogenate were taken for the biochemical determination.

Protein determination was conducted using the method by Lowry et al. (1951). Carbohydrates were determined by Hewitt's method (1958). Lipid extraction was performed using the method by Folch et al. (1957) and a modification of Bligh and Dyer's method (1959).

Energetic substrate concentration mg/g dry weight curves were interpreted as follows: An increase was considered as indicative of accumulation and a decline as indicative of substrate use in the corresponding organ.

The reproductive cycle analysis included an average of 20 specimens per month. The degree of gonad development was defined from histologic section (7 μm thick) stained with the hematoxylin and eosin technique (Humason 1979), assigning one of the following categories proposed by Villalejo-Fuerte and García-Domínguez (1998) for this species, undifferentiated, developing, ripe, spawning, and spent. Bottom water temperature was recorded at the time of collections.

A Spearman's rank correlation analysis (r_s) was used to determine the relationship of the gametogenic cycle stages with protein, lipid, and carbohydrate concentrations in the adductor muscle, digestive gland, gonad, and water temperature. Before performing the correlation analysis, logarithmic transformations were performed for energetic substrates, and arc-sin transformation were conducted for percentages of the reproductive cycle stages, aimed at obtaining data normality and homoscedasticity (Sokal & Rohlf 1995). Only those results where a significant correlation was found are reported below.

RESULTS

Biochemical Composition

The trend in the protein concentration curve is similar for the three organs analyzed. During the summer, protein concentration reaches high values and remains relatively unchanged. In autumn, there is a noticeable decline, with low concentrations remaining until the end of this season. In the winter, protein concentration in the gonad and digestive gland shows a recovery, reaching high values in mid-winter and decreasing by early spring. In the muscle, proteins show a steady increase that lasts until mid-spring, reaching high values also in the digestive gland and gonad, then decreasing at the end of the spring (Fig. 2A).

Lipid concentration in the adductor muscle did not show noticeable variations during the study period. In the digestive gland, high concentrations were found at the beginning of the summer, which declined throughout this season and remained low, although with some variations, during the autumn. In winter, there is a clear recovery, reaching the peak value in mid-winter and then declining, with some fluctuations, afterwards and during the spring. In the gonad, the highest lipid concentration was recorded during the summer, with lower values in all other seasons (Fig. 2B).

During the summer, carbohydrate concentration drops in the three organs analyzed (August), with drops being more pronounced in the muscle and gonad. In late summer and early autumn, a considerable rise occurs in both gonad and muscle, remaining unchanged in the gland. During autumn, there is a decline in the muscle and gonad, remaining low in early winter whereas there is a considerable increase in the digestive gland (November); at the end of the autumn, carbohydrates decrease, reaching low values at the beginning of the winter. During the winter, carbohydrates in the muscle and digestive gland rise steadily, reaching peak values during the spring. In the gonad, there is a slight increase in mid-winter, decreasing afterwards until mid-spring, then recovering at the end of this season (Fig. 2C).

Temperature

During the study period, bottom water temperature ranged from 17 to 24.5°C, the highest values recorded in July (24.5°C) and October 1996 (24°C). The lowest temperature occurred in January 1997 (17°C; Fig. 2D). Spawning took place during a temperature rise from 22.5 to 24°C, and gametogenesis occurred when temperature rose from 17 to 18°C (Fig. 2D).

Reproductive Cycle

The bivalve population enters a reproductive inactivity stage at the end of the autumn (undifferentiated stage near 100% in November), high values being maintained (around 70%) during the winter. The reproductive activity (gametogenesis) starts at the end of the winter, and in springtime 100% of the population is undergoing this stage. The first ripe individuals appear at the end of the spring, and in the summer 90% of the population is ripe. The population spawns in the autumn (90% in October). Gamete resorption is rapid because the post-spawning stage only takes place in early winter with low percentages (Fig. 3A–D).

DISCUSSION

In general, proteins were the main constituent of the gonad, digestive gland, and adductor muscle. Lipids were important in the digestive gland, whereas in the gonad they were highest before

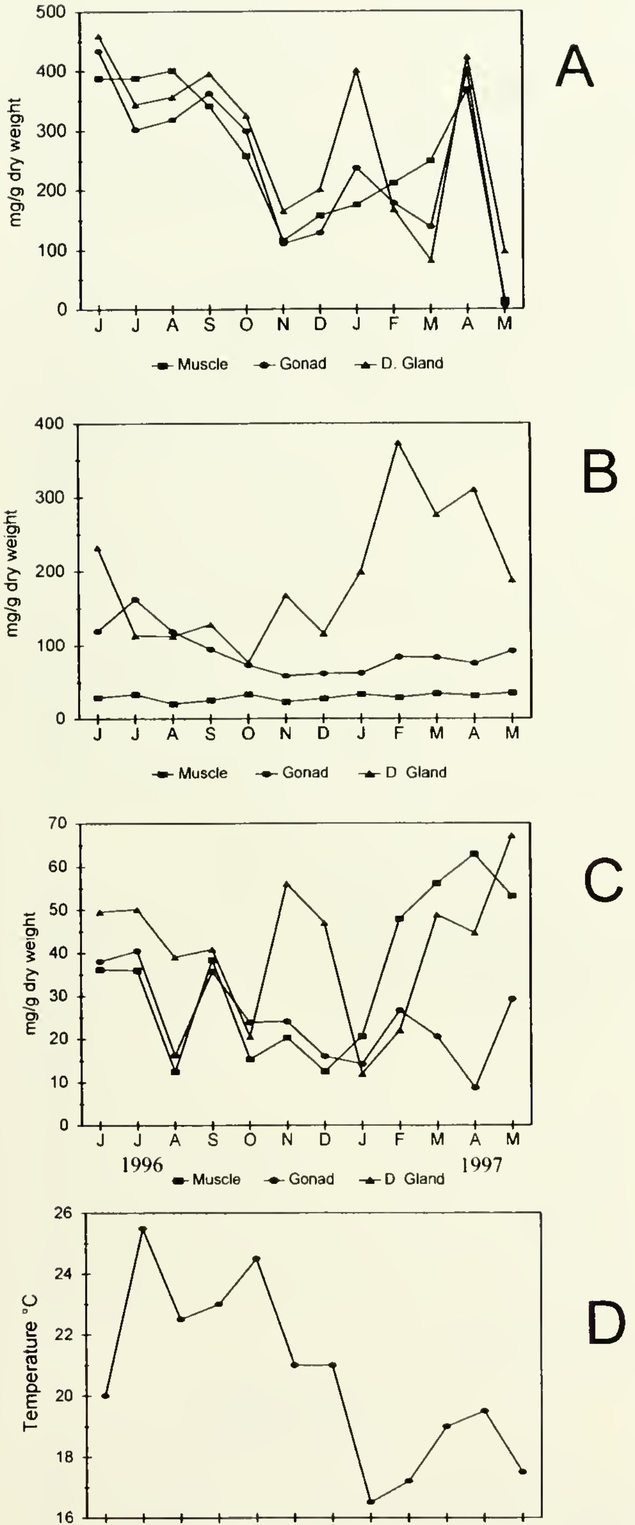

Figure 2. Variation of biochemical components in *Spondylus leucacanthus*. A, proteins; B, lipids; C, carbohydrates in muscle, digestive gland, and gonad; and D, bottom water temperature at Danzante island, Gulf of California.

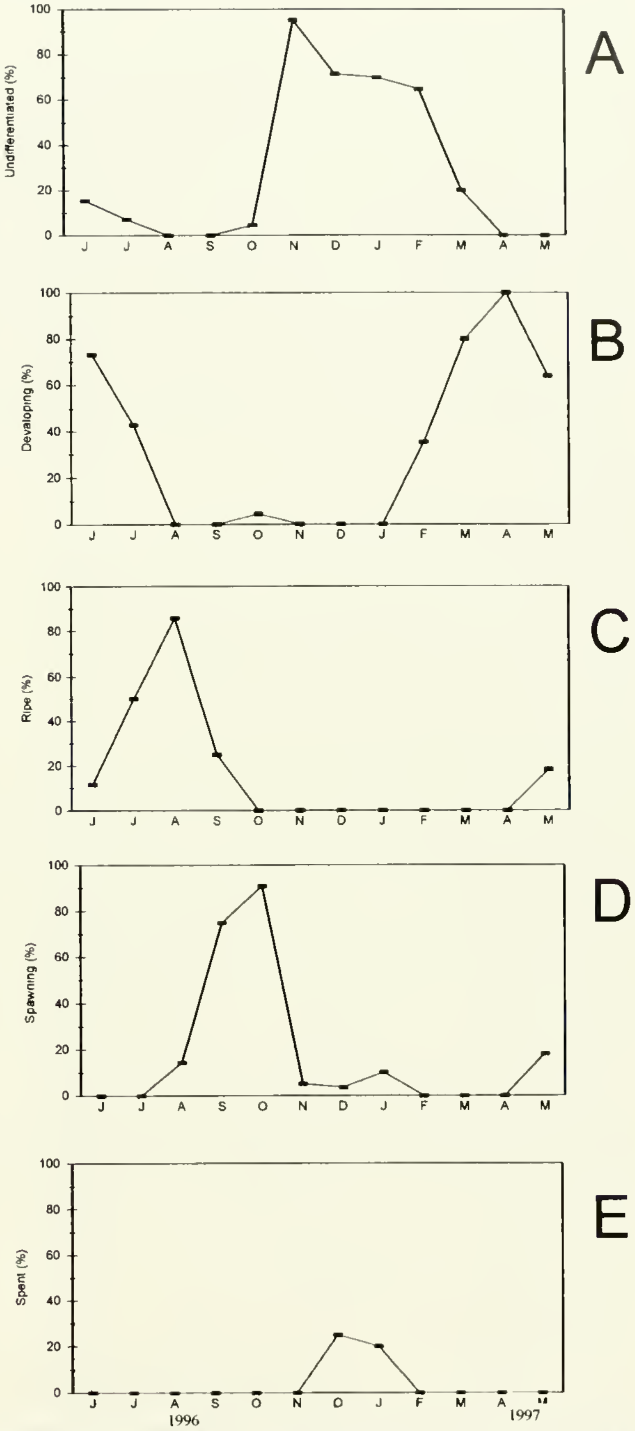

Figure 3. Reproductive cycle stages in *Spondylus leucacanthus*. A, inactivity; B, gametogenesis; C, maturity; D, spawning; E, post-spawning.

spawning and in the muscle they showed low and virtually unchanged concentrations during the study period. Carbohydrates were found chiefly in the adductor muscle and digestive gland, whereas the gonad showed lower values. These same trends in energetic substrate concentration were found in *Pecten maximus* (Strohmeier et al. 2000). During gonad maturation of many marine bivalves, an increase of biochemical compounds is observed in the female gonad, followed by a drop during spawning (Ansell 1974, Taylor & Venn 1979, Barber & Blake 1981, Sundet & Vahl 1981, Pazos et al. 1996).

The slight variation of proteins during the summer, when the population is ripe, suggests a low demand of this energetic substrate during this stage. The trend in the lipid curve for the digestive gland suggests that lipids are used during the ripe stage; however the correlation obtained is low ($r_s = 0.55$) and nonsignificant. Lipid transfer from the digestive gland to the ovary has been demonstrated in *Chlamys hericia* (Vasallo 1973). Furthermore, digestive gland carbohydrates show a significant correlation with the ripe stage ($r_s = 0.83$, $P < 0.05$), indicating its use during this stage.

It is likely that during the last gamete growth stage, food is also used as an energy source. In this same population, ripe organisms have been found in July, coinciding with a peak in food availability, which may provide a portion of the nutrients required for the gonad's final ripening (Muñetón-Gómez et al. 2001). Similar behavior was reported for *Placopecten magellanicus*, which reside southeast of Terranova (Thompson 1977). In other bivalve species like *Donax vittatus* and *Tellina tenuis*, the accumulation of reserve glycogen seems to be related with the season when the highest phytoplankton biomass occurs (Ansell & Trevaillion 1967, Ansell 1972). American oysters (*Crassostrea virginica*) held at 14 to 19°C were able to exploit a large phytoplankton bloom and synthesize glycogen (Ruddy et al. 1975).

In *S. leucacanthus*, spawning is an event that demands a heavy energy expenditure, requiring the use of protein and carbohydrate from the adductor muscle, the gland, and the gonad. However, it is in this latter organ that a significant correlation is found ($r_s = -0.63$, $P < 0.05$). Lipids do not appear as an important source in this stage. Based on the analyses of morpho-physiologic indexes, gut content, and phytoplankton abundance in the environment, the required energy expenditure during spawning in this species had been suggested to be partially supported by reserves stored in the muscle, the digestive gland, and the gonad (Villalejo-Fuerte & García-Domínguez 1998, Muñetón-Gómez et al. 2001).

When spawning ends, lipids and proteins remain low whereas carbohydrates are stored in the digestive gland, providing the energy required for the resorption of residual gametes during the stage known as spent that occurs at the end of the autumn. In *Crassostra virginica*, the concentration of neutral lipids decreased considerably during the spawning (Trider & Castell 1980) in *C. gigas* was observed an increased in lipid during the gametogenesis phase (Deslous-Paoli & Héral 1988).

When the population enters reproductive inactivity (undifferentiated stage) in early winter, there is a reorganization in the gonad (Villalejo-Fuerte & García-Domínguez 1998); during this stage, carbohydrates from the digestive gland are used in the first place ($r_s = 0.59$, $P < 0.05$), followed by proteins stored in the digestive gland and the gonad.

Gametogenesis starts at the end of the winter and in early spring. Energy for the initial gamete development is provided by lipids from the digestive gland, an event occurring similarly in *Spondylus calcifer* (Villalejo-Fuerte et al. 2002). Proteins from the three organs analyzed are used afterwards, most probably during the gamete final development stages. In this respect, this species has been shown to undergo rapid gamete growth at the beginning of gametogenesis, followed by a slowdown at the end of this stage (Villalejo-Fuerte & García-Domínguez 1998).

Temperature has been reported to influence the gametogenic cycle through the regulation of nutrient transfer from reserve-storing organs (Sastry & Blake 1971, Barber & Blake 1981, MacDonald & Bourne 1987). Our findings suggest that nutrient transfer and use takes place when temperature varies as a result of the summer to autumn (spawning) and winter to spring (developing) seasonal changes. This had been previously suggested for this species by Villalejo-Fuerte and García-Domínguez (1998) and for *A. circularis* (Villalejo-Fuerte & Ceballos-Vázquez 1996). The reserve storage process takes place when the lowest temperatures occur.

The biochemical composition of marine bivalves is affected by exogenous factors, including food availability and temperature, as well as by endogenous factors such as reproduction (Gabbott 1975, Bayne 1976, Barber & Blake 1981, Boadas et al. 1997, Claereboudt & Himmelman 1997). "Opportunistic species" use the energy directly obtained from food for gonad development, and energetic substrate storage and gamete production cycles may overlap temporarily, whereas "conservative species" use previously stored energy reserves (Bayne 1976).

Based on the findings of this study, it is confirmed that *S. leucacanthus* has a markedly seasonal reproductive cycle. This species shows a reproductive inactivity period that is well delimited throughout the year, characterized by the accumulation of energy reserves in the adductor muscle, the digestive gland and the gonad. The reproductive cycle stages that demand a higher expenditure of reserves are developing and spawning. According to these features, it can be concluded that this species has a conservative reproductive strategy, which is a characteristic of iteroparous species that largely use energy reserves, supplemented by energy obtained from food for energetic expenditures.

Similar strategies have been identified in other bivalves. *Scapharca broughtonii* behaves as a typical conservative species, with gametogenesis taking place during the winter and spring at the expense of reserve glycogen stored during the autumn, and spawning occurring during the summer (Park et al. 2001); by contrast, *Crassostrea gigas* was shown to behave as an opportunistic species, given that gametogenesis starts simultaneously with reserve accumulation and proceeds until gonadic maturity is reached, coinciding with the highest level of biochemical components followed by a rapid drop of these substances during spawning (Kang et al. 2000). *Argopecten ventricosus* preferentially uses food available in the environment when it is abundant but makes use of reserves in the adductor muscle when food is scarce (Luna-González et al. 2000). In *Cerastoderma edule*, gametogenesis may occur at the expense of glycogen reserves or simultaneously with glycogen storage, depending on the amount of available food (Navarro et al. 1989).

ABSTRACT Study of spatial and temporal distribution of European flat oyster larvae in relation to temperature and salinity has conducted over a two-year period at four study sites in a Mali Ston Bay, largest bivalve production area in the Eastern Adriatic Sea. In 2000, significant number of larvae was noted in a period from May till September, with a peak in July at all study sites. Lower number of flat oyster larvae in 2001, than in 2000, were noted at three study sites, while larvae appeared to be similarly abundant in both years at site Bistrina. Maximal recorded number of larvae was 5029 ind/m^3 at site Bistrina in August 2001. Our results show between year and between site variations in distribution of oyster larvae.

KEY WORDS: bivalve, oyster, *Ostrea edulis*, larvae, Adriatic Sea

INTRODUCTION

The Bay of Mali Ston is the largest bivalve production area in the Eastern Adriatic Sea, with a tradition of collection and aquaculture that extends for few centuries, and according to some authors, even from the time of the Roman Empire (Basioli 1968). Today, production is still based on small family farms. Most important species cultured in this region is European flat oyster *Ostrea edulis* (Linnaeus, 1758), and according to Benović (1997), about 1.2 million oysters per year were produced in the1980s. In the early 1990s, due to the war situation in this region, aquaculture production was largely neglected and it is only in last few years that interest has been generated to improve oyster aquaculture in Mali Ston Bay as a result of market demands caused by developing tourism industry. According to Šimunović (2001), current annual production is only 300 thousand pieces of oysters.

European flat oyster is one of the few indigenous bivalve species in European commercial aquaculture. Since the mid-nineteenth century, in other European countries flat oyster beds have progressively shrunk making this species a scarce and expensive item (Cano et al. 1997). Naturally occurring flat oyster beds are of great interest as a natural source of seed for achieving a steady and viable culture of *O. edulis* (Cano et al. 1997). This gives Mali Ston Bay exceptional importance since it is one of the rare places in the Mediterranean where both an adequate collection of *O. edulis* spat and subsequent aquaculture are still possible.

A previous study conducted in Mali Ston Bay, described two oyster spawning periods, one in the spring and the other in the fall (Morović & Šimunović 1980). Between 1985 to 2000, local farmers noticed insufficient attachment of oyster spat. Change was especially evident in relation to fall-spat settlement, which according to farmers, did not occur in some years (Maškarić 2001, pers. com.). Therefore, a study of spatial and temporal distribution of oyster larvae in relation to environmental characteristics was undertaken with the objective of improving collection of oyster spat and its aquaculture in this region and to gain a better insight into possibilities of spat collection that could potentially be used for *O. edulis* aquaculture in other parts of Mediterranean.

Study Site

Mali Ston Bay is an extended and ramified bay situated between the mainland and the Pelješac peninsula (Fig. 1). It is relatively shallow (maximal depth = 26 m) and characterized by strong marine currents and underwater freshwater springs, which along with precipitation, lower the salinity of the bay and bring organic matter from the surrounding terrestrial area (Šimunović 1981). Abundant and constant sedimentation influences formation of soft-mud sediments. Owing to the high level of fresh water input, the concentration of nutrients is high, but there are no signs of eutrophication (Vukadin 1981, Carić et al. 1992). Analysis of zooplankton community has indicated that the bay is a naturally moderate eutrophic ecosystem (Lučić & Kršinić 1998). As a consequence, production in the entire bay area is high, providing a rich diet for filter feeders (Bahun 1981). To protect this unique ecosystem and its bivalve aquaculture production, Mali Ston Bay was declared a reserve in the sea.

MATERIALS AND METHODS

Investigation was conducted at four sites within the Bay of Mali Ston: Bistrina (9 m), Soca (8 m), Krstac (15 m), and Bjejevica (14 m) (Fig. 1), in a period from May 2000 until March 2002. Samples were collected by vertical tows of plankton net (1.5 m long, 56 cm in diameter, and 125 μm in mesh size) for 8 to 15 m, depending on a maximal depth of a study site. Sampling was conducted a few times a month, depending on the number of larvae in the water column and weather conditions, and was more intensive during the summer period. Collected samples were preserved in 4% formaldehyde solution and analyzed on a microscope in a laboratory within 24 h after the collection. Oyster larvae were determined according to Rees (1950) and Loosanoff et al. (1966), and their numbers were calculated per cubic meter of seawater. Temperature and salinity were measured with the WTW multiline hydrographical probe at three depths on each site: surface, mid water column and one meter above the bottom. Degree of association between larval number and environmental parameters was determined with Pearson's rank correlation analysis.

RESULTS

The surface temperature ranged between 7.0°C (Soca, January 2002) and 26.9°C (Bjejevica, August 2000). The rise in surface temperature above 21°C occurred in late May and temperature did not drop below 21°C before mid September, in both years and at all study sites. It is interesting to note that in 2000, surface temperature was higher in December than in November. In early fall

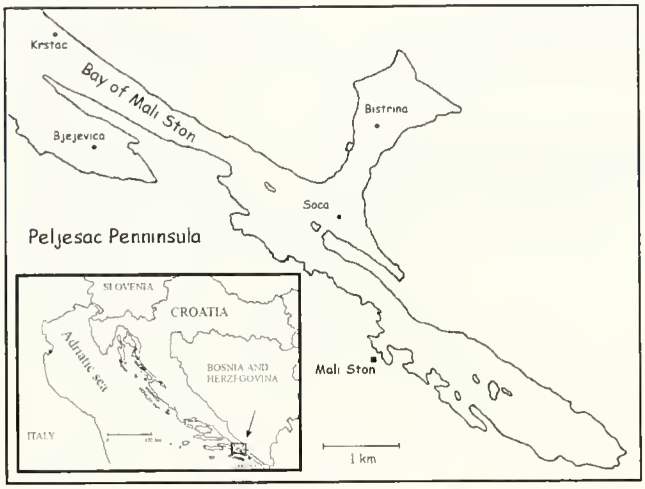

Figure 1. Location of Mali Ston Bay and four study sites: Bistrina, Soca, Krstac, and Bjejevica.

of 2001, surface temperature decreased slowly and was very similar in September and October at all study sites, that was followed by exceptionally low surface temperatures that dropped below 10°C in December and January.

In the late spring and early summer periods, due to stratification of a water column, bottom temperature is a few degrees lower than surface temperature. Toward the end of the summer, isothermia was observed in a water column, while during the fall and winter periods near bottom temperatures were higher than surface or mid water column temperatures (Table 1).

The surface salinity values ranged between 26.6 psu (Bistrina, May 2001) and 39.7 psu (Soca, March 2001). High variations in surface salinity were observed at Bistrina and Soca in a period from October till May and in Krstac and Bjejevica from October till February (Fig. 2). Near bottom layer was characterized with higher salinity values, than surface and mid water column layer, throughout the year.

European flat oyster larvae were present in the Bay of Mali Ston in varying numbers throughout the year. Maximal number of larvae recorded in a given month, and average surface temperature recorded in that month, are shown in Figure 3. High numbers of *Ostrea edulis* larvae were recorded in samples collected from May till September, while larvae were present in some samples, but not abundant, from November till April. Absence of larvae was primarily noted in samples collected between January and March 2002 at all study sites.

In year 2000, the highest larval numbers were recorded in July at all sites, with the highest value being recorded in the cove of Bjejevica (4875 ind./m^3) in late July. Minimal, maximal and mean values for number of *O. edulis* larvae recorded in study period are shown in Table 2. In 2001, maximal number of larvae collected in each month appeared to be lower than in 2000 at sites Soca, Krstac, and Bjejevica. At site Bistrina, the highest number of oyster larvae was recorded in August 2001 (5029 ind./m^3) while the number of larvae observed in other months of that year appears to be similar to values obtained for oyster larvae in year 2000.

There was a statistically significant positive correlation (P = 0.05) between number of *O. edulis* larvae and surface temperature and mid water column temperature (Table 3). Correlation between larvae number and near bottom temperature was significant only at

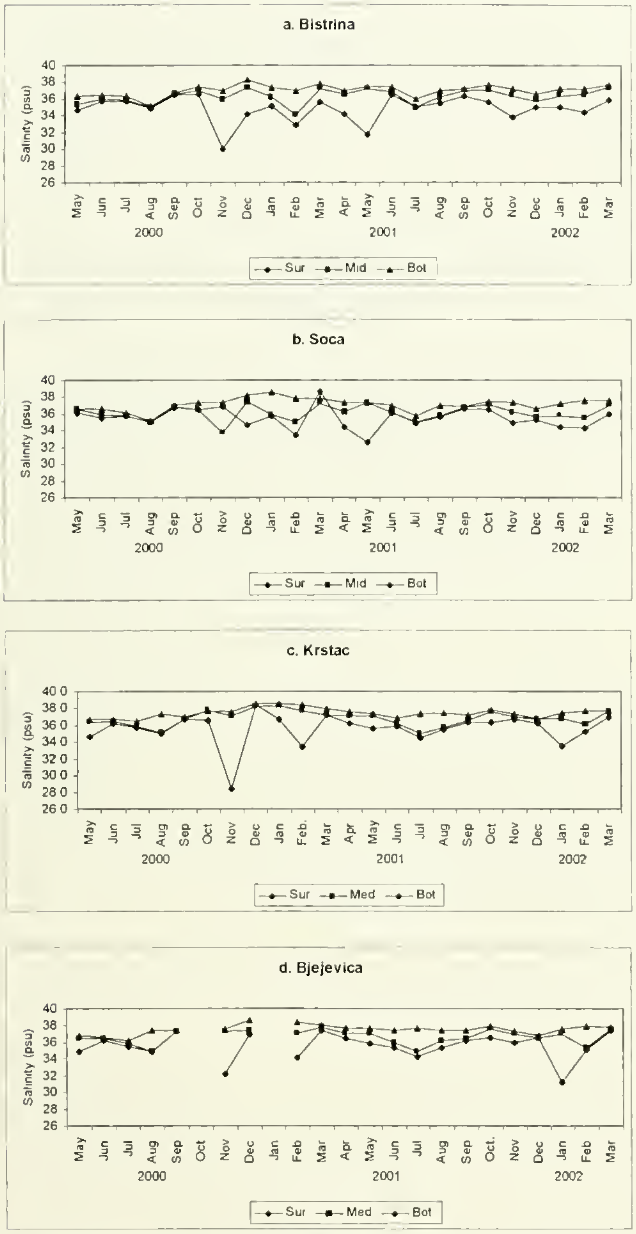

Figure 2. Time trend over a two-year study period for surface (Sur.), mid water column (Mid.) and near bottom (Bot.) salinity (psu) at four study sites: (a) Bistrina, (b) Soca, (c) Krstac, and (d) Bjejevica.

two shallower sites—Bistrina and Soca. Salinity values were not correlated with number of oyster larvae observed in samples, except at site Soca for near bottom salinity and at site Krstac for mid water column salinity.

DISCUSSION

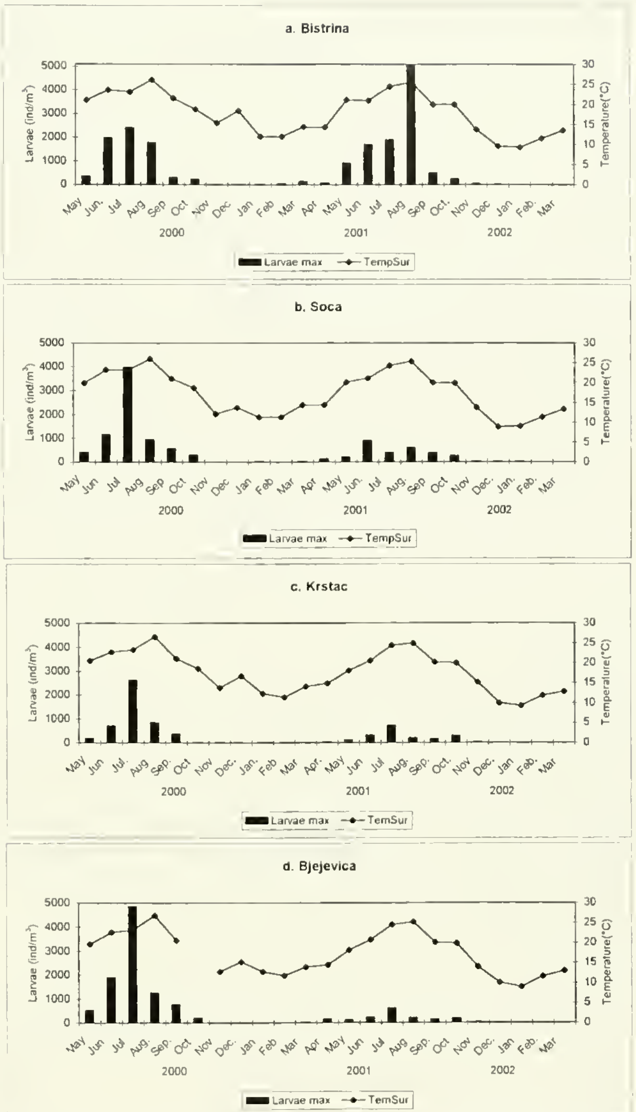

Figure 3. Time trend over a two-year study period for number of flat oyster larvae (ind/m^3) and temperature (°C) at for study sites: (a) Bistrina, (b) Soca, (c) Krstac, and (d) Bjejevica.

Traditionally, the Bay of Mali Ston was well known as an area where the European flat oyster has two spawning peaks per year, one in the late spring (May and June) and other in the autumn (September and October) (Morović & Šimunović, 1980). However, during the last 15 years, change in spawning season, was observed by local farmers. Results of this research confirm their observations. Although larvae were present throughout the year, the quantities suitable for commercial collection occurred several times during the warmest season, between May to September. Therefore, our results point out that in the summer period of 2000 and 2001, two previously known spawning peaks were combined to form a single, longer spawning period. Cano et al. (1997) also observed only one oyster spawning peak in Mar Menor (Spain) where significant oyster larvae numbers appeared at temperature

Temp. S. = surface temperature; Temp. M. = mid water column temperature; Temp. B. = temperature one meter above the bottom; Sal. S. = surface salinity; Sal. M. = mid water column salinity; Sal. B. = salinity one meter above the bottom. Level of significance: * $0.01 < p < 0.05$; ** $0.001 < p < 0.01$; *** $p < 0.001$; N.S. = non-significant.

from 15°C to 19°C, and maximum larvae number was noted at temperature between 24°C and 26°C.

The rise in mean temperature above 21°C in Mali Ston bay in early June correlates with the increased number of oyster larvae: over 500 individuals per m^3 at all sites from mid-June of 2000. The number of larvae reached the highest level in July, when the mean temperature of the water column was between 20°C and 24°C. When the mean water column temperature dropped to values between 12°C and 18°C, larval presence became negligible. The new spawning cycle and increase in larval numbers began again in April of 2001, correlating with the temperature increase above 14°C. This high dependence of initiation and duration of gametogenesis in *Ostrea edulis* on water temperature was already noted in many previous studies (e.g., Hrs–Brenko 1971, Sastry 1975, Mann 1979, Wilson & Simons 1985). In the summer of 2001 larval distribution was different than in summer of 2000. At sites Soca, Krstac, and Bjejevica lower number of larvae was collected in 2001 than in 2000. At site Bistrina, highest number of oyster larvae was observed in August 2001 while in other months larval distribution was very similar with respect to two observation years.

According to Morović and Šimunović (1980), maximum number of flat oyster larvae in Mali Ston bay in 1976 occurred in the first days of September and the minimum in August, while high numbers were also found in June and July, pointing out between year variation in distribution of oyster larvae.

Maximal number of larvae noted in this study is significantly different than values noted by Morović and Šimunović (1980). These authors noted over 75 thousand oyster larvae in 1 m^3 at site Krstac in May of 1974, while maximal number of larvae noted in this study was only 5029 ind/m^3. Observed differences might be attributed to reduced size of the flat oyster brood stock, water temperature, food availability, and water quality. Value obtained by Morović and Šimunović (1980) is also high when compared with the maximal number of oyster larvae recorded by Hrs–Brenko (1977) at several locations in Northern Adriatic where only up to 1000 ind/m^3 were recorded. Further on, Cano et al. (1997) also recorded a significantly smaller number of flat oyster larvae (6,000 ind/m^3) at one location in Spain.

In relation to environmental parameters recorded in this study, there was no apparent difference between year-temperature and salinity in the period between May and September that could explain the difference in numbers of flat oyster larvae observed in 2000 and 2001. In both years salinity in the bay was lower in comparison to open Adriatic waters (Vukadin 1981) and was within optimal values for larval survival. However, since flat oysters are filter feeders and phytoplankton is generally known to be the main source of nutrition for bivalve filter feeders (Dame 1996), possible explanation might be related to difference in distribution of phytoplankton biomass. According to Ninčević (unpublished data), phytoplankton biomass in Mali Ston Bay was lower in summer of 2001 than in summer of 2000. Another possible explanation for the reduced number of larvae in 2001 might be presence of unidentified species of ctenophore within the bay (Bolotin 2002, unpublished data). According to Dame (1996), ctenophores and jellyfish are the most commonly reported bivalve larval predators. However, at this point it is not possible to explain why the number of larvae decreased at three study sites in 2001 but did not decreased at site Bistrina.

To provide an explanation for observed differences in larvae distribution, further research should be conducted at all study sites, measure other environmental parameters, such as chlorophyl *a* and nutrients, as well as identification of ctenophore species. Observation of gonad maturation and settlement success should also be included to obtain a complete picture on reproductive effort and settlement of European flat oyster in this unique bay and to improve the aquaculture production.

ABSTRACT Despite the commercial importance and abundance of knobbed whelks on the east coast of the United States, very little life history information exists for juveniles in the egg capsule and the first few critical weeks post hatching. As a result, various intertidal sandy-mud flats around Wassaw Sound, Georgia were monitored from early April 2001 when copulating and egg-laying whelks were first observed to early June 2001 when most egg capsules had opened and the hatchlings had begun to disperse. During this spawning event, egg strings were collected, the length of the embryonated (mean = 339.86 mm) and unembryonated (mean = 199.67 mm) portions were measured, and the number of embryonated capsules per string (mean = 89.76) was determined. The middle section of the embryonated portion comprised the largest capsules (mean height = 22.12 mm, mean width = 31.11 mm, mean thickness = 6.03 mm) and had the highest number of encapsulated embryos with an average of 46 (up to 99). Egg strings were also hatched in the laboratory with the intention of examining the effects of diet (meat, macroalgae, and microalgae) and temperature (20, 25, and 30°C) on the growth and survival rates of newly hatched juveniles. Optimum growth and survival conditions resulted in those reared on a meat diet in aquaria maintained at 20°C.

KEY WORDS: knobbed whelk, *Busycon carica*, egg capsules, hatchlings

INTRODUCTION

The knobbed whelk, *Busycon carica* (Gmelin 1791), is a common prosobranch gastropod (Family Melongenidae) along the east coast of the United States from Cape Cod, Massachusetts to Cape Canaveral, Florida on sandy mud, in shallow water to 4.6 m (Rehder 1981). The reproductive cycle of *B. carica* has not been determined in Georgia, however, Walker (1988) reported spawning in the spring and fall based on the appearance of egg strings and copulating whelks. In North Carolina (Magalhaes 1948) also found biannual spawning between May to June and September to November. In South Carolina, *B. carica* was reported to reproduce in the fall (October to November) and spring (April) (Stevens 1976). Stevens (1976) suggested that the fall reproductive period was more important than the spring based on a comparison of body weights, digestive gland weights, and ovarian indices. Weinheimer (1982) reported that *B. carica* from South Carolina are not restricted to one or two breeding seasons, but reproduce from September to May. In Virginia, spawning was reported between mid August and November (Castagna & Kraeuter 1994).

Fertilization occurs internally in *Busycon* (Weinheimer 1982). Males are equipped with a large muscular penis, and the female oviduct is composed of a series of chambers and glands. Fertilized eggs are surrounded by a transparent viscous mass of albumin and are laid in protective disciform egg capsules arranged on a helicoid string (D'Asaro 1997). Several whelk species are reported to migrate to favorable egg laying sites during the breeding season (Power & Keegan 2001). In coastal Georgia, egg strings are commonly encountered near the low water mark on intertidal sandy mud flats. Ram et al. (1982) determined an egg deposition rate of 1.9 ± 1.5 h/capsule in the laboratory. According to Magalhaes (1948) long strings are usually laid over several days.

Egg strings in Virginia were reported to contain between 42 and 121 capsules (Castagna & Kraeuter 1994). The average embryos per egg capsule in Chesapeake Bay ranged from 46 to 67 (Harasewych 1982). Castagna and Kraeuter (1994) determined the average number of embryos per capsule varied according to position on the egg string, averaging 52 in the middle section and decreasing in the beginning and terminal portions. The female always begins by anchoring one end of the egg string deep into the substrate by several structurally modified capsules to prevent the string from being washed ashore (Magalhaes 1948). Ram (1977) and Ram et al. (1982) induced spawning in the knobbed whelk by stimulation with nervous system extractions. Spawning always began with a number of unembryonated capsules, a choice dictated by genome. It has not been determined how the female adjusts the number of anchoring capsules. Studies have found that the egg capsules in the anchoring portion are typically thinner walled and closely spaced (Harasewych 1982). The number of unembryonated capsules in this anchoring portion has been reported to range from 8 to 22 (Castagna & Kraeuter 1994), from 13 to 17 (Ram et al. 1982), and to average 21 (D'Asaro 1997).

The young pass the veliger stage within the egg capsule and emerge as fully developed miniature "adults." In Virginia, Castagna and Kraeuter (1994) found that egg strings deposited in the fall hatched from mid-March through early-May in the following year. The average size for hatchling juveniles is ~4 mm in length (Magalhaes 1948, Castagna & Kraeuter 1994).

Most studies that have been conducted were on adult whelks (Morton 1987). Very little information exists about the ecology of post hatchling knobbed whelks. As an adult, the knobbed whelk is a predator of bivalve species. There has been no research published on the habitat and nutritional requirements of juveniles in the wild. In Virginia, juvenile whelks were hatched and raised inside polypropylene bags in the laboratory to estimate post hatching growth rates (Kraeuter et al. 1989). There was limited information provided on rearing conditions (i.e., the temperature and diet). Length measurements were taken five times during the first year and one to three times per year for the subsequent nine years. The juveniles were fed live clams when they reached ~20 mm in length. Growth

rates averaged 13.2 mm/y over the ten-year period, however juveniles grew from 4 to 36.5 mm (32.5 mm/y) in the first year. The only other published growth study on juvenile knobbed whelks was by Magalhaes (1948). She maintained juveniles in the laboratory for one month only and observed one individual added 1.5 mm in length in 22 days. This experiment attempts to determine the optimum food source for juvenile knobbed whelks with respect to growth and survival rates. Temperature is also considered since warmer temperatures foster accelerated growth.

MATERIALS AND METHODS

Weekly field trips to intertidal sandy-mud flats around Wassaw Sound, Georgia were carried out from April 2001, when copulating and egg-laying whelks were first observed, to early June 2001 when most egg capsules had opened and the hatchlings had begun to disperse. On each occasion, notes were taken on the behavior (i.e., copulating, depositing eggs, and feeding). If a whelk was in the process of laying, an estimate was made of the number of capsules already produced, her position was taken with a hand held global positioning system, and the location was physically marked with a metal stake. Once the strings were completed, the number of egg capsules per string was determined (excluding the anchoring section). The condition of the egg capsules was also monitored regularly to determine the larval developmental period in the field.

At the end of May 2001, egg strings were collected and returned to the Shellfish Research & Aquaculture Laboratory on Skidaway Island. Ten strings were selected to examine the capsule morphometrics, length, width, and thickness, as defined by D'Asaro (1997). The length of unembryonated and embryonated sections of each string was determined with a fish measuring board. Each string was then divided into four portions: the unembryonated anchor, and an inner, middle, and outer portion of the embryonated section. Five capsules were randomly selected from each section, the dimensions were measured and the capsules were opened to count the developing embryos.

Egg strings were also maintained at the laboratory in an open system raceway until hatching began. Hatchling juveniles were collected, measured for length, and isolated for growth rate experiments using diet and temperature variables. Three dietary treatments were chosen for the growth study: macroalgae, microalgae, and meat. Sea lettuce, *Ulva* sp., was harvested from Wassaw Sound and the Skidaway River for the macroalgae series. Benthic microalgae (species unknown) was cultured on mats in a closed system saltwater tank using nylon mesh as a substrate. The third diet consisted of chopped meat: clams, *Mercenaria mercenaria* (L.), brittle stars, *Ophiophragmus wurdemani* (Lyman), bloodworms, *Glycera dibranchiata* (Ehlers), and mussels, *Geukensia demissa* (Dillwyn), depending on what was available. Temperature was included in the design. At the time of hatching, water temperatures averaged 25°C (taken from the nearby Skidaway River), therefore three glass aquaria were set up in temperature controlled rooms, at 20, 25, and 30°C. For the duration of the experiment, the salinities were maintained at 35‰. Plastic jars (120.6 × 69.8 mm) were used to contain the juveniles. To help water circulation, thirty 2-mm holes were drilled in the top and bottom of the jars and 15 on each side. There were three replicates for each combination of diet and temperature treatment resulting in 27 containers, each holding 50 haphazardly chosen hatchlings. Jars were labeled and temperatures and salinities in the aquaria were tested and maintained regularly. The water in the aquaria was aerated, and changed monthly. All the juveniles were provided with an abundance of food, which was cleaned out and replaced approximately every three days. Juvenile shell length (to the nearest 0.01 mm) and body weight (to the nearest 0.0001 g) were recorded every two weeks using an electronic calipers and balance. The animals were first blotted dry by placing on a paper towel. Dead juveniles were removed and counted to determine mortality rates. The experiment was conducted over an eight-week period.

Statistical analysis of growth and survival data was performed using SAS (SAS Institute, Inc., Cary, NC). The two main effects (temperature and diet) and a nested effect (containers) on growth (length and weight) were analyzed by performing a nested factorial using GLM (General Linear Model) SAS. Survival data were arcsine transformed prior to analysis [$X' = \text{arcsine} \sqrt{(x/100)}$]. Two main effects were again analyzed (temperature and diet), with repeated measures of both factors using a GLM (SAS). An α level of $P = 0.05$ was used to determine if significant difference in mean juvenile length, weight, and survival occurred between different diets and temperature treatments.

At the termination of the eight-week laboratory growth experiment, we returned to the sites of egg deposition in Wassaw Sound to search for juveniles that had presumably dispersed on hatching. A circular area with a diameter of approximately 4 m was searched around approximately twenty marked egg cases. The goal was to obtain juveniles to compare the growth obtained in the laboratory with growth in their natural habitat. Methods for searching consisted of scooping up handfuls of the surface layer of sediment at low tide and sieving on a 1.40 mm screen. Submerged sites at lower tidal levels were searched by gently feeling the surface of the sediment.

RESULTS

The abundance of copulating whelks peaked in early April 2001 and was observed with decreasing frequency throughout the rest of the month. This period coincided with a dramatic increase in local water temperatures (Fig. 1). Often copulation was observed even while the female was in the process of depositing egg capsules (Fig. 2). Typically the larger female lay partially buried in the substrate and was surrounded by several smaller sized males (average of 3, but up to 9 observed). A large variation in the rate of egg deposition was observed: 1 to 23 capsules per day (7.69 ± 2.12, mean ± SE). This is a coarse estimate since the egg strings were observed once per week. An approximate total area of 2,500 m^2 was searched for whelks and eggs. By the end of April, most egg strings were complete and whelks were less abundant on the sandy-mud flats. From a total of 51 complete egg strings (0.02 m^2), the number of embryonated egg capsules per egg string averaged 89.76 ± 3.61, and ranged from 40 to 157. Egg capsules began to soften and deteriorate quickly, the escape aperture was open on all capsules examined on June 4, 2001 (approximately six weeks later). While all capsules were open at this time, only one third of those examined were empty, the remainder still held the fully developed hatchlings.

The average length of the unembryonated section for the ten egg strings selected for morphometric analysis was 199.67 ± 15.21 mm (ranged from 130 to 275 mm). For the embryonated section the average length was 339.86 ± 26.17 mm (ranged from 245 to 450 mm). The number of unembryonated capsules per egg string ranged from 6 to 26 (mean = 13.67 ± 1.97). The number of developing embryos per egg capsule ranged from 0 to 99. The

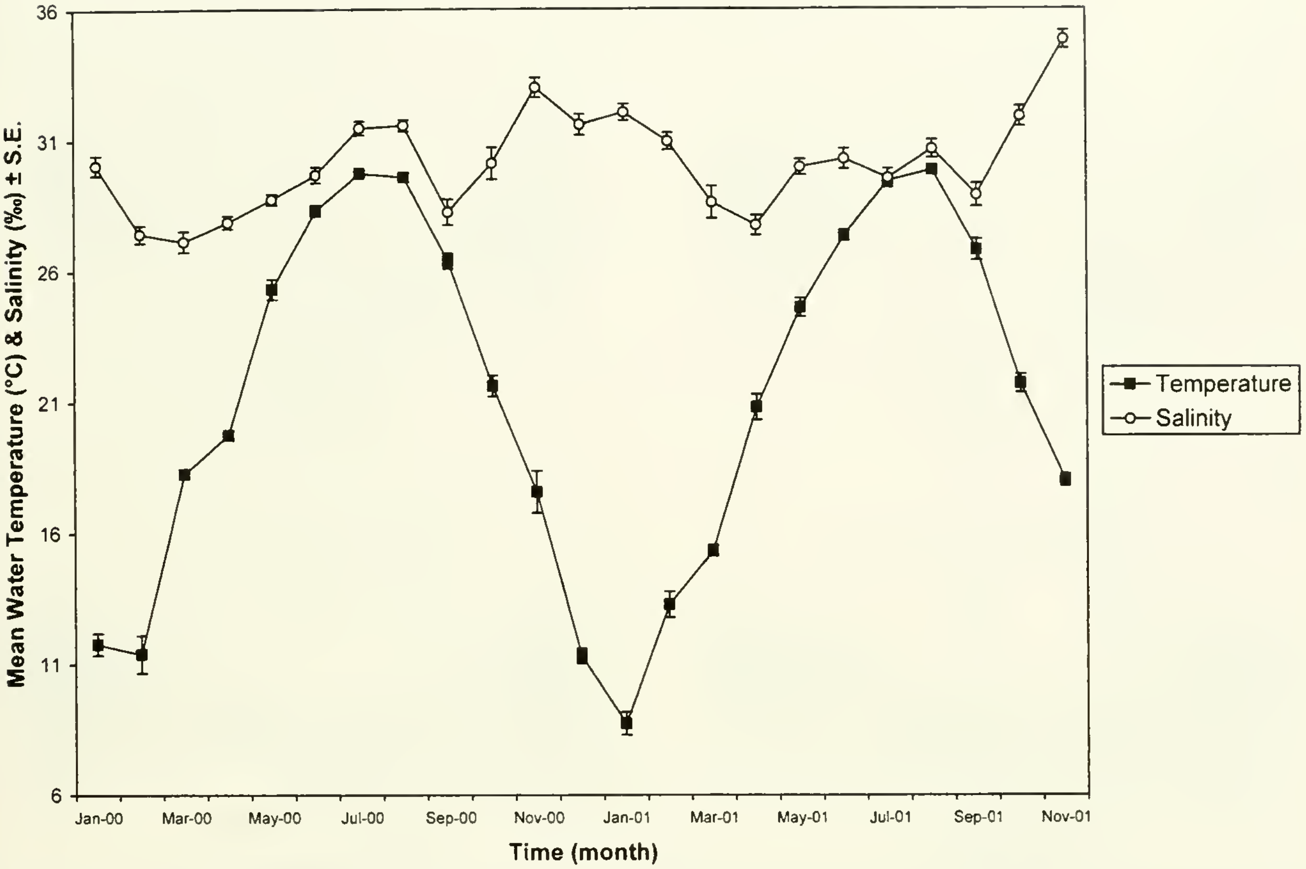

Figure 1. The mean monthly water temperature and salinity of the Skidaway River, Georgia from January 2000 to November 2001 (vertical bars indicate ± 1 standard error from the mean).

middle portion of the embryonated section of the egg strings had longer, thicker, and wider capsules with a higher number of embryos per egg capsule. The inner and outer portions averaged 23.41 ± 2.77 embryos per capsule, with capsule dimensions of 20.20 ± 0.47 mm in length, 27.26 ± 0.69 mm in width and 5.66 ± 0.09 mm in thickness. The middle portions had an average of 45.86 ± 3.95 embryos per capsule, with capsule dimensions of 22.12 ± 0.41 mm in length, 31.11 ± 0.56 mm in width, and 6.03 ± 0.14 mm in thickness.

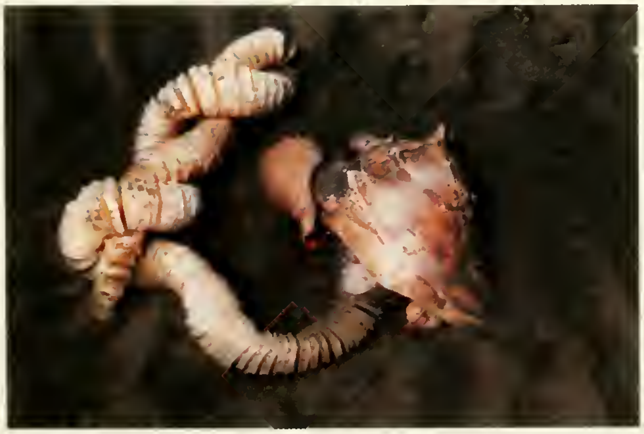

Figure 2. Small male knobbed whelk, *Busycon carica*, copulating with a larger female that is also in the process of depositing an egg string.

In the laboratory, the egg strings maintained in raceways also began to hatch in early June 2001. On hatching the juveniles averaged 5.60 ± 0.02 mm in shell length and 23.10 ± 0.24 mg in weight (n = 540). These were haphazardly assigned to the three different diet (meat, algae and diatoms) and temperature (20, 25, and 30°C) treatments. Figure 3 and Figure 4, present the growth rates of these juveniles for a period of eight weeks, in terms of shell length (mm) and weight (mg), respectively. Figure 5 presents the percentage survival rate at the termination of the experiment for each temperature and diet treatment. Growth in terms of length and weight was significantly affected by diet (P = 0.003 and 0.001, respectively). Duncan's Multiple Range Test revealed no difference in the growth of whelks fed on the macroalgae and microalgae diets (macroalgae: mean length 5.67 mm, mean weight 21.29 mg; microalgae: mean length 5.65 mm, mean weight 21.47 mg), however those fed on the meat diet were significantly larger (mean length 6.35 mm, mean weight 27.81 mg). Survival was not significantly affected by diet (P = 0.2084). There was a significant (P = 0.001) temperature effect on survival. Duncan's Multiple Range Test revealed no difference in survival at temperatures 25°C and 30°C (15.31% and 7.73%), but a much greater survival rate occurred at 20°C (69.50%). Percent survival rates decreased with temperature increase for all dietary treatments (Fig. 5).

It proved very difficult to locate juvenile knobbed whelks on the intertidal flats in August and September. The best approach proved to be feeling the surface layer of sediment when a shallow depth of water covered the flats. Even with this approach only nine

Figure 3. A–C. D: The overall growth rate (shell length, mm) per diet and temperature treatment over eight weeks.

juveniles were recovered (Table 1), from a total area of approximately 250 m^2 (~0.04 m^{-2}). The wild juveniles located, averaged a much larger size (mean shell length = 21.2 mm) than those reared in our laboratory treatments.

DISCUSSION

Copulation occurred throughout April 2001 during which average seawater temperatures increased rapidly from a mean of 15.3°C in March 2001 to 20.8°C in April 2001. Walker (1988) observed six pairs of copulating whelks in Wassaw Sound in March 1980 (mean water temperature 14.3°C). We do not believe that whelks commenced spawning earlier than April in 2001, since intertidal flats were thoroughly searched throughout March 2001 as part of an ongoing whelk mark and recapture study. Another spawning event may take place in Georgia, when seawater temperatures drop to a similar range in the fall. Along the eastern coast of the United States, the reported spawning period of the knobbed whelk is progressively later as one moves northwards: March to April in Georgia (Walker 1988, present study) and South Carolina (Stevens 1976), May to June in North Carolina (Magalhaes 1948), and mid August to November in Virginia (Castagna & Kraeuter 1994).

In the natural environment, the timing of the reproductive period is usually synchronized with conditions that are most favorable for maximization of juvenile survival and continuity of the species (Sastry 1986). Gastropod egg capsules are preyed on by fish, crustaceans, other prosobranchs, polychaete worms, and even shorebirds (Penchaszadeh et al. 2000). Predator activity typically increases in the warm temperatures of the early summer months. However, these months also permit a more rapid embryonic development of encapsulated larvae that may reduce overall losses. A rapid developmental period of six weeks was observed in the present study, which concurs with findings for the pear whelk in Florida (6 wk: Kent 1983). This is however, significantly lower than the six-month period (mid summer to following spring) reported for the same species in the cooler northern waters of Virginia (Castagna & Kraeuter 1994). Embryonic development of encapsulated knobbed whelks has been noted to temporarily arrest and resume after egg capsules were refrigerated for four days at 0°C (Dr. DeEtte Walker, pers. comm., UGA Dept. of Genetics). According to Hain and Arnaud (1992) embryonic development for related species can be up to thirty times longer in Antarctic than in tropical waters.

Although most egg capsules in the field were open in early June, two-thirds of all capsules examined still held hatchlings. A gradual dispersal has also been noted for juveniles of the lightning whelk, with many found within and between the opened capsules (D'Asaro 1997). Juveniles may use the structure as a refugium. Egg strings also provide a substratum for algae, diatoms and even other invertebrates in their juvenile stages and could therefore also serve as a food source for newly hatched whelks.

In this study the hatchlings (n = 540) averaged 5.60 mm in

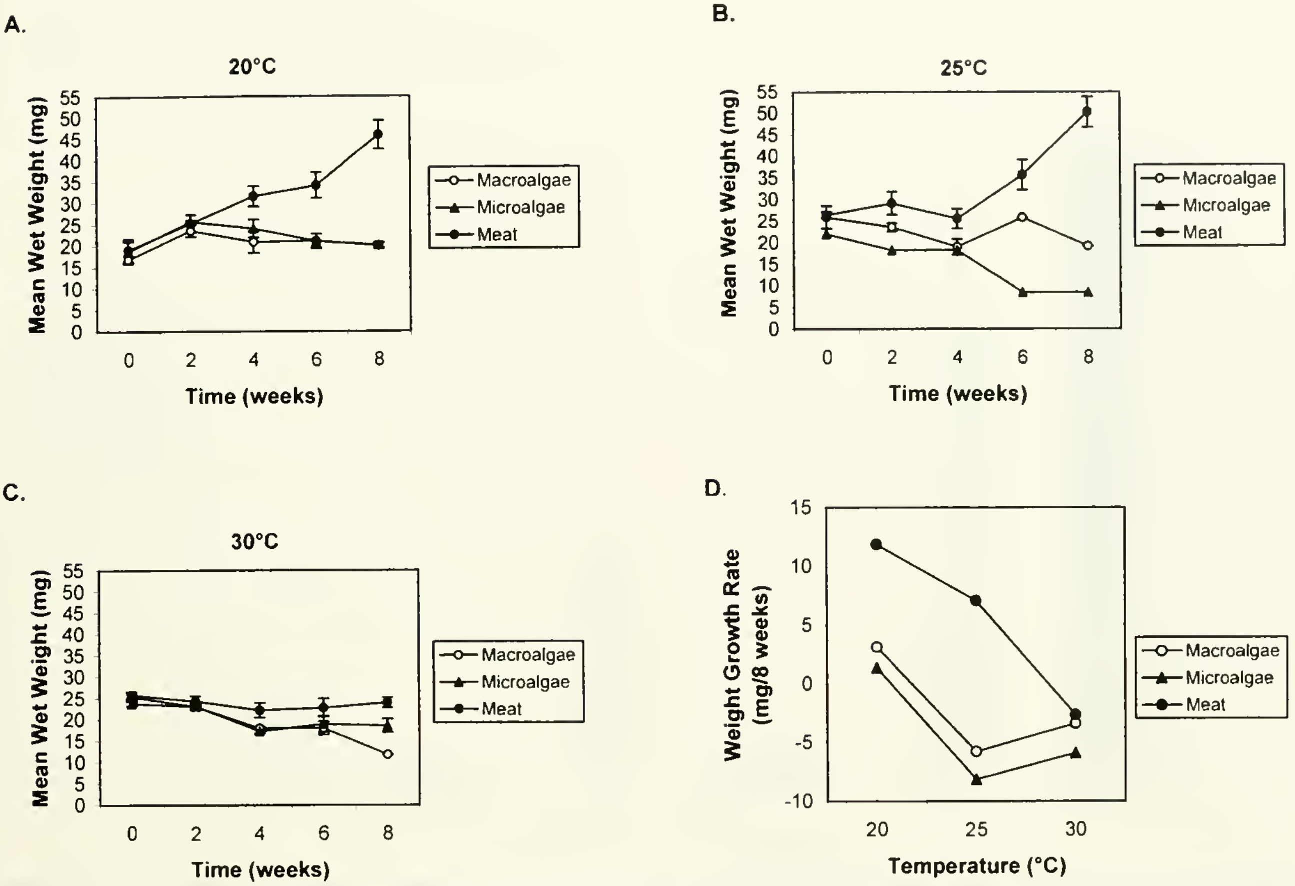

Figure 4. A–C. The mean wet weight (mg ± SE) of knobbed whelks reared in the laboratory on macroalgae, microalgae and meat diets at temperatures of 20, 25, and 30°C, respectively, for eight weeks post hatching. D: The overall growth rate (wet weight, mg) per diet and temperature treatment over eight weeks.

shell length (ranged from 3.31 to 6.96 mm). This is larger than the 4 mm previously recorded for whelks in North Carolina (Magalhaes 1948) and Virginia (Castagna & Kraeuter 1994). Similarly to residence time within the capsules, the size at hatching may also be influenced by environmental factors including water temperature.

In this study, there was a large range in the number of encapsulated embryos per egg capsule (ranging from 0–99). The middle section of the embryonated portion comprised the largest sized capsules (mean length 22.12 mm, mean width 31.11 mm, mean thickness 6.03 mm) and contained the highest number of embryos (mean = 46). The inner and outer portion capsules contained about half the number of embryos (mean = 23) and were smaller (averaging 21.45 mm and 18.96 mm in length, 29.27 mm and 25.26 mm in width, and 5.60 mm and 5.71 mm in thickness, respectively). The middle section of egg strings in Virginia was reported to contain a slightly higher average of 52 embryos, but the number of embryos in the outer capsules was not provided (Castagna & Kraeuter 1994). In shape, egg capsules were taken to roughly approximate a prism on an elliptic base. The following formula was used to obtain the mean number of embryos per unit of capsule space for the middle, inner and outer portions of egg strings = (# embryos)(4) / (π) (length) (width) (thickness). Embryos were packed closer in the middle capsules (14.07 cm^{-3}) than in either the inner (8.45 cm^{-3}) and outer (10.95 cm^{-3}) portions.

There is typically a wide variation in the number of embryos occurring in egg capsules within the family Melongenidae, e.g., the lightning whelk is reported to have between 25 and 200 (Perry & Schwengel 1955), the channeled whelk between 73 and 130 (Conklin 1907), and the pear whelk between 9 and 50 (Odhner 1927, D'Asaro 1997). The number of knobbed whelk egg capsules per egg string averaged 90 and ranged from 40 to 157, which is similar to the range 42–121 reported from Virginia (Castagna & Kraeuter 1994). This species appears to have more egg capsules per egg string than the channeled whelk (up to 70: Conklin 1907), but less than the lightning whelk (up to 175: Perry & Schwengel 1955), which could be expected in relation to size (shell length) differences between the species (channeled: <19 cm; knobbed: <22.9 cm; lightning: <40.6 cm, Rehder 1981). Miloslavich and Dufresne (1994) have directly related the size (shell length) of female *Buccinum undatum* whelks depositing egg capsules to the number of capsules, the size of the capsules, and to the number of developing embryos within. According to Spight and Emlen (1976), the fecundity of an organism increases with an increase in size and age.

From the growth and survival data presented for juveniles at the laboratory, it is clear that a carnivorous diet is optimal post hatching. Cannibalism at this stage was also observed in the treatments provided with macroalgae and microalgae diets. Morton (1987) suggested that juveniles of *Hemifusus tuba* might consume one another outside of the capsules to enhance the survival of an individual in the transition time needed to discover natural prey. Survival rates were much reduced at 25°C and 30°C indicating that the temperature was approaching the upper physiologic tolerance. Most tropical marine organisms cannot survive at temperatures

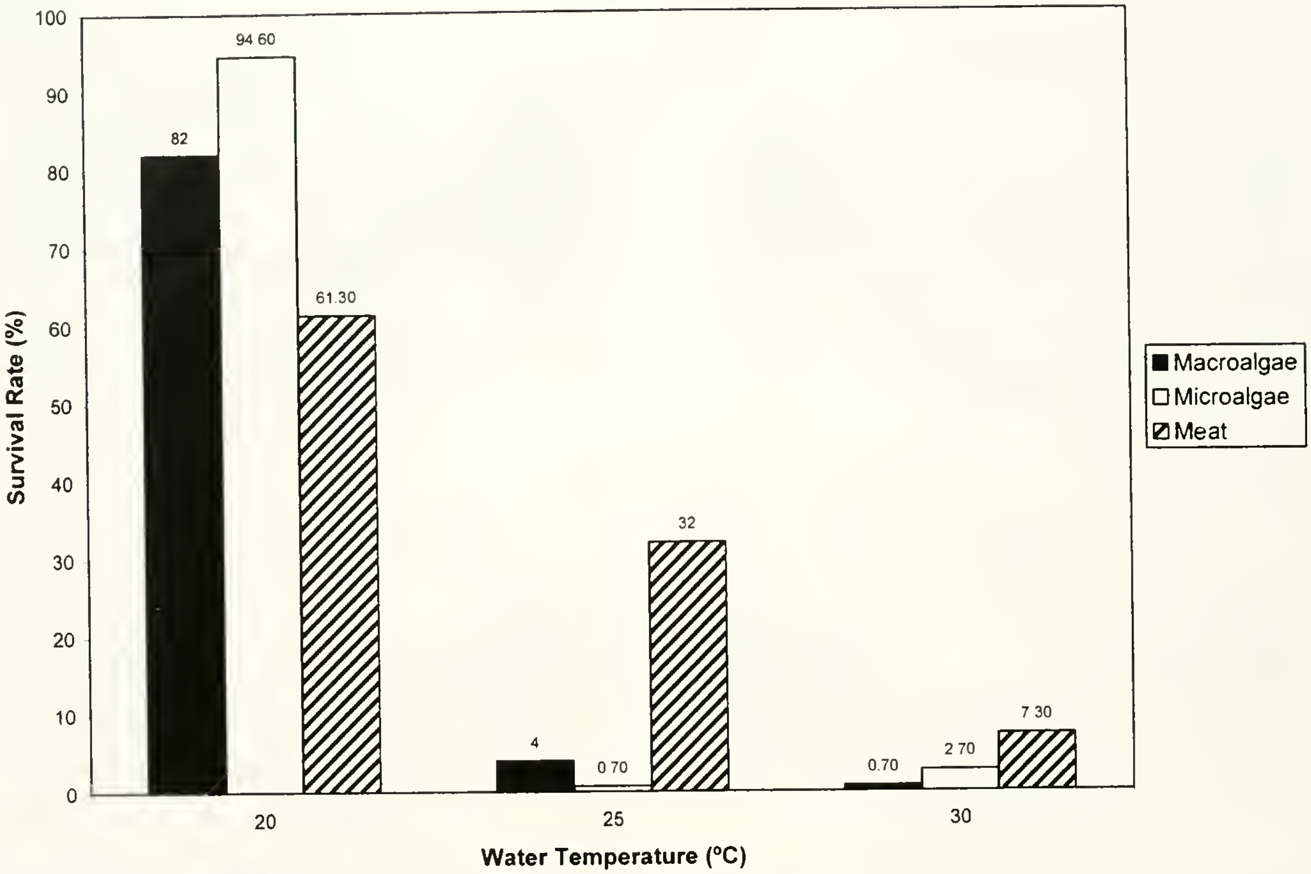

Figure 5. The percentage survival rate of knobbed whelks reared in the laboratory on macroalgae, microalgae and meat diets at temperatures of 20, 25, and 30°C, respectively, for eight weeks post hatching.

higher than 35°C (Kinne 1963). Juveniles that hatched in June 2001 would have experienced temperatures up to 30°C on the intertidal flats, but would also have had the ability to bury themselves in the substrate. Chaitanawisuti and Kritsanapuntu (1998, 1997) found that the highest growth rates of hatchery reared juvenile spotted Babylon, *Babylonia areolata* (Link 1807) whelks occurred in treatments provided with sand substrate and flow through seawater, while the lowest occurred in those with no sand substrate and static seawater. In our experimental treatments, both water flow and a sand substrate were not provided and may have led to sub-optimal growth and survival rates. The lack of substrate has been shown to induce interactive energy expenditure by juvenile queen conchs (Siddal 1984).

Catterall and Poiner (1983) describe small juvenile colonies (area of 2–15 m in diameter) of the gastropod *Strombus luhuanus* with between 5 to 100 individuals per meter squared. These colonies may persist for up to two years and become larger in area and less dense as members grow and mature. This type of spatial segregation may also occur for juvenile knobbed whelks in the wild. It is likely that juveniles spend a large proportion of time completely buried in the sand, particularly when the tide retreats, which would explain our difficulty in locating them. We only found juveniles at the surface of the sediment after the tide had advanced over the intertidal flats. In the laboratory the largest sized juvenile at the termination of our rearing experiment (8 weeks later) was approximately 12.5 mm. The average size of the juveniles found in the wild was much larger at 21.2 mm. These wild juveniles may have resulted from the previous fall spawning event and would therefore be approximately eight months old, which resembles the annual year one growth rate of 34.5 mm reported by Kraeuter et al. (1989) in Virginia.

ABSTRACT The recent discovery of adult veined rapa whelks *Rapana venosa* (Valenciennes, 1846) in the Lower Chesapeake Bay, U.S.A. offers cause for both ecological and economic concern. Adult rapa whelks are large predatory gastropods that consume bivalves including commercially valuable species such as hard clams, *Mercenaria mercenaria* (Linnaeus, 1758). Laboratory feeding experiments were used to estimate daily consumption rates of two sizes of whelks feeding on two size classes of hard clams. Large rapa whelks (shell length, SL >101 mm) are capable of consuming up to 2.7 g wet weight of clam tissue daily, equivalent to 0.8% of their body weight. Small whelks (60–100 mm SL) ingest an average of 3.6% of their body weight per day.

KEY WORDS: rapa whelk, *Rapana venosa*, hard clam, *Mercenaria mercenaria*, predation, Chesapeake Bay

INTRODUCTION

The veined rapa whelk, *Rapana venosa*, (Valenciennes 1846; Gastropoda: Muricidae) was discovered in the Hampton Roads region of the Chesapeake Bay, USA, in the summer of 1998 (Harding & Mann 1999). The species is native to the Sea of Japan, Yellow Sea, East China Sea and the Bohai Sea (Tsi et al. 1983) but was introduced to the Black Sea in the 1940's (Drapkin 1953) and has since spread to the Aegean Sea (Koutsoubas & Voultsiadou-Koukoura 1990) and the Adriatic Sea (Ghisotti 1974). Recently a female specimen together with egg masses was found in the Rio del Plata, an estuary between Argentina and Uruguay in South America (Pastorino et al. 2000).

The predatory activity of rapa whelks in the Black Sea is considered by Zolotarev (1996) to be the prime reason for the decimation of native Black Sea oyster, scallop and mussel populations. Given this history, there is both ecological and economic concern for the future of shellfish stocks in the Hampton Roads region of the Chesapeake Bay. Hard clam, *Mercenaria mercenaria*, populations are of particular concern in that the Hampton Roads region supports a substantial local commercial hard clam fishery. Laboratory feeding experiments were used to quantify daily feeding rates for two size classes of adult rapa whelks offered hard clams.

MATERIALS AND METHODS

Twelve adult rapa whelks, collected from the lower Chesapeake Bay, USA, between March and May 2000, were separated into two different size classes: small (60–100 mm shell length (SL), the maximum dimension from the apex of the spire to the end of the siphonal canal) and large (101–160 mm SL). Rapa whelks were maintained individually in 60 × 40 × 30 cm plastic net cages submerged in a shallow flume (250 × 70 × 30 cm) with a constant flow of unfiltered York River water as described in Savini (2001). The bottom of each cage was covered with 15 cm of clean hard sand substrate. Rapa whelks were starved for 48 hours prior to the addition of hard clams (prey) to each enclosure. Each whelk was given five small (50–70 mm maximum dimension, hereafter shell height, SH) and five large (71–100 mm SH) hard clams as potential prey. Clams were arranged in the experimental cages so that whelks initially had the same probability of encountering each size of prey (i.e., whelks at the center of a circle with clams of alternating size classes spaced evenly around the circumference).

The experimental flume was covered with a fixed plastic net to prevent escape of the whelks and maintained on a 14/10 h natural light/dark schedule. Water temperature and salinity data were collected daily from the flume for the 38 day duration of the experiment (June 11 to July 18, 2000). Experimental cages were examined daily and the empty shells of all prey were removed and measured. Clams that were consumed were replaced daily with clams of similar dimensions thus maintaining constant prey availability.

A size range (30–100 mm SH) of fifty hard clams was selected from the pool of potential prey items and used to create size-weight relationships for the prey. Individual hard clams were measured (SH, mm) and weighed (g) prior to the removal of soft tissue. Clam soft tissue was weighed (wet weight, g) to the nearest 0.1 g.

Data Analyses

Significance levels for all statistical tests were established at $P = 0.05$ *a priori*. Bartlett's test for homogeneity of variance and the Ryan-Joiner test for normality were used prior to analyses. When appropriate, Fisher's test was used for post-hoc multiple comparisons.

Feeding Rates

The numbers of clams consumed by each size class of whelks during the entire experimental period were compared using a one-way ANOVA with individual whelk as a factor. The number of clams consumed satisfied the assumptions of homogeneity of variance and normality without transformation. Daily feeding rates were calculated for each whelk by dividing the total number of clams consumed during the experimental period by the duration of the experiment (38 days).

Consumption on a Weight-Weight Basis

Clam wet and dry tissue equivalents consumed by whelks were compared using a two-way ANOVA with whelk size class and individual whelk as factors. Tissue equivalent data satisfied the assumptions of homogeneity of variance and normality without transformation.

RESULTS

Average water temperature during the experimental period was 26°C (±1°C). Average salinity was 21 ppt (±1 ppt). During the 38 day experiment, the six small whelks ate a total of 19 clams while the six large whelks consumed a total of 15 clams. There was no significant difference in the total number of clams eaten by small and large whelks (ANOVA, $F = 0.67$; $P > 0.05$). Small rapa whelks did not show any clear size preference when offered hard clams as prey (Fig. 1) although small whelks consumed a total of 11 small clams and 8 large clams. It should be noted that 5 of the 11 small clams were consumed by one individual. Large rapa whelks consumed large clams more frequently than small clams (4 small clams vs. 11 large clams; see Fig. 1).

Clam Size-Weight Relationships

Clam tissue wet and dry weights were plotted in relation to shell height and used to calculate shell height-wet tissue weight relationships for hard clam prey. These relationships were used to calculate wet tissue equivalents for each clam consumed by an individual whelk and were described with the following equations:

$$\mathrm{Log}\ (\mathrm{CWWgt}) = -3.93 + 2.77 * (\mathrm{Log\ SH}); \qquad R^2 = 0.96$$

where CWWgt is clam tissue wet weight (g) and SH is clam shell height.

Rapa Whelk Size-Weight Relationships

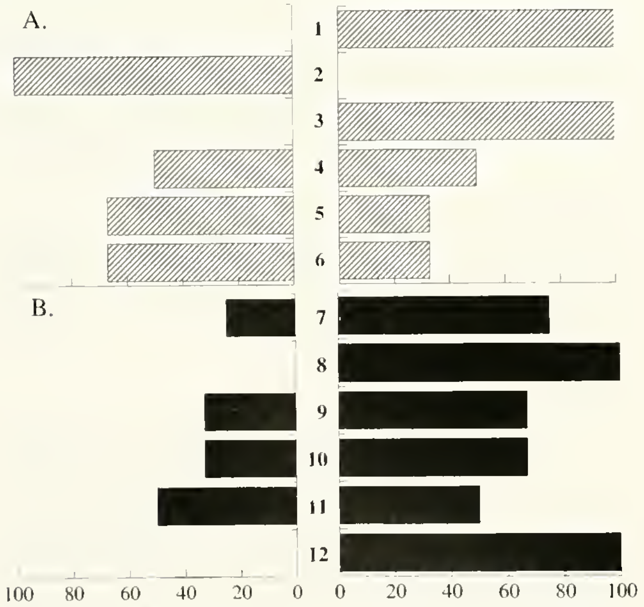

Figure 1. Percentage of small (50–70 mm SH) and large (71–100 mm SH) hard clams eaten in each experimental cage by each rapa whelk during the whole experimental period (June 11 to July 18, 2000). A) N. 1–6 = small whelks (60–100 mm SL), B) N. 7–12 = large whelks (101–160 mm SL).

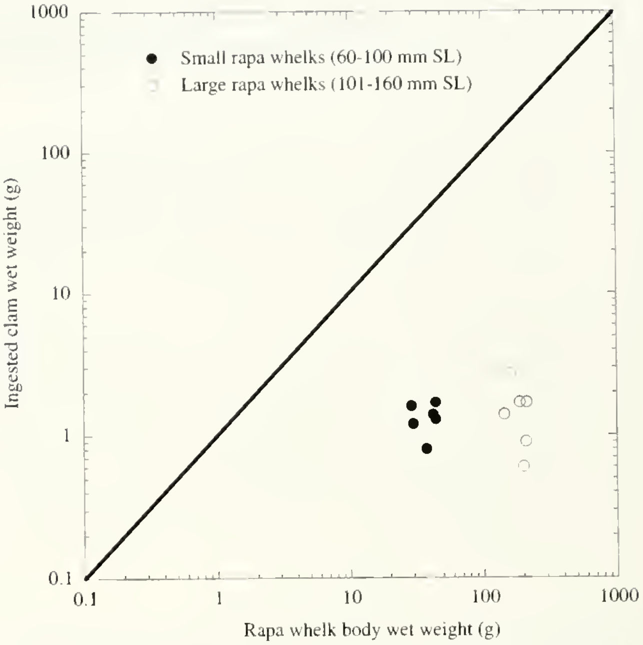

Figure 2. Daily ingested clam wet weight (g) in relation to rapa wet weight (g) observed in laboratory feeding experiments during June and July, 2000. The solid diagonal line represents clam consumption equal to the body weight of the predator (whelk) or a 1:1 consumption relationship on a prey wet weight: predator wet weight basis. Points above the line indicate prey consumption at a rate greater than one while points below the line indicate daily consumption rates less than the body weight of the predator.

Rapa whelk tissue wet weight was plotted in relation to shell length and used to calculate a shell length–wet tissue weight relationship for whelk predators. This relationship is based on 150 animals (80–165 mm SL) collected from lower Chesapeake Bay, USA between October 1999 and July 2000 (Harding and Mann, unpublished data):

$$\mathrm{WWWgt} = 6.4908 * e(0.0229 * \mathrm{SL}), \qquad R^2 = 0.69$$

where WWWgt is whelk tissue wet weight (g) and SL is whelk shell length (mm).

On the basis of tissue wet weight, large whelks consumed significantly more prey flesh tissue than small whelks (ANOVA, $F = 4.45$, $P < 0.05$). Individual small whelks ate proportionately more hard clam tissue on a clam wet weight: whelk wet weight basis than large whelks (Fig. 2). Maximum daily clam consumption rates of 5.6% of body wet weight were recorded for small whelks as compared to 1.6% of body wet weight for large whelks.

DISCUSSION

Large rapa whelks (101–160 mm SL) are able to consume up to 2.7 grams of clam tissue (wet weight) per day or 0.8% of their body weight per day at water temperatures of approximately 26°C. In contrast, small rapa whelks (60–100 mm SL) ingested an average 3.6% of their body weight every day, which is more than four times that observed for larger rapa whelks at similar water temperatures on a weight-specific basis. Edwards and Huebner (1977) suggest that temperature affects feeding rate in the moon snail *Polinices* by increasing predators' metabolic rate, and thus the requirement for a larger amount of food. The present investigation was conducted during warmer months and is probably indicative of the maximum feeding activity of rapa whelks. There is considerable variation in reported ingestion rates for predatory gastropods with values up to 25% of its body weight per day reported for the moon snail, *Polinices duplicatus* (Thorson 1971).

The hard clam fishery in the lower Chesapeake Bay is already in decline. Hard clam landings during 1999 were less than 10% of landings during 1973 (Virginia Marine Resources Commission, Newport News, VA). The observed decline in hard clam stocks may be related to increased anthropogenic impacts on the Chesapeake Bay ecosystem in the past 20 years including overfishing, water pollution and disease. Habitat changes are considered the major threats to estuarine ecosystem (Smith et al. 1999). The superimposition of a novel invading predator on this already stressed population has clear ecological and economic implications.

Virnstein (1977), found that particularly in Chesapeake Bay, densities of infaunal species are not controlled by competitive interactions for food or space but mainly by the action of predators. If the introduction of *Rapana venosa* into the lower Chesapeake Bay results in a large scale successful invasion, rapa whelks could have a serious negative impact on the density and distribution of the native hard clam population in the lower Chesapeake Bay. At this time we do not have a good estimate of the resident population of rapa whelks in the Chesapeake Bay but is possible to use our data for a hypothetical calculation to estimate potential impact of the whelk on the clam population. The rapa whelk distribution in the Chesapeake Bay, which extends from the mouth of the Rappahannock River in the North, to the Chesapeake Bay Bridge tunnel in the southeast and to the Lafayette River in the south (Harding & Mann 1999, Mann & Harding 2000), is within the historic distribution of *M. mercenaria* (Roegner & Mann 1991). The 1999 summer fishing season for hard clams in the lower Chesapeake Bay produced a harvest of 27388 kg or approximately 3,040,000 individual clams. Based on the predation rates observed in this study, a population of 1000 rapa whelks in the lower Bay could reduce this yield by between 0.3 to 0.9%.

ECONOMIC ANALYSIS OF A PILOT COMMERCIAL HATCHERY-BASED OPERATION FOR SPOTTED BABYLON, *BABYLONIA AREOLATA* LINK 1807, JUVENILES IN THAILAND

N. CHAITANAWISUTI,[1] S. KRITSANAPUNTU,[2] AND Y. NATSUKARI[3]

[2]*Department of Bioproducts, Prince of Songkla University (Suratani campus), Suratani, 84100;*
[3]*Department of Fisheries, Nagasaki university, 1-14, Bunkyo-Machi, 852-8521 Japan*

ABSTRACT An economic analysis of constructing and operating a pilot hatchery and nursery for the commercial production of spotted babylon, *Babylonia areolota*, juveniles in Thailand was presented on the basis of proven practical techniques and published data from larval culture trials. The total initial investment requirement for the construction of a spotted babylon hatchery producing 1.2 million juveniles per year was 9,310.5 US$. Annual ownership costs were estimated to be 2,497.5 US$, with annual operating costs of 5,311.8 US$. Total annual cost for the juvenile production (Hatchery) phase of spotted babylon was 7,809.3 US$, and the cost of producing 1.2 million juveniles in this hatchery design was estimated at 6.09 US$ per 1,000 juveniles. Under the basic assumptions in this study (juvenile production of 1.2 million/year), a selling price of 13.8 US$ per 1,000 juveniles results in a positive cash flow by year 2. Price and survival sensitivity resulted in substantial variability in net returns. This pilot hatchery operation is marginally feasible under these conditions if costs can be lowered considerably by improving growth and survival.

KEY WORDS: Spotted babylon, *Babylonia areolata*, economic analysis, hatchery-based operation

INTRODUCTION

Spotted babylon, *Babylonia areolata* (Link), are promising a new aquacultural marine gastropod in Thailand. Fast growth, high survival, and low feed conversion ratio (FCR) in grow-out culture provide this species with the biologic production and market characteristics necessary for a profitable aquaculture venture (Chaitanawisuti & Kritsanapuntu 1999a, Chaitanawisuti & Kritsanapuntu 1999b). Considerable interest has developed recently regarding the commercial culture of spotted babylon in Thailand because of a growing demand and an expanding domestic market for seafood, as well as a catastrophic decline in the natural spotted babylon population in the Gulf of Thailand. An accurate economic assessment of culturing spotted babylon in Thailand is required before producers can make informed decisions regarding the potential of this enterprise. A lack of economic data can be an important constraint to the successful development of spotted babylon aquaculture in Thailand. A financial investment analysis describes the relationships between yield (growth and survival), market price, fixed and variable costs, and profitability indicators. From 1998 to 2000, Chulalongkorn University conducted a collaborative research and development project with the National Research Council of Thailand (NRCT) to develop the land-based aquaculture system for large-scale hatchery and grow-out operations for spotted babylon in Thailand. Thereafter, the methods and techniques are intended to transfer for the economically hatchery-based operations in Thailand. This study was the first attempt to present estimates of the cost of producing juvenile spotted babylon, *B. areolata*, under a successful management scheme. The specific objectives were performed to identify the investment requirements, annual ownership and annual operating costs associated with the hatchery, and the net returns, returns on investment and cash flow according to selected survival and prices of juvenile.

MATERIALS AND METHODS

Hatchery Operation

A pilot commercial-scale hatchery in this study is designed to produce a total of 100,000 juveniles in 30-day production cycle for transfer to growout phase of culture. The design and operation of the hatchery was based upon the techniques of Chaitanawisuti and Kritsanapuntu (1997). The data necessary to estimate investment requirements for the hatchery were mainly gathered from a pilot research. The broodstock spawned and reared the larvae up through the post-set stage to 1.0 cm juvenile. The process involves manipulating adult snails until natural spawning occurs. The egg capsules are collected and placed in rearing tanks, where they develop into veliger larvae. The set are then placed in rearing units in which algae-enriched water is offered once daily. The algae are cultured from unicellular algal flask cultures of preferred species (*Chaetoceros calcitrans* and *Tetraselmis* sp.) in a controlled system. The average monthly productions of egg capsule and veliger larvae are approximately 8,180 and 7,116,600, respectively (Chaitanawisuti & Kritsanapuntu 1999b). The initial stocking density rate was specified at 500 larvae L^{-1} of water. The entire hatchery process require 14–18 days to go from spawning to newly settled juveniles ready for placement in the nursery system. This method requires a substantial level of capital investment and technical expertise to produce a consistently high quality of algae supply. The nursery is a critical link in the spotted babylon culture process. Placing hatchery juveniles directly into the grow-out system may induce unacceptably high mortality levels. The nursery provides an intermediate step that nurtures hatchery-reared juveniles to a size less vulnerable to the stress of grow-out operation. In addition, growing juveniles to the size required for the grow-out stage within the intensive hatchery environment would likely not be cost effective. The length of time (30–45 days) required by a nursery to produce 1.0-cm juveniles from newly settled juveniles. Based on this pilot hatchery, an average survival of veliger larvae to 1.0 cm juveniles is approximately 1.5%.

Financial Analysis

Financial analysis was based on investment cost, production, and marketing data from the pilot-scale trials. The components of the economic analysis include the following.

For the initial investment, the building used for hatchery operations included a 300-m² space made of concrete floor and sheet zinc roof with no window and wall for reducing construction cost and entrance of natural light. The hatchery design consists of three

Electricity	827.5	15.58
Interest on operating cost	179.6	3.38
Total operating cost	5,311.6	100

rectangular broodstock rearing tanks (3.0 × 3.0 × 0.7 m canvas tanks), 30 cylindrical larvae rearing tanks (500-L plastic tanks), 20 cylindrical (nursery tanks (500-L plastic tanks), 15 conical algae culture tanks (500-L plastic tanks), and 4 mass algae culture tanks (4-ton concrete tanks). A small 3.0 × 3.0 m room is also included for algae culture and stock maintenance. Sand filter rated at 150 L per minute are specified for filtering water before its initial use in the hatchery. Two sets of 2-horsepower pumps rated seawater used are necessary to transport water through the system. Two 10-ton canvas tanks were used as seawater stocking tanks. The two-horsepower blower is designed to provide a high volume of dissolved oxygen, low pressure, and uncontaminated air necessary for larval survival and to keep food suspended in the water column after it has been introduced into the larval culture tank. Operating a hatchery requires the regular monitoring of water-quality variables such as pH, salinity, water temperature, ammonia, nitrite, and nitrate levels, and these parameters are maintained at satisfactory levels for optimum growth and survival. A refractometer is specified for salinity measurements and a seawater test kit is specified for the determination of important water-quality parameters. Other designated equipment includes a refrigerator for the storage of supplemental feed ingredients and algae stocks. A binocular microscope is needed for the daily inspection of the quantity of food and growth of the larvae. PVC pipes and fittings are used to transport seawater and air from their sources to the culture system. Additional miscellaneous equipment also is specified for the daily operation of the hatchery. Interest rates for capital cost is based on 2000 bank loan rate of 3.5% for business enterprise.

Annual ownership costs mainly consisted of annual depreciation and interest on investment. These costs are fixed and incurred in the long run regardless of whether the facilities are operated. Annual depreciation was based on the expected useful life of each equipment item. A zero salvage value was assumed on all items constituting the facilities. The hatchery building, canvas tanks, and plastic tanks were assumed to have a useful life of 10 years because of the seawater environment. The life expectancies of equipment ranged from 3–5 years. Interest rates are based on 2000 bank loan rates of 3.5% of the original prices for all investment items.

Annual operating costs are incurred upon actual operation of the hatchery and include repairs and maintenance, labor, feed, utilities, and interest on operating capital. The annual cost of repairs and maintenance for the hatchery was computed as 5.0% of purchase price. Two labor requirements were estimated based on the particular needs for full-time operation of the hatchery. Labor cost for each individual was calculated at a rate of 114.9 US$ per month, without fringe benefits. Feed cost is based upon the assumption that larvae are fed microalgae for 14 days of the cycle.

TABLE 2.

Estimated depreciation, interest charges, and repairs and maintenance of hatchery production for *B. areolata* juveniles.

Item	Cost (US$)	Economic Life (yr)	Annual Depreciation (US$)	Annual Interest Charges (US$)	Annual Repair and Maintenance (US$)

TABLE 4.

Estimated annual costs for hatchery production of spotted babylon, *B. areolata*, juveniles.

Item	Cost (US$)	Percent of Total
Ownership costs		
Depreciation	2,153.1	27.57
Interest on investment	344.4	4.41
Total ownership cost	2,497.5	31.98
Operating costs		
Repairs and maintenance	408.0	5.23
Hired labor	2,758.6	35.33
Feed	724.1	9.28
Broodstock purchase	413.8	5.29
Electricity	827.6	10.59
Interest on operating capital	179.6	2.30
Total operating cost	5,311.8	68.02
Total annual cost	7,809.3	100

Thereafter, feed is principally composed of the fresh meat of fish. The cost of purchasing and caring for broodstock was estimated to be 4.6 US$/kg of spotted babylon. Based on the production scenario, the hatchery designed in the present study requires 40 kg of broodstock. This estimate was based on the assumption that approximately 52,200 larvae are produced from one female broodstock and an average of 1.5% survival of juveniles was expected. Electricity is used for operating the various pumps and lighting units in the hatchery. The average charge of electricity was assumed to be 68.9 US$ per month. Interest rates are based on 2000 bank loan rates of 3.5% per year for all depreciable items that compose the hatchery.

Return Analysis

Net returns and returns on investment for hatchery production were computed at final survivals ranging from 1.0–3.5% and the selling price of juvenile ranging from 9.2–22.9 US$ per 1,000 juveniles. Gross return was computed for each level of survival and each selling price. Net return was calculated from the gross return minus the total annual cost. Return to capital and management was computed for each level of survival and each selling price by subtracting annual operating cost from gross returns. Subsequently, return on investment was estimated by dividing returns to capital and management by initial capital investment (Fuller et al. 1992). An annual production budget was developed from the variable and fixed costs, and cash flow budgets were developed to examine profitability in relation to the timing of expenditures and earning. Net cash flow was determined by projecting estimated revenues and costs over a 10-year period because an aquaculture enterprise would be an attractive investment opportunity if it were profitable within this period. The initial investment was charged in the first year, and costs in subsequent year included annual variable and fixed costs. (Rubino 1992, Head et al. 1996).

TABLE 5.

Estimated total annual cost for production of spotted babylon, *B. areolata*, juveniles at selected survival rates.

Survival Rate (%)	Annual Production (Juvenile)	Annual Costs (US$)	Cost per 1,000 Juveniles (US$)
0.5	426,996	7,809.3	18.29
1.0	853,992	7,809.3	9.14
1.5	1,280,988	7,809.3	6.09
2.0	1,707,984	7,809.3	4.57
2.5	2,134,980	7,809.3	3.66
3.0	2,561,976	7,809.3	3.05
4.0	3,415,968	7,809.3	2.29

Survival rate is calculated from veliger larvae to juveniles of 1.0-cm shell length with an average monthly egg capsule and veliger production of 8,180 and 7,116,600, respectively.

TABLE 6.

Gross return for hatchery production of spotted babylon, *B. areolata*, juveniles at selected survival rates and selling prices.

Survival (%)	Selling Price (US$ per 1,000 Juveniles)				
	9.2	13.8	16.1	18.4	22.9
0.5	3,928.3	5,892.5	6,874.6	7,856.7	9,778.2
1.0	7,856.7	11,785.0	13,749.3	15,713.4	19,556.4
1.5	11,785.1	17,677.6	20,623.9	23,570.1	29,334.6
2.0	15,713.4	23,570.2	27,498.5	31,426.9	39,112.8
2.5	19,641.8	29,462.7	34,373.2	39,283.6	48,891.0
3.0	23,570.2	35,355.3	41,247.8	47,140.3	58,669.3
4.0	31,426.9	47,140.4	54,997.1	62,853.8	78,225.7

Gross return was calculated for each level of survival and selling price.

RESULTS

Total investment requirements for construction of the hatchery were 9,310.5 US$ (Table 1). The building was the largest cost component (37.04%) of the hatchery. The rearing tank, land, water supply and storage tanks, and algal culture tanks are the second most expensive items in equipping the hatchery, representing 13.57%, 12.35%, 11.11%, and 9.87% of total investment, respectively. These five components of the hatchery represent 83.94% of total investment requirements for production of spotted babylon juveniles. Annual ownership costs were estimated to be 2,497.5 US$ with annual depreciation and interest of 2,153.1 and 344.4 US$, respectively (Table 2). The annual operating cost is estimated to be 5,311.8 US$. Hired labor was the largest cost component (51.94%) of the operating cost, followed by electricity, feed, and repairs and maintenance of which comprised 15.58%, 13.63%, and 7.68%, respectively (Table 3). Total annual cost for the juvenile

Return to capital and management for hatchery production of spotted babylon, *B. areolata*, juveniles at selected survival rates and selling prices.

Survival (%)	Selling Price (US$ per 1,000 Juveniles)				
	9.2	13.8	16.1	18.4	22.9
0.5	−1,383.5	580.7	1,562.8	2,544.9	4,466.4
1.0	2,544.9	6,473.2	8,437.5	10,401.6	14,244.6
1.5	6,473.3	12,365.8	15,312.1	18,258.3	24,022.8
2.0	10,401.6	18,258.4	22,186.7	26,115.1	33,801.0
2.5	14,330.0	24,150.9	29,061.4	33,971.8	43,579.2
3.0	18,258.4	30,043.5	35,936.0	41,828.5	53,357.5
4.0	26,115.1	41,828.6	49,685.3	57,542.0	72,913.9

Return to capital and management was calculated for each level of survival and selling price by subtracting annual operating cost (5,311.8 US$) from gross returns.

production (hatchery) phase of spotted babylon culture was 7,809.3 US$ (Table 4). Annual ownership and operating costs accounted for 31.98% and 68.02% of the total annual cost, respectively. The major ownership cost item was depreciation on investment representing 27.57% of total annual cost. Hired labors was the highest operating cost item, representing 35.33% of total annual cost. The cost associated with producing juvenile spotted babylon is expressed as US$ per 1,000 juveniles (43.5 Thai Baht is approximately 1US$). The cost of producing 1,200,000 juveniles in this hatchery design was estimated at 6.09 US$ per 1,000 juveniles. However, as the total number of juveniles produced per year decreases, then cost increases. For example, if 426,996 juveniles (approximately 0.5% survival) are produced, utilizing the same level of inputs, the estimated cost of production increases to 18.29 USS per 1,000 juveniles. Estimated total annual cost for production of juveniles at selected survivals is presented in Table 5. At 1.5% survival in this study reveals the 13.8 US$ Baht breakeven price. Thereafter, gross return and net return at these levels are 17,677.6 US$ and 9,868.3 US$, respectively (Tables 6 and 7). Return to capital and management and return on investment at these levels are 12,365.8 US$ and 1.33, respectively (Tables 8 and 9). Under the basic assumptions in this study (juvenile production of 1.2 million/year), a selling price of 13.8 US$ per 1,000 juveniles results in a positive cash flow by year 2 (Table 10).

TABLE 9.

Return on investment for hatchery production of spotted babylon, *B. areolata*, juveniles at selected survival rates and selling prices.

Survival (%)	Selling Price (US$ per 1,000 Juveniles)				
	9.2	13.8	16.1	18.4	22.9
0.5	−0.15	0.06	0.17	0.27	0.48
1.0	0.27	0.69	0.91	1.12	1.53
1.5	0.69	1.33	1.64	1.96	2.58
2.0	1.11	1.96	2.38	2.80	3.63
2.5	1.54	2.59	3.12	3.65	4.68
3.0	1.96	3.22	3.85	4.49	5.73
4.0	2.80	4.49	5.34	6.18	7.83

Return on investment was calculated by dividing return to capital and management by initial capital investment (9,310.5 US$).

DISCUSSION

Based on juvenile production of 1.5% survival and selling price of 13.8 US$ per 1,000 juveniles, the culture system is economically feasible under the assumptions used. The cost of producing *B. areolata* postlarvae according to the procedures and assumptions outlined in this study is considerably higher when the survival is very poor. The stand-alone hatchery operation becomes profitable at output level of 1.2 million juveniles. Additional research needs to refine the lower limit of profitability and the nature of marginal costs (i.e., the change in variable costs with changes in output) within this range of facility sizes. An underlying assumption in this analysis shows that survival rate and market price are sensitive to farm output. However, potential investors must assess the impact to local market prices resulting from large production levels. The analysis assumes a constant market price, which may not be valid as the production volumes from large-scale operations are released onto the market. In general, prices are sensitive to changes in supplies. Prices decrease (increase) as spotted babylon landing increase (decrease). This relationship is not incorporated into the preceding analysis, which focuses primarily on cost changes as output levels vary. Investors in spotted babylon aquaculture should be aware of the potential negative effects on market prices as output levels increase. Costs presented in this study are based on limited available data. An economic analysis of a pilot hatchery production for spotted babylon would be commercially

TABLE 10.

Ten-year cash flow of a pilot hatchery production for spotted babylon, *B. areolata* juveniles.

Year	Variable Cost (US$)	Fixed Cost (US$)	Investment (US$)	Total Annual Cost (US$)	Receipt (US$)	Net Return (US$)	Cumulative (US$)
Year 1	5,311.8	2,497.5	9,310.5	17,119.8	17,677.6	9,868.3	−7,251.5
Year 2	5,311.8	2,497.5	0	7,809.3	17,677.6	9,868.3	2,616.8
Year 3	5,311.8	2,497.5	0	7,809.3	17,677.6	9,868.3	12,485.1
Year 4	5,311.8	2,497.5	0	7,809.3	17,677.6	9,868.3	22,353.4
Year 5	5,311.8	2,497.5	0	7,809.3	17,677.6	9,868.3	32,221.7
Year 6	5,311.8	2,497.5	0	7,809.3	17,677.6	9,868.3	42,090.0
Year 7	5,311.8	2,497.5	0	7,809.3	17,677.6	9,868.3	51,958.3
Year 8	5,311.8	2,497.5	0	7,809.3	17,677.6	9,868.3	61,826.6
Year 9	5,311.8	2,497.5	0	7,809.3	17,677.6	9,868.3	71,694.9
Year 10	5,311.8	2,497.5	0	7,809.3	17,677.6	9,868.3	81,563.2

Based on an annual production of 1.2 million juveniles per year and selling price of 13.8 US$ per 1,000 juveniles.

feasible at current selling price at survival rate of 1.5%, marginally feasible. This study serves as a guideline for understanding the economics of commercial juvenile production. Deviation from the hatchery specifications and management techniques of this study will likely result in altered costs. Costs can be lowered considerably by improving growth and survival rate. This economic analysis is intended as a guide and must be modified to reflect individual situations.

ACKNOWLEDGMENTS

We would like to thank National Research Council of Thailand (NRCT) for its support of the project and Professor Piamsak Menasveta and Associated Dr. Somkiat Piyatiratitivorakul for their advice and guidance. Last, we would like to thank Soonthorn Thepmoon, Siriwan Kathinmai, Mongkol Maklit, and Sailom Tantulvawit for their assistance during the hatchery work.

INCIDENTAL DAMAGE OF BLACKLIP ABALONE (*HALIOTIS RUBRA*) BY COMMERCIAL DIVERS IN NEW SOUTH WALES, AUSTRALIA

P. T. GIBSON,[1] D. G. WORTHINGTON,[1] C. BLOUNT,[1] AND N. L. ANDREW[2,]*
[1]New South Wales Fisheries, Cronulla Fisheries Centre, PO Box 21, Cronulla, NSW, 2230, Australia and [2]National Institute of Water and Atmospheric Research, P.O. Box 14-901, Kilbirnie, Wellington, New Zealand

ABSTRACT Rates of incidental damage to blacklip abalone (*Haliotis rubra*) were investigated in a retained, commercial catch in New South Wales, Australia. On average, 10.2% (8.9–11.6%, 95% CI) of retained abalone were damaged, but there was no relationship between the level of experience of divers and the degree or frequency of damage. Most damage was relatively minor, such as small abrasions to the foot or cuts to the mantle, and wounds healed rapidly in aquaria. Major damage, such as large cuts and abrasions to the foot, occurred in 4.2% (3.6–4.9%) of retained abalone. For individuals with major damage, any mortality was rapid and significantly greater than for undamaged abalone in aquaria. Rates of growth were also lower for individuals with major damage. An average of 19.1% (17.2–21.1%) of abalone removed from the reef were found to be under the minimum legal size and replaced. Experienced divers removed and replaced significantly fewer abalone under the minimum legal size (11% vs. 23.8% of those handled) than inexperienced divers. Using the estimated rates described here, approximately 40 tons of abalone are estimated to be damaged by the fishery each year. Most damaged abalone are retained, heal rapidly in aquaria, and can be exported live, but approximately 3 tons of damaged abalone (both retained and discarded) may die.

KEY WORDS: abalone, commercial fishing, damage, incidental, mortality

INTRODUCTION

Incidental damage to species not targeted by a fishery can be a substantial source of mortality (e.g., Broadhurst 2000). Damage to individuals of species that are targeted but subsequently found to be inappropriate for market also can be substantial (e.g., Blount & Worthington 2001). These types of mortality are most common in fisheries with nonselective collection methods (e.g., prawn trawls), or those with uncertainty about the quality or size of the product (e.g., sea urchin roe). Despite this, incidental mortality may be an issue in selective fisheries when a minimum size limit requires the handling of individuals (to identify their size) before they are retained. Damage and any consequent mortality to individuals 1) above the size limit and retained and 2) below the size limit and returned can be problematic in fisheries where most of the product is sent live to markets.

Compared with many other fisheries, commercial fishing for abalone in New South Wales (NSW) is relatively benign, with minimal direct impact on other species or on abalone not being targeted for collection. In NSW, divers use a blunt, chisel-shaped iron to remove individual abalone from the reef. Abalone are then quickly measured and, if larger than the size limit (115 mm in shell length, hereafter referred to as legal size), placed in bags that are sent to the surface for more controlled measuring. Any individuals that are removed from the rock, measured, and found to be below the size limit (hereafter referred to as undersized), either by the diver in the water or on the boat, are returned to the reef by hand. Although this process is relatively simple, the action of levering individuals off the bottom can result in cuts and abrasions to the foot of the abalone. Similarly, damage can occur during handling and storage of the catch on the boat before landing at processing factories.

There has recently been a major change in management of the NSW abalone fishery. Before 1995, each of the 37 shareholders was required to harvest the quota they owned, except in exceptional circumstances such as illness. This resulted in a group of shareholders that entered the fishery in the early 1970s and had collected abalone commercially for over 20 y. The change during 1995 enabled shareholders to nominate a diver to collect abalone on their behalf and, as a consequence, there was an influx of inexperienced divers. This change generated concern within the industry about the impact of increased rates of damage by inexperienced divers on populations of abalone. In addition, over the same time period, the fishery began to export live almost all abalone that were landed. This has also led to concern within the industry over the handling of abalone by divers and the rates of recovery of damaged abalone before export.

Different types of damage are likely to have different effects on abalone, ranging from decreased growth and reproduction to death. Even the slightest disturbance, such as tagging, has been known to reduce growth rates and, in some cases, increase mortality (McShane et al. 1986). There is also some evidence from aquaculture that suggests small disturbances may disrupt reproduction (our unpublished data). Abalone have no clotting agent in their blood, so that damage to the foot that severs any of the major arteries is likely to lead to death (Armstrong et al. 1971). Any type of injury may also inhibit their ability to feed or attach to the reef, leaving them more susceptible to predation (Pirker 1992). When disturbed, abalone also clamp down on the reef, making them considerably harder to remove, which may further increase the likelihood of damage.

In this article, we describe the frequency of different types of damage to abalone by commercial divers in NSW. We estimate rates of damage in the commercial catch and the number of abalone that are removed from the rock, measured, found to be undersized, and replaced. Finally, to investigate the possible effects of damage to abalone that are not retained, we estimated the rates of recovery, growth, and mortality of individuals with different types of damage when maintained in aquaria. This has implications for marketing because retained abalone are held in tanks at processing plants before export.

MATERIALS AND METHODS

Frequency of Damage by Commercial Divers

To estimate the frequency of different types of damage by commercial divers, a two-phase sampling design was used. First, divers' daily catches were haphazardly selected for sampling in commercial processing factories from August 1996–December 1997. An individual bin (holding 50–100 abalone) from the diver's catch was then randomly selected, and the length of all abalone within measured to the nearest mm and weighed to the nearest 5 g.

---

*Corresponding author. E-mail: gibsonp@fisheries.nsw.gov.au

Damage was categorized into several types and magnitudes based on injuries observed in the commercial catch. Categories (in order of increasing severity) were: no damage (ND), abrasions to the edge of the foot or mantle (MA), cuts to the edge of the foot or mantle (MC), small (<10 mm) abrasions to the foot (FA1), small (<10 mm) cuts to the foot (FC1), large (>10 mm) abrasions to the foot (FA2), large (>10 mm) cuts to the foot (FC2), and major breaks to the shell (BS). These categories were further grouped into minor damage (MA, MC, FA1) and major damage (FC1, FA2, FC2, BS), based on their likely effects on abalone. For the analyses presented here, individuals with more than one type of damage were categorized to the most severe grouping. Confidence limits were calculated using the binomial distribution, and a generalized logit model was used to relate the size of abalone to rates of minor and major damage (see Richards et al. 1994).

Although the sampling design described above provided detailed information on the frequency of damage, a second sampling design was used to provide less detailed but more comprehensive information. In this design, all abalone from all divers' daily catch supplied to one commercial processing factory were assessed for damage over a four month period (July to August 1999). Abalone were assessed as either damaged, not damaged, or dead. In total 68,900 abalone from 15 divers on 207 diver-days were assessed in this design, compared with only 9,732 in the first design. Although the second sampling design is more comprehensive than the first in terms of the absolute number of abalone sampled, it covers only a proportion of the year and only one major processing factory.

To estimate the rates of damage to abalone in the nonretained catch, information was collected on the frequency of removing, measuring, and replacing undersized abalone. Commercial divers were supplied with a logbook to record the number of undersized abalone removed and replaced and the number of legal-sized abalone retained in their first bag (divers retain harvested abalone in rope catch bags) of the day. Six commercial divers completed this logbook for a period of 15–30 days each between April–December 1999.

Recovery, Growth, and Mortality of Damaged Abalone

To investigate the effects of damage on individual abalone, two experiments were conducted in aquaria at a commercial processing factory. Experiment 1 began on 31 October 1996 and included 242 damaged abalone selected from the commercial catch. Replicate individuals from each damage category were placed in one of three randomly chosen aquaria. The number of replicate individuals within a damage category was related to the frequency of the category in the commercial catch supplied to the factory on that day (Table 1). Every two weeks, all individuals were briefly removed from the aquaria and any damage reassessed. A BS treatment was not included because individuals with this type of major damage were often dead before landing or were known to die rapidly thereafter.

In experiment 2, the effects of damage on growth were examined and the damage categories with the highest mortality in experiment 1 were further investigated. On 9 April 1997, at least 50 abalone from each of four damage categories (ND, FC1, FA2, and FC2) were selected at the factory from the commercial catch and placed in one of three randomly chosen aquaria (Table 1). Individuals were not disturbed throughout the six weeks of the experiment.

TABLE 1.

Number of abalone within each treatment of different types of damage, and within each tank for both the first and second experiments.

	Damage Category							
Tank	**ND**	**MA**	**MC**	**FA1**	**FC1**	**FA2**	**FC2**	**Total**
Experiment 1								
1	16	5	9	12	10	21	7	80
2	4	6	14	15	9	25	7	80
3	21	8	14	12	10	10	7	82
Total	41	19	37	39	29	56	21	242
Experiment 2								
1	17	—	—	—	17	17	19	70
2	17	—	—	—	16	16	19	68
3	17	—	—	—	17	17	18	69
Total	51	—	—	—	50	50	56	207

Damage categories in order of increasing severity, are no damage (ND), abrasions to the edge of the foot or mantle (MA), cuts to the edge of the foot or mantle (MC), small abrasions to the foot <10 mm (FA1), small cuts to the foot <10 mm (FC1), large abrasions to the foot >10 mm (FA2) and large cuts to the foot >10 mm (FC2).

All abalone used in both experiments were initially measured (i.e., maximum shell length, maximum shell width, and wet weight), and a small plastic tag was attached to the shell with glue. Each experiment lasted for six weeks, and the animals were fed fresh drift algae as required. The tanks were checked daily for dead abalone, which were removed immediately. In experiment 1, abalone were disturbed every two weeks to investigate recovery of their wounds. This disturbance may have affected growth, so in experiment 2, abalone were not disturbed and weighed at the end of the experiment to investigate growth. Results from both experiments were combined to investigate mortality.

RESULTS

Frequency of Damage by Commercial Divers

In total, 9,732 abalone from 29 divers on 123 days were examined for damage. On average, 10.2% (8.9–11.6%, 95% CI) of abalone retained by commercial divers were damaged. There was significant variation among divers in the rate of damage to abalone (t test of highest vs. lowest, $P < 0.05$). Total rates of damage varied among divers from 1–17% of abalone retained, with little relationship to the experience of divers ($R^2 < 0.1$, $P > 0.05$, Fig. 1). To some extent, this was caused by large variation in rates of damage among days for individual divers, with daily rates of total damage ranging from 1–30% of abalone retained, and an average coefficient of variation among days of 67%.

Most damage was relatively minor, occurring in 6.0% of abalone retained (5.2–6.9%, 95% CI), but some divers had significantly greater rates of major damage than others (t test of highest vs. lowest, $P < 0.05$, Fig. 1). For example, rates of minor damage varied among divers from 0–13%, and rates of major damage ranged from 0–12%. Major damage occurred in 4.2% (3.6–4.9%, 95% CI) of abalone retained. Again, there was no relationship between the rates of different types of damage and the experience

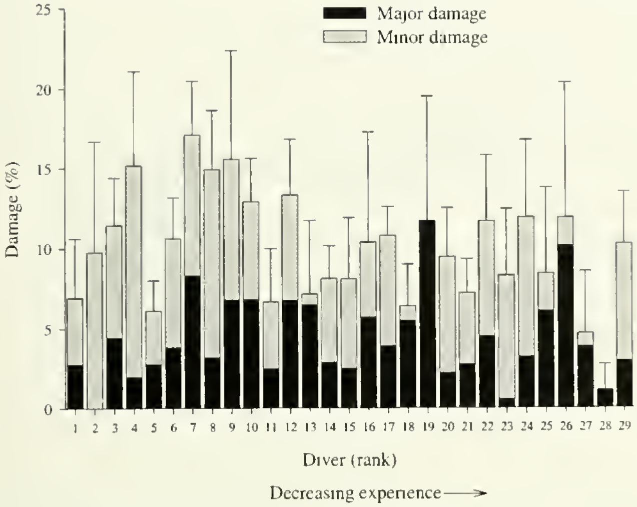

Figure 1. Number of abalone with major and minor damage as a percentage of all abalone sampled in the commercial catch of 29 divers. Error is 95% CI on total damage.

of divers (both $R^2 < 0.1$, $P > 0.05$). MA was the most common type of damage (3.7%) whereas FA2 (1.8%) was the most common type of major damage (Fig. 2). Rates of different types of damage varied greatly among divers and days. For example, rates of FC2 ranged among days from 0–8% and FA2 ranged from 0–16%. There was little relationship between the rates of different types of damage among days (all $R^2 < 0.07$, $P > 0.05$), but rates of damage were related to the size of abalone. Large abalone were more likely to be damaged than small ones (Fig. 3). For example, individuals of 115 mm were predicted to have rates of minor and major damage of 6.9% and 2.4%, whereas individuals of 140 mm were predicted to have rates of 9.1% and 4.7%, respectively.

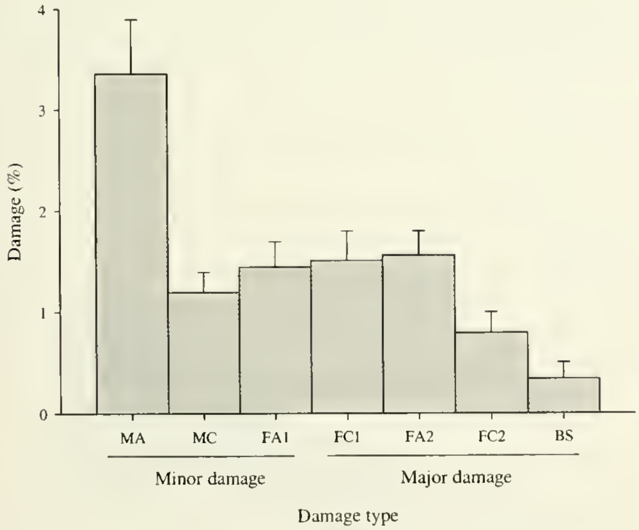

Figure 2. Number of abalone with different types of damage as a percentage (+95% CI) of all abalone sampled in the commercial catch. Damage categories were abrasions to the edge of the foot or mantle (MA), cuts to the edge of the foot or mantle (MC), small (<10 mm) abrasions to the foot (FA1), small (<10 mm) cuts to the foot (FC1), large (>10 mm) abrasions to the foot (FA2), large (>10 mm) cuts to the foot (FC2), and major breaks to the shell (BS).

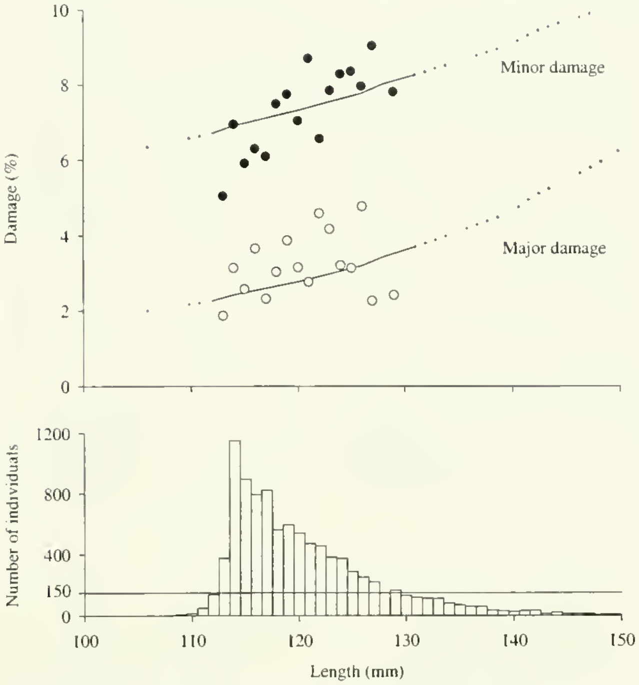

Figure 3. Top, number of abalone with major and minor damage as a percentage of all abalone sampled. Bottom, number of abalone sampled in each size class from the commercial catch in NSW. Percentage damage is shown for those size classes with more than 150 individuals. A generalized logit model was used to fit the solid line for size classes with more than 150 individuals and a dotted line for those size classes with less.

The second sampling design provided a significantly greater estimate (t test, $P < 0.05$) of the total rate of damage at 14.1% (12.6–15.8%, 95% CI). This included 0.7% (0.6–0.8%, 95% CI) of abalone that were dead at landing. Rates of total damage by individual divers ranged from 7–34% and were related to the size of the daily catch ($R^2 = 0.03$, $P < 0.05$). For example, at an average catch of 140 kg per day, predicted rates of damage were 12%, which was 4.5% lower than at a catch of 40 kg per day. Despite these differences, there was large variation in rates of damage for all catches, with a standard error of 9.4%.

On average, 19.1% (17.2–21.1%, 95% CI) of abalone removed from the reef were replaced. Rates of replacement varied among divers from 10–31%, with the two most experienced divers having significantly lower rates than others (i.e., 11.0% vs. 23.8%, t test, $P < 0.05$). There was large variation in rates of removal and replacement for individual divers, with daily rates ranging from 0–34% for the experienced divers and from 3–55% for the inexperienced, with an average coefficient of variation among days of 51%.

Recovery, Growth, and Mortality of Damaged Abalone

Recovery of wounds of abalone occurred rapidly, and at a similar rate among treatments. After 6 wk, there was no visible wound in 35.8% (30–42.0%, 95% CI) of previously damaged abalone, varying among treatments from 32–54% (Fig. 4). In addition, most remaining damaged abalone were recovering, so that after 6 wk only 21.3% (15.8–27.2%, 95% CI) of all abalone had failed to show any visible recovery. Abalone within the ND treatment remained undamaged throughout the experiment.

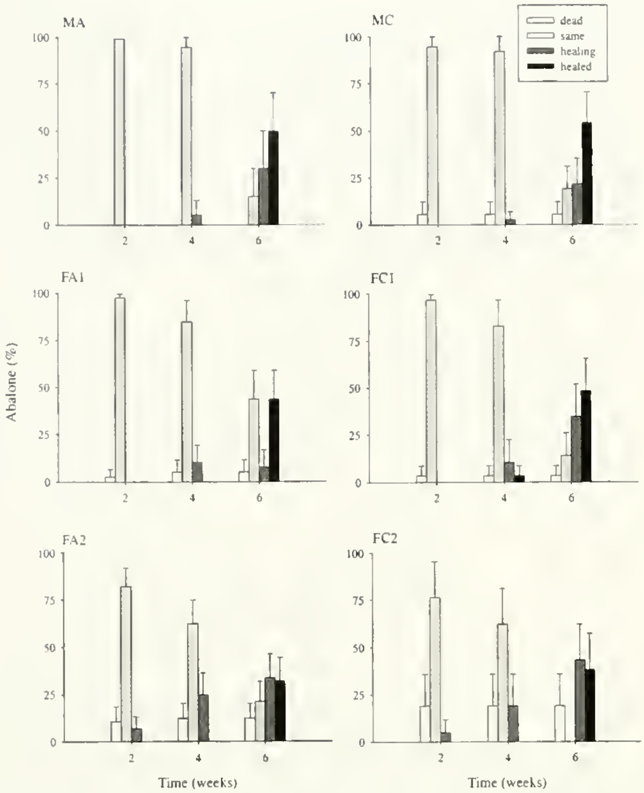

Figure 4. Number of abalone with different types of damage in four categories of wound progression over a 6-wk period, as a percentage (+95% CI) of the original number damaged. Damage categories were abrasions to the edge of the foot or mantle (MA), cuts to the edge of the foot or mantle (MC), small (<10 mm) abrasions to the foot (FA1), small (<10 mm) cuts to the foot (FC1), large (>10 mm) abrasions to the foot (FA2), and large (>10 mm) cuts to the foot (FC2).

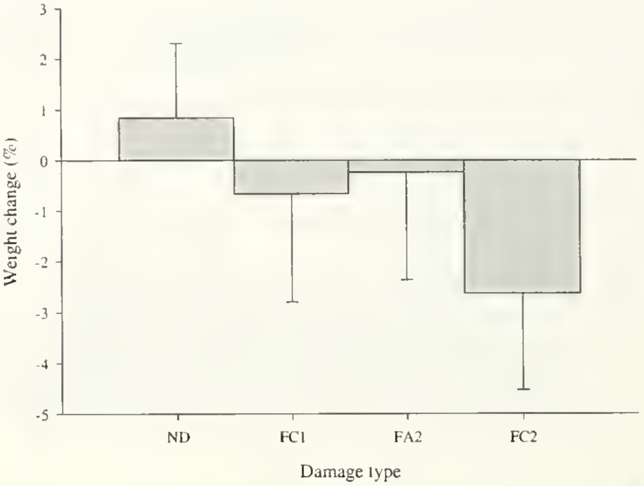

Figure 5. Change in weight as a percentage of original weight (+95% CI) for abalone with different types of damage after 6 weeks in experimental aquaria. Damage categories are no damage (ND), small (<10 mm) cuts to the foot (FC1), large (>10 mm) abrasions to the foot (FA2), and large (>10 mm) cuts to the foot (FC2).

Rates of growth of damaged abalone were significantly different among treatments (*t* test, FC2 vs. ND, $P < 0.05$). Individuals within the ND treatments increased their weight by 0.8% over the 6 wk of the experiment (Fig. 5). Within all other treatments, the average rate of growth was negative. Growth of individuals within the FC2 treatment was significantly less than ND (Fig. 5). The remaining treatments were not significantly different from ND (*t* tests, FA2 vs. ND, FC1 vs. ND, $P > 0.05$), but followed a consistent gradient of greater weight loss with increasing injury.

In experiment 1, rates of mortality of damaged abalone were significantly different among treatments after 6 wk in aquaria (Fig. 4). FC2 and FA2 caused the highest mortality of 19% (4.8–38.1%, 95% CI) and 12.5% (5.4–21.4%, 95% CI), respectively. The remaining treatments had much lower rates of mortality ranging from 0–5.1%. One individual within the ND treatment died (i.e., 2.4%), and 88% of all the mortality occurred in the first two weeks of the experiment. In experiment 2, results were similar, with generally lower rates of mortality. The highest mortality again occurred for FC2 with 14.3% (5.4–23.2%, 95% CI), whereas mortality in the other treatments ranged from 2–6%. One individual within the ND treatment died (i.e., 2%), and 79% of the mortality occurred in the first 2 wk of the experiment. When rates from both experiments were combined (Fig. 6), FC2 treatments caused the highest mortality averaging 15.6% (7.8–24.7%, 95% CI) followed by 8.5% for FA2 treatments (3.8–14.2%, 95% CI) and FC1 with 5.1% (1.3–10.1%, 95% CI). There was significantly greater mortality in the major damage treatments than ND ($\chi^2 = 5.25$, 1 df, $P < 0.05$). Most of this mortality was attributable to FC2 treatments, which were significantly greater than ND treatments ($\chi^2 = 9.84$, 1 df, $P < 0.01$) with all other comparisons not significant.

DISCUSSION

Frequency of Damage by Commercial Divers

Commercial divers damage a significant proportion of the abalone they retain in NSW. Most of the wounds are minor and heal quickly, but over 4% have major injuries that may affect their growth and survival (Fig. 2). Although rates of major damage were variable among divers and days, there was little apparent relationship to the experience of divers. Abalone size and size of the daily catch did explain some of the variation in rates of damage. The

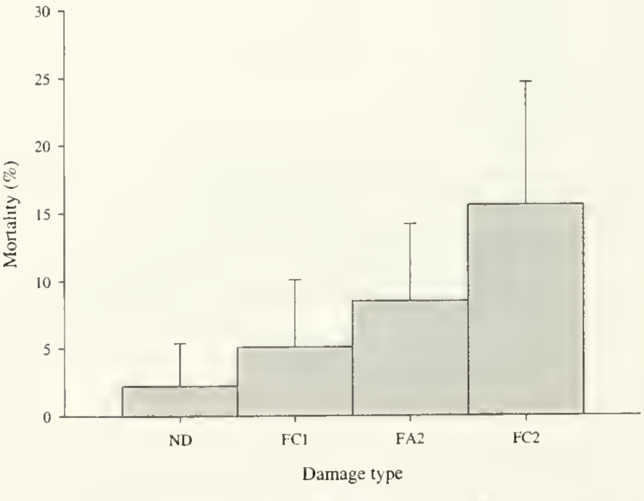

Figure 6. Mortality of abalone with different types of damage as a percentage (+95% CI) of the original number damaged after 6 wk in an experimental aquaria. Damage categories are no damage (ND), small (<10 mm) cuts to the foot (FC1), large (>10 mm) abrasions to the foot (FA2), and large (>10 mm) cuts to the foot (FC2).

rates of damage were greater for larger abalone and small daily catches, but this effect was small compared with variation among divers and among days for individual divers. Local wind and swell conditions are known to affect catch rates (Worthington et al. 1998) and are likely to influence rates of damage to abalone due to the difficulty of handling during harvesting and transport in strong winds and large swells.

The rate of damage in the commercial catch varied among divers from 1–17%, and averaged 10.2% (Fig. 1). Although the second sampling design provided a greater rate of damage (14.1%), it represented only one major processing factory over a small portion of the year. Rates of damage in NSW were considerably lower than those found for other abalone fisheries. Pirker (1992) found rates of damage between 44–78% in the commercial fishery for *Haliotis iris* in New Zealand, whereas Bruge et al. (1975) found rates above 90% in the recreational fishery for *H. rufescens* in California. Several differences among the fisheries may explain these differences. For example, in NSW a limited number of commercial divers use surface-supplied air and blunt irons to remove abalone from the reef. Perhaps most importantly, the NSW fishery exports most of the catch live and divers are encouraged by beach price to minimize the damage to their catch. Since this study was completed, further improvements in the handling of abalone by commercial divers have been made so that current rates of damage may be even lower. These include recirculating seawater-holding tanks on board fishing vessels, divers being encouraged by beach price to handle their catch appropriately, and an improved knowledge of handling techniques throughout the industry.

In contrast to the frequency of damage to retained abalone, the rate of removal and replacement of undersized abalone was related to the experience of divers. Experienced divers removed and replaced fewer undersized abalone. For a given catch of abalone, this would reduce the rate of damage caused by their removal. The lower rate of removal and replacement by experienced divers could be caused by a variety of factors. For example, more experienced divers may be able to identify undersized individuals or areas where there is little need to remove and measure individuals. Alternatively, less-experienced divers generally have lower catch rates and may be forced to work in times and places more experienced divers can avoid. Some populations are dominated by individuals who are close to legal size (Andrew et al. 1997) and fishing in these areas would require more measuring. Indeed, in some areas few, if any, individuals reach legal size (Worthington et al. 1995), and this can lead to inexperienced divers measuring large numbers of abalone to identify any individuals above the size limit. Damage to undersized individuals at these sites could be a substantial source of mortality (see also Tegner et al. 1989).

Recovery, Growth, and Mortality of Damaged Abalone

Rates of mortality and growth largely depended on the type of injury sustained. Damage to the foot that results in severing of any of the major arteries is likely to lead to death (Armstrong et al. 1971). Minor injuries can be controlled and repaired with the aid of muscle contractions (Armstrong et al. 1971). Within the aquaria, major damage resulted in mortality rates of up to 19% and reduced body weight (Figs. 5 and 6). Mortality rates and growth reduction may be much greater in the wild because of increased vulnerability to infection and predators (Bruge et al. 1975, Pirker 1992). For similar reasons, reductions in reproductive ability, such as reabsorption of eggs (observed when abalone are disturbed in aquaculture), may also be more intense in the wild.

Within aquaria, most mortality occurred within the first two weeks. Recovery of damaged abalone was rapid in aquaria, with most individuals completely recovered or recovering after six weeks (Fig. 4). These results confirm the usefulness of retaining damaged abalone within aquaria until their wounds have recovered and they are appropriate for live export. Most importantly, the rapid time for mortality or recovery is consistent with potential tanking times in the industry within NSW.

The estimated rates of damage and mortality can be used to estimate the total weight of abalone being damaged and killed each year by the fishery. During 2000, approximately 1 million abalones were retained and landed by the commercial fishery. With the estimated rate of removal and replacement of undersized abalone from this study (i.e., 19.1%), this suggests almost 1.2 million abalone were exposed to potential damage by being removed from the rock. At the observed rate of damage in the commercial catch (i.e., 10.2%), almost 120,000 individuals or approximately 40 tons may be damaged by the commercial fishery each year. Of these damaged abalone, approximately 8 tons are undersized and replaced on the reef, and the fishery retains 32 tons. Most of the damaged individuals probably recover rapidly but, even at the low rates of mortality likely in aquaria, the fishery may kill approximately 3 tons of abalone each year (i.e., 0.81% of those removed from the reef, estimated from rates of damage and mortality). Of this, approximately 500 kg are undersized abalone that are replaced, suggesting such mortality has a relatively minor impact on the productivity of the population. Furthermore, although many-damaged abalones that are replaced may survive, they are still likely to suffer complications, including reduced growth and lower reproduction.

Damage in the recreational and illegal abalone fisheries in NSW may also have important effects. For example, illegal fishers do not observe the minimum length limit and kill many undersized abalone. Many recreational fishers also handle and retain undersized abalone (unpublished data) with the potential for high rates of damage because they are not permitted to use scuba and generally have little experience removing abalone. Recreational divers often use unconventional tools to remove abalone, which may cause high rates of damage. During 1997, the recreational catch was estimated at 52 tons (unpublished data), when the commercial catch was over 330 tons. As a result, total rates of damage may be similar between the two sectors.

Early in the history of the commercial fishery for abalone in NSW there was no minimum legal size. In 1972, a minimum legal size was introduced at 100 mm, but most abalone were well above this size and almost all individuals removed from the rock were retained. With the progression of size limit upwards to the current 115 mm minimum legal size, and the decline in the size-structure of the population, more removal, measurement, and replacement of under-size abalone has occurred. Current management measures, such as temporal closures, attempt to minimize the disturbance and damage to abalone, particularly during reproductive season. Beach price incentives have also been developed by the industry to encourage the landing of undamaged individuals and to create an awareness of the damage to the resource caused by injuring abalone that are not retained. Incidental damage of undersized individuals in the NSW abalone fishery is small when compared with some other abalone fisheries, but could still be a significant source of mortality. This is obviously undesirable in an already heavily exploited fishery.

ACKNOWLEDGMENTS

The authors thank Rowan Chick, Penny Brett, Nokome Bentley, Greg Otton, Ross Werner, John Vairy, and the divers who participated with the logbook for their ongoing assistance. We also thank Southern Ocean Seafoods, NSW Abalone, and Australian Shellfish Enterprises for providing us with access to their factories and their abalone. We also thank Steve Kennelly and Doug Ferrell for reviewing the manuscript. The commercial abalone divers of NSW provided funding for this work.

THE EFFECT OF NONNUTRITIVE FILLERS ON THE DIGESTIBILITY OF A MANUFACTURED ABALONE DIET

MEEGAN E. VANDEPEER,[1]* PATRICK W. HONE,[2] JON N. HAVENHAND,[3] AND ROBERT J. VAN BARNEVELD[4]

Ltd., 19–27 Coonan Rd. South Maclean, Queensland, Australia 4280*

ABSTRACT In this study the effects on nutrient digestibility of adding nonnutritive fillers (kaolin, bentonite, sand and diatomaceous earth) to a research diet for greenlip abalone, *Haliotis laevigata* Donovan, were investigated. The addition of kaolin significantly improved the gross energy digestibility of the diet with the greatest improvement in gross energy digestibility occurring at the highest level of inclusion investigated (20%). Possible explanations for the positive effect of kaolin on nutrient digestion in abalone include assisting with the breakdown of diets through an abrasive/grinding effect, increasing gut transit time, decreasing digesta viscosity or through supplementation of minerals that may be deficient.

KEY WORDS: abalone, digestibility, kaolin, bentonite, sand, diatomaceous earth

INTRODUCTION

Silicates, more commonly known as bentonite, kaolin, zeolites and other clays, have been used in poultry and swine nutrition for many years (Dias et al. 1998). The reason for their inclusion is due to their binding and lubricating property in the production of pelleted feeds. There is also suggestion that some clay products may have direct beneficial effects on animal performance, however, results from studies aimed at establishing this have produced mixed results. Experiments with pigs, chickens and fish have shown responses ranging from increases in growth, feed efficiency and nutrient utilization (Kurnick & Reid 1960, Onagi 1966, Kondo & Wagai 1968, Quinsberry 1968, Han et al. 1975, Han et al. 1976, Smith et al. 1980) to negative or no responses (Reinitz 1983, Reinitz 1984, Dias et al. 1998).

Because kaolin contributes no protein or energy, it is regularly used as a filler in research diets for abalone at the South Australian Research and Development Institute's Aquatic Sciences Center. Since the addition of silicates, including kaolin, have been reported to improve nutrient utilization in other animals, it is important that its effects on nutrient digestion in abalone be investigated. The aim of this study is to assess whether four, nonnutritive, fillers (beach sand, diatomaceous earth, kaolin and sodium bentonite) affect the digestibility of a research diet for greenlip abalone, *Haliotis laevigata*.

MATERIALS AND METHODS

Diets

The basal diet used in all experiments was developed by the South Australian Research and Development Institute's Aquatic Sciences Center. The exact diet formulation is confidential; however, semolina constitutes the largest percentage of the diet followed by soy flour, which is the main source of protein. Chromic oxide was included in the diets at 0.5% by dry weight at the expense of semolina, as an indigestible marker for use in calculating the apparent protein and energy digestibility. All diets were initially hand mixed and then mixed in a spiral action dough mixer ('Impastrice', Hill Equipment and Refrigeration, Adelaide, South Australia). The mixture was then fed through a commercial pasta machine (La Prestigiosa medium, IPA, Vicenza, Italy) where it was made into 300 mm long strips using a die with slots 18 × 1.5 mm. The strips were dried on mesh trays overnight in a forced draft oven at 55°C.

Experiment 1—The Effect of Different Nonnutritive Fillers on the Protein and Energy Digestibility of a Manufactured Abalone Diet

Six diets were formulated in total, including the basal diet (Table 1). Four of the diets consisted of the basal diet with 5% of the semolina substituted for one of the following nonnutritive fillers: kaolin, bentonite, diatomaceous earth, and beach sand. The fifth diet contained 5% of pre-gelatinized waxy maize starch (Wades BO11C, Goodman Fielder Mills, NSW, Australia). The beach sand was obtained from West Beach, South Australia and was autoclaved at 121°C for 20 min before inclusion in the diet. The size of the sand grains ranged from around 192–346 μm. Each dietary treatment was randomly allocated to one of 18 digestibility tanks to provide three replicate fecal samples per diet.

Experiment 2—The Effect of Kaolin Inclusion Level on the Protein and Energy Digestibility of a Manufactured Abalone Diet

Six diets were formulated in total including the basal diet and the basal diet with 5% pre-gelatinized waxy maize as in experiment 1 (Table 2). The other four diets contained increasing levels of kaolin (5%, 10%, 15%, and 20%) again at the expense of semolina. The six diets were randomly allocated to one of 18 digestibility tanks to provide three replicate fecal samples per diet.

Abalone and Feeding

Juvenile greenlip abalone (shell length 40–60 mm) were used in the experiments. The abalone had been obtained from a commercial hatchery and raised on manufactured abalone feed. The abalone were preconditioned for one week on the test diet assigned to their tank. During both the pre-conditioning and experiment periods the animals were fed to excess every day at approximately 1700 h.

* diatomaceous earth.

Tanks and Collection System

Conical shaped digestibility tanks were used. Abalone were housed in 20-L buckets (approximately 80–100 per bucket) that fitted inside the tanks. All the buckets were fitted with plastic mesh bottoms (1.3 cm × 1.5 cm mesh) allowing containment of the abalone while permitting feces to drop into the collection tube at the base of the tank. Three 25 cm lengths of PVC pipe (8 cm in diameter) were placed in the buckets as shelters for the abalone. Attached to the bottom of each digestibility tank was a screw-on collection tube (11 cm long, 15 mm diameter). Tanks were on a flow-through water system at a rate of about 2 L/min. The seawater was filtered to 30 μm by primary sand filters, then to 10 μm by secondary composite sand filters before entering the tanks. Aeration was supplied at 0.5 L/min to each tank at all times by an air stone. Water temperature and lighting were controlled during the experiment with temperature maintained at 18.0°C ± 1.0 and a light regimen of 12 h light: 12 h dark. Salinity was 35–36‰ throughout the experiment.

Fecal Collection

Feces were collected by settlement every day until 5–6 g of feces (dry weight) was collected for each replicate sample. This took approximately 2 wk for each replicate. On each day of fecal collection the buckets containing the abalone were removed and the digestibility tanks were drained of water and all fittings were cleaned of feces and uneaten feed. Following cleaning, the tanks were refilled and the buckets replaced. Collection tubes were fitted by 0900 h. A small foam container was placed underneath each tube and filled with ice to keep the collecting feces cold and thus reduce its degradation by microbes. The feces were collected from the tubes at about 1630 h by gently pouring the contents onto a 1 mm diameter mesh. The mesh was then placed into a petri dish and frozen at −30°C. The following day the frozen fecal sample was scraped off the mesh, pooled into a composite sample, and stored in the freezer until required for analysis. Prior to analysis the samples were freeze-dried and ground with a mortar and pestle.

Chemical Analyses

Dry matter was determined by drying samples at 100°C overnight until a constant weight was achieved. Gross energy was determined using a Parr 1281 bomb calorimeter. Crude protein was determined by the combustion method using a LECO® CN-2000 Carbon and Nitrogen Analyser (Royal Australian Chemical Institute 1999). Chromic oxide was determined using atomic absorption spectroscopy based on a modification of the methods described by Hillebrand et al. (1953). The modified methodology involved preliminary ignition of the sample at 500°C to remove organic material and the dissolution of the sample in hydrochloric acid instead of sulphuric acid (M. Frith, personal communication, University of Tasmania, Launceston, Australia).

Digestibility Determination

The apparent digestibilities of nutrients in the diets were calculated using the following formula (Hardy 1997):

$$\text{Apparent digestibility} = 1 - \left(\frac{Cr_{diet} \times Nutrient_{feces}}{Cr_{feces} \times Nutrient_{diet}}\right)$$

where *Cr* is chromium content and *Nutrient* is nutrient or energy content of the diet.

Statistical Analysis

The data were analyzed by use of general linear model and the treatment means were compared by least significant difference. Prior to analysis, data were analyzed using a univariate procedure and normal plots to establish that the data were in fact normally distributed, which was the case. The presence of outliers was assessed using the RANK procedure in SAS (SAS Institute Inc., 1988) and normal scores computed from the ranks following Blom (1958). As no outliers were detected using the RANK procedure, all data were used in the calculation of digestibility estimates for all parameters, respectively.

RESULTS

Experiment 1—The Effect of Different Nonnutritive Fillers on the Protein and Energy Digestibility of a Manufactured Abalone Diet

Although very close, no significant difference was found among the six diets in their apparent protein digestibility for abalone at the 0.05 significance level ($F_{5,10}$ = 2.76; P = 0.0804) (Table 3). However, the diets were significantly different at the 0.10 significances level. This was entirely due to the 5% bentonite diet having significantly lower apparent protein digestibility than all the other diets. A significant difference was observed in the apparent dry matter digestibility ($F_{5,10}$ = 6.93; P = 0.0048) and

TABLE 2.

Composition, proximate analysis and gross energy content (MJ/kg) of experimental diets from experiment 2 (g/kg, air dry basis)

	Basal Diet	5% Starch	5% Kaolin	10% Kaolin	15% Kaolin	20% Kaolin
Basal diet	995.0	945.0	945.0	895.0	845.0	695.0

Gross energy (MJ/kg)	17.65	17.74	16.87	15.97	15.11	14.21
Crude protein (N × 6.25)	315.3	308.1	310.3	302.2	297.2	291.3
Dry matter	914.7	920.6	924.9	928.0	936.7	940.7

apparent gross energy digestibility of the diets ($F_{5,10} = 3.29$, $P = 0.0516$) (Table 3). The diet containing 5% starch had significantly higher apparent dry matter digestibility than all the other diets (Table 3). No significant differences in dry matter digestibility occurred among the diets with fillers and the control diet (Table 3). The diet with 5% starch had significantly higher apparent gross energy digestibility than all the other diets, excluding the kaolin diet (Table 3). There was no significant difference in apparent gross energy digestibility among the control, bentonite, diatomaceous earth and sand diets. Similarly, there was no significant difference in apparent gross energy digestibility among the kaolin, bentonite, diatomaceous earth and sand diets, but the kaolin diet did have significantly higher apparent gross energy digestibility than the control diet (Table 3).

Experiment 2—The Effect of Kaolin Inclusion Level on the Protein and Energy Digestibility of a Manufactured Abalone Diet

The digestibility coefficients for the control diet and that with 5% starch were comparable with those from experiment 1 (Table 3 and Table 4). No significant difference in protein digestibility occurred among the six diets in experiment 2 ($F_{5,10} = 1.41$, $P = 0.3017$) but there were significant differences among the diets in apparent gross energy ($F_{5,10} = 18.99$, $P = 0.0001$) and dry matter digestibility ($F_{5,10} = 8.56$, $P = 0.0022$) (Table 4). The diet with 5% starch had significantly higher apparent dry matter digestibility than all the other diets (Table 4). The diet with 10% kaolin had significantly higher dry matter digestibility than the control diet, but not the other kaolin diets. Apparent gross energy digestibility significantly increased with increasing level of kaolin in the diet (Table 4). The diet with 20% kaolin had significantly higher gross energy digestibility than all other diets (Table 4).

DISCUSSION

Substitution of semolina with kaolin in a manufactured diet for juvenile greenlip abalone increased the apparent digestibility of its gross energy. The gross energy digestibility of the manufactured diet significantly increased with increasing inclusion level of kaolin (Table 4). Unlike kaolin, the addition of other inert fillers (sand, bentonite and diatomaceous earth) did not significantly improve abalone's apparent gross energy digestibility of the diet when included at 5% (Table 3). It is possible that these fillers may improve the apparent gross energy digestibility if included in diets at higher levels.

The improved digestibility/growth rates observed in other animals fed diets supplemented with inert fillers such as kaolin, may have resulted, singly or in combination, from their assisting with the breakdown of diets through an abrasive/grinding effect, increasing gut transit time and through supplementation of minerals that may be deficient. Any of these mechanisms could also explain why kaolin significantly improved the gross energy digestibility of a commercial diet for juvenile abalone. Two other possible mecha-

nisms are its reducing digesta viscosity and osmotic pressure in the lumen.

Reduction in Osmotic Pressure in the Lumen

The increase in apparent gross energy digestibility of diets with the increased level of kaolin could be related to the unusual oligosaccharides in soyflour, the second largest component of the diet in this study. Pedersen (1989) suggested that the post-weaning diarrhea found in piglets fed soy-based diets might not be due solely to an allergic reaction elicited by soy antigens, but to the soy's oligosaccharides. The accumulation of these components in the intestine not only provides a substrate for the growth of undesirable bacteria, but also could lead to an "osmotic" diarrhea that occurs when body fluid is drawn into the lumen of the gut to counter a raised osmotic pressure (Pedersen 1989). Soyflour may possibly produce the same response in the gut of abalone. The positive effect kaolin had might be related to its ability to counteract this osmotic diarrhea caused by soyflour and thus increase the digestibility of dietary nutrients. Evidence for this is that the addition of zeolites (alumino-silicates) to piglet diets has been found to reduce diarrhea. Inclusion of zeolite to the diet of piglets severely affected with scours (prolonged diarrhea in livestock) markedly reversed the progress of this disease within a few days (Morita 1967). Similarly, the incidence of scours in young swine fed a diet supplemented with 5% clinoptilolite was significantly reduced (England 1975). Zeolites are characterized by their ability to lose and gain water reversibly and by a very effective ion exchange capacity (Mumpton & Fishman 1977, White & Ohlrogge 1974). It is these properties of zeolites (ion exchange and reversible binding of water) that could have reduced diarrhea in piglets when added to their diet. Kaolin, also an alumino-silicate, could have had the same effect in the gut of abalone resulting in the increased gross energy digestibility of the diet.

Abrasive or Grinding Effect

Kaolin may perform a similar function to sand and grit that abalone ingest while feeding on their natural diet, assisting in grinding up and breakdown of food. Insoluble grit given to chickens remains in their gizzard and assists in grinding, crushing and breaking up food particles (Bruce 1976). Silt is believed to have a similar effect in the style sac of mussels (Murken 1976). Sand and grit, which may have a grinding effect in the gut, is taken in by wild abalone when they feed on their natural diet algae. In the wild, abalone consume algae by either catching it as it drifts past or by grazing it off rocks. When they graze rocks, they also take in sand and other sediments. The fine sand and grit can be seen in their intestine when dissected. A study on the composition of food in the stomachs of wild *H. laevigata*, *H. rubra* and *H. roei* (Shepherd 1973) revealed algae, and other browsed matter, including sand grains, small gastropods, bryozoa and detrital matter. The stomachs of *H. laevigata* and *H. scalaris* also contained quartz sand (Shepherd & Cannon 1988). Kaolin contains approximately 46.3% silica (Reis 1908). Like sand, silica may have an abrasive/grinding action in the gut of abalone. However, the mechanism that kaolin improves digestion in abalone through its grinding effect in the abalone's gizzard implies that the addition of sand, bentonite and diatomaceous earth would be expected to increase their digestibility. Therefore, it does not seem likely that a grinding effect of kaolin caused the increase in digestibility observed in this present study.

Supplementation of Minerals

It is possible kaolin is not nonnutritive but is actually supplying essential minerals that abalone require but that are deficient in manufactured diets. Deshimaru and Kuroki (1974), using a semi-purified diet, found that mineral rich diets (as high as 19.5% ash) produced the best growth of *Penaeus japonicus*. Similarly, Wheeler and Oltjen (1977) reported faster daily weight gains, feed conversion efficiency and carcass quality in finishing steers fed a corn and hay ration containing 8% protein and 3.5% cement kiln dust to replace trace minerals, than in control animals receiving an otherwise similar diet containing 12% protein plus trace minerals. They speculated that the cement kiln dust may have provided hitherto unknown but necessary trace minerals. Also, increasing levels of bentonite in a high roughage ration for steers reduced the retention of dietary calcium but increased the retention of phosphorous (Martin et al. 1969). Thus kaolin may have provided minerals essential for certain enzyme systems and biochemical functions involved in digestion in abalone but lacking in the diet used in this study.

Alteration of Gut Transport Time

It is possible that kaolin increases digestion in abalone by altering gut transport time. Increased gut transport time can increase digestibility, because the food is exposed for a longer time to digestive enzymes. The improved caloric efficiency by the addition of kaolin to poultry diets as observed by Osterhaut (1967), was due possibly to a slowing down of the rate of feed passage through the intestinal tract (Quinsberry 1968). Kurnick and Reid (1960), in their study of the effect of the addition of bentonite to 3 diets differing in energy levels for Leghorn cockerels, observed a significant increase in growth rate with the feeding of 2.5% bentonite to the low energy level diet. For each diet, the feeding of bentonite in the diet slightly delayed the passage of feed through the digestive tract. Similarly, by testing the effect of inclusion of silica, cellulose and chabamin at 10% and 20% in diets for European seabass juveniles Dias et al. (1998) observed that in fish fed the control diet, the totality of the feces was expelled after 31 h, whereas in those fed with 20% bulk incorporated diets, fecal egestion continued over 35 h. By contrast, however, Grove et al. (1978) reported that the gastric evacuation time in rainbow trout was reduced from 15 h to 10 h when the energy content of the feed pellet was reduced by 50% by dilution with kaolin.

In the wild, herbivores, such as abalone, eat macrophytes, which are low in digestibility and possess high levels of indigestible materials that pass rapidly through the gut (Wee 1992). Their relatively long guts increase retention time and allow enzymes to work on the ingested material to optimize nutrient extraction and absorption. Wild abalone take approximately 24 h to digest preferred species of algae and species less digestible may remain identifiable in abalone guts for more than 48 h (Foale & Day 1992, Day & Cook 1995). The addition of indigestible kaolin to the diet may have affected transit time in a manner similar to that of poorly digestible algal species that remain in the gut for a longer period of time, thereby increasing exposure to digestive enzymes. The digesta transit times of the diets in this study were not measured and thus cannot be compared, however, an increase in transit time caused by the addition of kaolin can not be ruled out as a possible mechanism for the increase in energy digestibility of the diet.

Reduction in Diet Viscosity

Kaolin may have increased the gross energy digestibility of the commercial diet by reducing its viscosity and hence increasing access to it by digestive enzymes. The basal diet used in this study consisted mainly of semolina and soyflour. It is well known, particularly for poultry, that soluble polysaccharide (fiber), such as arabinoxylans in wheat (semolina) and β-glucans in barley and oats elicit negative effects on digestion through increasing intestinal viscosity (Annison 1990, Bedford et al. 1991, Choct & Annison 1992, Annison 1993, Choct et al. 1996, Dusel et al. 1997). High gut viscosity decreases the rate of diffusion of substrates and digestive enzymes and hinders their effective interaction at the mucosal surface (Choct 1997). The viscous polysaccharides probably complex directly with digestive enzymes and reduce their activity (Ikeda & Kusano 1983). As with poultry, non-starch polysaccharides in wheat may also elicit negative effects on digestion in abalone through increasing intestinal viscosity. Therefore, the significant improvement in digestion by the addition of kaolin may be because it decreases intestinal viscosity.

If kaolin did increase the digestibility in abalone by decreasing the diet's viscosity, the fact that other fillers used (bentonite, diatomaceous earth and sand) had no effect on its digestibility may be due to their physical/chemical properties. The contradictory results of the effects of nonnutritive fillers incorporation on feed evacuation time in fish are, in some cases, related to the different physico-chemical properties of the various bulk agents tested (Dias et al. 1998). The properties, such as ion binding or water holding capacity, have a strong influence on solubility, gelling and viscosity of food during its passage through the intestinal tract. The phenomenon of gelation caused by polysaccharides is because they are hydrophylic molecules and consequently have the ability to hold water. Kaolin is hydrophilic, disperses in water readily, is non-expanding, has low viscosity, low sorptivity, and a low surface charge (Murray 1993). Thus, it may reduce viscosity caused by soluble polysaccharides in diets by binding with water and reducing the polysaccharide's gelation ability. The same did not occur with the other fillers and this may be due to their different chemical properties. For example, bentonite, albeit hydrophilic, has high viscosity, high sorptivity, is expanding, and has a high surface charge (Murray 1993). The effect of nonnutritive fillers seems related to their physico-chemical properties and properties of other ingredients in the diet. Thus, the positive effect of kaolin on digestibility may have been related to the basal ingredients in the diets and it may not have a positive effect on diets with different basal ingredients.

THE DIGESTIBILITY OF WHOLE AND DEHULLED LUPINS *(LUPINUS ANGUSTIFOLIUS)* FED TO JUVENILE GREENLIP ABALONE, *HALIOTIS LAEVIGATA*

MEEGAN E. VANDEPEER,[1] PATRICK W. HONE,[2] JON N. HAVENHAND,[3] AND ROBERT J. VAN BARNEVELD[4]

[1]South Australian Research and Development Institute, PO Box 120, Henley Beach, South Australia 5022; [2]Fisheries Research and Development Corporation, PO Box 222, Deakin West, Australian Capital Territory 2600; [3]Flinders University, GPO Box 2100, Adelaide, South Australia 5001; [4]Barneveld Nutrition Pty. Ltd., 19–27 Coonan Road, South Maclean, Queensland, Australia 4280

ABSTRACT The apparent digestibility of protein, amino acids, and gross energy from whole and dehulled lupins (*Lupinus angustifolius*) and defatted soyflour was investigated for greenlip abalone, *Haliotis laevigata* Donovan. Protein digestibility of all three feedstuffs was high with a coefficient of 0.91 obtained for soyflour and whole lupins and a coefficient of 0.92 obtained for dehulled lupins. Gross energy digestibility was much more variable with the energy from soyflour being significantly more digestible (coefficient of 0.87) than that from dehulled lupins (coefficient of 0.83), which was significantly more digestible than the energy from whole lupins (coefficient of 0.50). The significantly lower energy digestibility of the whole lupins compared with the dehulled lupins could possibly be due to abalone's poor ability to digest cellulose, which is the major component of the hull of *L. angustifolius*.

KEY WORDS: abalone, digestibility, lupins, *Lupinus angustifolius, Haliotis laevigata*

INTRODUCTION

In Australia, lupins, in particular the species *Lupinus angustifolius*, are used as a source of dietary protein and energy for both pigs and poultry. *L. angustifolius* has protein levels ranging from 271.9 to 372.3 g/kg and a gross energy content of 17.9–18.6 MJ/kg (Petterson et al. 1997). Lupins are an attractive feedstuff for use in animal diets, as selective breeding programs have produced varieties of lupins with low concentrations of anti-nutritive factors such as alkaloids (Annison et al. 1996).

Successful results have been obtained on incorporation of *L. angustifolius* in manufactured diets for a range of aquaculture species including juvenile prawns, silver perch, snapper, carp, gilthead seabream and rainbow trout (Jenkins et al. 1994, Viola 1988, Robaina et al. 1995, Gomes et al. 1995, Smith et al. 1998, Allan et al. 1998). Jenkins et al. (1994) found no significant differences in growth rates of snapper when fed balanced diets containing either 20% soybean meal, 15% *L. angustifolius* seed meal plus 13% soybean or 28% *L. angustifolius* seed meal. Similarly, excellent results *with L. angustifolius* have been found for carp. Growth of carp fed a diet containing 30% lupins exceeded that of a control diet by 25% while carp fed a diet containing 45% lupins grew at the same rate as those on the control diet (Viola et al. 1988). Robaina et al. (1995) found no significant difference in weight gain, protein efficiency ratio and feed efficiency between gilthead seabream (*Sparus aurata*) fed a fishmeal based control diet and a control diet with 30% of the fishmeal protein replaced by *L. angustifolius* as a source of protein. Positive results have also been reported for prawns with no significant differences in daily growth rate, feed intake, feed conversion rate, protein conversion efficiency or apparent protein utilization of *P. monodon* when fed diets containing either dehulled *L. angustifolius* or deffated soybean meal as the main source of protein (Sudaryono et al. 1999).

This study was undertaken to determine the apparent digestibility of protein, amino acids and gross energy from the lupin, *Lupinus angustifolius,* for greenlip abalone, *Haliotis laevigata.* A potential problem that could affect abalone's ability to digest energy from *L. angustifolius* is the large proportion of cellulose in its hull. To investigate this the digestibility of both whole and dehulled *L. angustifolius* for abalone was determined.

MATERIALS AND METHODS

Diets

Two lupin diets, one containing whole, and the other containing dehulled *L. angustifolius,* were formulated (Table 1). A diet containing defatted soyflour was formulated as a control diet for comparative purposes ("Bakers Nutrisoy" brand; Archer Daniels Midland Company, Decatur, Illinois). Each feedstuff was the sole source of protein in the diet and each diet was formulated to have a crude protein content of 160 g/kg. The lupins were ground in a hammer mill and then in a ball mill before inclusion in the diets. Equal amounts of vitamins and minerals, as described by Uki et al. (1985), Jack Mackerel oil (Triabunna Fish Oils, Triabunna, Tasmania), and pre-gelatinized maize starch were added to each diet. Kaolin was included as filler and chromic oxide was included as an indigestible marker (0.5%) for use in digestibility calculations. Shipton and Britz (2001) found that chromic oxide was a suitable marker in protein digestibility studies on *Haliotis midae* as it was inert, was not absorbed, did not interfere with the digestive process, and moved through the intestine at a similar rate to the protein. Proximate analyses of the experimental diets and of each feedstuff were determined (Table 2 and Table 3).

Diet Allocations

The three diets were randomly allocated to 4 of 12 digestibility tanks to provide four replicate fecal samples per diet based on a completely randomized design.

Abalone Feeding and Fecal Collection

Abalone and Feeding

Juvenile greenlip abalone (shell length 40–60 mm, 70 g wet weight) were used in the experiment. The abalone had been obtained from a commercial hatchery and raised on manufactured abalone feed. The abalone were preconditioned for one week on

Lysine	8.20	7.50	4.80

the test diet assigned to their tank. During both the preconditioning and experimental periods the animals were fed to excess every day at approximately 1700 h.

Tanks and Collection System

Conical shaped digestibility tanks were used. Abalone were housed in 20-L buckets (approximately 80–100 per bucket) that fitted inside the tanks. All the buckets were fitted with plastic mesh bottoms (1.3 × 1.5 cm mesh) allowing containment of the abalone while permitting feces to drop into the collection tube at the base of the tank. Three 25-cm lengths of PVC pipe (8 cm in diameter) were placed in the buckets as shelters for the abalone. Attached to the bottom of each digestibility tank was a screw-on collection tube (11 cm long, 15 mm diameter). Tanks were on a flow-through water system at a rate of about 2 L/min. The seawater was filtered to 30 μm by primary sand filters, then to 10 μm by secondary composite sand filters before entering the tanks. Aeration was supplied at 0.5 L/min to each tank at all times by an air stone. Water temperature and lighting were controlled during the experiment with temperature maintained at 18.0°C ± 1.0 and a light regimen of 12 h light: 12 h dark regimen. Salinity was 35–36‰ throughout the experiment

Fecal Collection

Fecal collection occurred every day until 6–10 g (dry weight) of feces was collected for each replicate sample. This took 22 days in total. On each day of fecal collection the buckets containing the abalone were removed and the digestibility tanks were drained of water and all fittings were cleaned of feces and uneaten feed. Abalone were out of water for about 1 to 2 min. Following cleaning, the tanks were refilled and the buckets replaced. Collection tubes were fitted by 0900 h A small foam container was placed underneath each tube and filled with ice to keep the collecting feces cold and thus reduce degradation by microbial action. The feces were collected from the tubes at about 1630 h by gently pouring the contents onto a 1 mm mesh. The mesh was then placed into a petri dish and frozen at −30°C. The following day the frozen fecal sample was scraped off the mesh, pooled into a composite sample, and replaced into the freezer until required for analysis. Prior to analysis the samples were freeze-dried and ground with a mortar and pestle.

Chemical Analyses

Chemical analysis for proximates (i.e., dry matter, ash, ether extract, neutral-detergent fiber, acid-detergent fiber, and crude fiber) were undertaken using the methods of the Association of Official Analytical Chemists (1984). Gross energy was determined using a Parr 1281 bomb calorimeter. Proteins were analyzed by the combustion method using a LECO® CN-2000 Carbon and Nitrogen Analyser (Royal Australian Chemical Institute 1999).

All amino acids were determined by the Water's PICOTAG amino acid analysis method (Sarwar et al. 1988) using pre-column phenylisothiocyanate (PITC) derivitization and liquid chromatography was used for the determination of all amino acids. Protein sources were hydrolyzed for 22 h in duplicate with 6 N HCL at 110°C for the determination of all amino acids, except for methionine and cystine. Hydrolysates for the determination of methionine as methionine sulfone and cystine as cysteic acid were prepared by performic acid oxidation of the protein prior to hydrolysis using 6 N HCL. Alpha-aminobutyric acid was used as an internal standard.

Chromic oxide was determined using atomic absorption spectroscopy based on a modification of Hillebrand et al.'s (1953) method. The modified method involved preliminary ignition of the sample at 500°C to remove organic material and the dissolution of the sample in hydrochloric acid instead of sulphuric acid (M. Frith,

personal communication, University of Tasmania, Launceston, Australia).

Digestibility Determination

The apparent digestibilities of nutrients in the diets were calculated using the following formula (Hardy 1997):

$$\text{Apparent digestibility} = 1 - \left(\frac{Cr_{diet} \times Nutrient_{feces}}{Cr_{feces} \times Nutrient_{diet}}\right)$$

where Cr is chromium content and *Nutrient* is nutrient or energy content of the diet.

The digestibility of gross energy for each ingredient was calculated by subtracting the amount of digestible energy contributed from the oil, sodium alginate and pre-gelatinized starch in each diet.

Statistical Analysis

The data were analyzed by a general linear model and the treatment means were compared by least significant difference. Prior to analysis, data were analyzed using a univariate procedure and normal plots to establish that the data were in fact normally distributed, as was the case. The presence of outliers was assessed using the RANK procedure in SAS (SAS Institute Inc., 1988) and normal scores computed from the ranks following Blom (1958). As no outliers were detected using the RANK procedure, all data were used in the calculation of digestibility estimates for all parameters, respectively.

RESULTS

A significant difference was found among the lupins and soyflour in abalone's digestibility of protein ($F_{2,6} = 17.22$, $P = 0.0033$), gross energy ($F_{2,6} = 1340.96$, $P = 0.0001$), arginine ($F_{2,6} = 7.24$, $P = 0.0251$), proline ($F_{2,6} = 10.87$, $P = 0.0101$), methionine ($F_{2,6} = 9.16$, $P = 0.0150$) and isoleucine ($F_{2,6} = 18.94$, $P = 0.0026$) (Table 4).

Dehulled lupins had significantly higher apparent gross energy digestibility for abalone than whole lupins, but had significantly lower gross energy digestibility for abalone than soyflour (Table 4). The protein from dehulled lupins was significantly more digestible than that from either whole lupins or soyflour (Table 4).

DISCUSSION

Dehulling significantly improves abalone's digestibility of energy from *L. angustifolius*. The low gross energy digestibility of whole *L. angustifolius* seeds and the significant increase in gross energy digestibility of dehulled compared with whole *L. angustifolius* has also been observed for other aquacultured species. For example, the gross energy digestibility increased from 45–74% for juvenile *P. monodon* (Smith et al. 1998) and from 59.4–74% for silver perch (*Bidyanus bidyanus*) (Allan et al. 1998) by use of dehulled as against whole *L. angustifolius* lupins.

The abalone's significantly lower digestibility of energy from whole compared with dehulled *L. angustifolius* indicates it has a poor capacity to digest the cellulose in lupins. Cellulose constitutes approximately 57.3–58.4% of the hull of *L. angustifolius* (Evans & Cheung, 1993) and thus is likely to be cause of abalone's poor gross energy digestibility of whole *L. angustifolius*. Indeed, Uki et al. (1985) demonstrated that the growth rate of *Haliotis discus hannai* decreased as the cellulose content of the diet increased from 0–20% and concluded that abalone must have a poor capacity for digesting it.

Some may expect that abalone should be able to digest cellulose, given that it forms the structural basis of many algae, their natural diet (McCandless 1985) and cellulase activity has been documented for a number of *Haliotis* spp. (Gianfreda et al. 1979, Elyakova et al. 1981, Boyen et al. 1990, Gomez–Pinchetti & Garcia–Reina 1993). A complication in interpretation of those results is that despite many studies, the origin of the cellulose activity in abalone is inconclusive. This is because most studies have not identified whether the cellulase was of microbial origin. Erasmus (1997) was the first to demonstrate that abalone possess a cellulase by detecting the presence of carboxymethylcellulase in gnotobiotic *H. midae*. Erasmus (1997) suggested that this cellulase was most likely to have been poly-β-glucanase, which hydrolyzes carboxymethylcellulose. Whether abalone possess the other two cellulases required to hydrolyze cellulose remains to be confirmed. The substrate carboxymethylcellulose does not require a true cellulase for hydrolysis. Erasmus et al. (1997) hypothesized that bacteria possibly secrete a true cellulase to completely degrade cellulose and abalone only partially hydrolyze the substrate. This hypothesis was supported by Enriquez et al. (2000) who examined the *in vitro* digestion of pure cellulose (alphacel) using stomach extracts from *Haliotis fulgens* and reported that bacteria play an important role in cellulose digestion in abalone, as stomach ex-

tracts showed significantly decreased cellulolytic activity in the presence of antibiotics.

A factor to consider when evaluating abalone's ability to digest cellulose based on previous studies done to determine cellulase activity, is that many have estimated cellulase activity by examining the production of glucose from abalone stomach homogenates incubated with α-cellulose. This type of cellulose is a powder prepared by treating dewaxed cotton (ethanol extracted) for 8 h with 1% boiling sodium hydroxide solution (Whistler & Smart 1953). Thus, it is probably much easier for the abalone's own endogenous enzymes and gut bacterial enzymes to digest then cellulose present naturally in algae or in land based plants. Evidence for this is that cellulose that has been treated with alkali to increase the proportion of amorphous cellulose is more rapidly decomposed than untreated cellulose (Whistler & Smart 1953). In addition bacterial attack of cellulose is inhibited by the presence of lignin (also a component of lupin hulls). Thus bacteria that readily hydrolyze isolated cellulose may have little, if any, effect on wood (Whistler & Smart 1953). In addition, algae contain only low levels of cellulose. In divisions Phaeophyta, Rhodophyta and much of the Chlorophyta, cellulose is a minor component of the structural polysaccharides. In fact, in Phaeophytes and Rhodophytes, the amount of á-cellulose ranges from 1 to 8% of thallus dry weight whereas the proportion is often 30% in terrestrial plants (Kloareg & Quatrano 1988). Thus it is possible that although abalone possess cellulase it does not necessarily mean that they are able to effectively hydrolyze the cellulose present in terrestrial plants, thereby resulting in the lower gross energy digestibility of the whole compared with dehulled lupins in this study.

Abalone must be able to digest the major energy reserves in the cotyledon of lupins (lipids and cell wall non-starch polysaccharides (Evans 1994) relatively well, as indicated by the significant increase in gross energy digestibility of the lupins after dehulling. The lipid content of the cotyledon is relatively low and comprises approximately 85 g/kg by dry weight (Evans & Cheung 1993). The predominant monosaccharides in the cotyledon non-starch polysaccharides are galactose (67%), arabinose (12%) and uronic acid (10%) residues (Evans & Cheung 1993), and are the constituent sugars of the reserve pectic substances. Pectin is also one of the principal polysaccharides in cell walls of algae (Chapman & Chapman 1973), and so it would not be surprising if abalone were able to digest it.

The finding of comparable digestibility of lupins and soyflour indicates that there is potential for use of lupins in manufactured feeds for abalone. Since lupins are considerably cheaper than defatted soyflour, the replacement of soyflour with lupins in diets would result in a reduction in the cost of manufactured feeds.

LARVAL ESCAPE THROUGH ABALONE CULTURE EFFLUENT SYSTEMS: AN ANALYSIS OF THE RISK

C. D. HAWKINS[1]* AND J. B. JONES[2]

[1]*Department of Agriculture, Western Australia, PO Box 16, Moora, WA 6510, Australia;* [2]*Department of Fisheries Western Australia, Research Division, P.O. Box 20, North Beach, WA 6020, Australia*

ABSTRACT Expansion of abalone culture in Western Australia has resulted in the acquisition of juvenile stock (*Haliotis laevigata*) from interstate, particularly South Australia. This movement has raised concerns about the possibility of compromising the genetic integrity of domestic wild stocks of abalone with exotic genetic material. Such a compromise could arise from the escape of larvae from a production system in the event of a spawning event during the growing period. The use of a fine mesh filter may reduce this risk but is considered impractical because of frequent blockage. A risk model was constructed, which interfaces with an abalone growth model, to predict spawning events and the likelihood of viable larvae surviving in the open sea until they mature and spawn again. The model predicts that the probability of a spawning event leading to larvae escaping, maturing and spawning again in the wild is in the order of 3.7×10^{-6} per production cycle (about 3 y), and if such an event occurred, around 10 abalone would reach maturity, or about 17 in the absence of a settling pond for effluent water before discharge. Sensitivity of the model to input variables and implications for further research are discussed.

KEY WORDS: abalone culture, larval escape, risk analysis

INTRODUCTION

Abalone (*Haliotis* spp.) are highly prized edible marine gastropod mollusks. Their culture is increasing around the coastline of Australia with national production anticipated in the order of 485 tons in 2000–2001 (Hone & Fleming 1997). Increasing world prices for abalone have increased the viability of abalone aquaculture, with the majority of Australian aquaculture production being in South Australia, Victoria, and Tasmania. The industry is comparable to most intensive animal production systems, with a degree of specialization occurring. In particular, the potential exists for the production of large quantities of juvenile abalone for sale to grower units enabling growers to focus on a single aspect of production by purchasing stock from a specialist producer.

Production occurs in both sea- and land-based systems, with a trend toward land-based systems. Land-based systems tend to be operated close to the ocean, with sea-water supplied from the ocean, and effluent returned some distance from the inlet system. Australian abalone farms vary in size and layout. The profitability of such farms with either a 100 or 200 ton annual production was modeled by Weston et al. (2001).

Development of the industry in Western Australia is expanding, although only a small number of hatcheries have been established to date. To facilitate industry development, there has been pressure on Government to permit the introduction of juvenile stock from other states in Australia. Movement of any aquaculture stock into Western Australia is subject to an environmental assessment process. When assessing the movement of juvenile green-lip abalone (*Haliotis laevigata*) from South Australia to Western Australia, a concern was expressed that the genetic integrity of the Western Australian stocks could be compromised. During the growing period of some three years, it was hypothesized that a spawning event could occur in the growing tanks, resulting in discharge of viable juvenile abalone into the wild. Although the species of abalone in Western Australia is the same as that around other parts of the coastline, biotypes may vary (Brown 1991, Elliot et al. 2001) and an exotic or hybrid biotype may establish in the wild following a spawning event (Gaffney et al. 1996).

This proposed risk to the genetic integrity of wild abalone has been the subject of unpublished consultancies, and there is evidence that in greenlip abalone, stocks are genetically differentiated, that differences are detectable over small distances, and that interaction between different stocks is limited. More recent data published by Hancock (2000) show only small differences among *Haliotis roei* populations in Western Australia and, on this basis, genetic zones should no longer be applied for broodstock collection with this species. For black lip abalone (*H. rubra*), genetic differences seem to be even smaller than for green lip, with data on other species being inadequate for reliable conclusions to be made (Westaway & Norriss 1997). However, the potential for introducing new genetic material into existing stocks, and the possibility of reducing genetic diversity remain of concern to environmentalists and the abalone aquaculture industry, and management of this perceived risk is appropriate. Recommended risk management strategies include the use of progeny derived from a sufficiently large number of parent stock to ensure adequate genetic diversity; obtaining broodstock from local populations; and locating the sea culture facilities at a prescribed distance from wild populations of abalone. In addition, circumstances may require that effluent tank water be discharged over sand or filtered to minimize the ability of escaped larvae to settle on a suitable substrate. Current policy in this state dictates the use of a settlement pond or sediment filter for land-based farms.

Other risk reduction measures have been suggested, including the culture of polyploid (specifically triploid) organisms and harvesting before sexual maturity is reached. However, these options are not viable using present technology, because polyploidy is difficult to guarantee, and sexual maturity may occur some considerable time before harvestable size is reached in some species.

One management strategy to minimize the risk of larval escape from abalone culture ventures is the use of an effluent filter to trap larvae should a spawning event occur. In practice, given the volume of water involved, the use of a fine-mesh (100 μm) filter on the discharge outlet from abalone farms poses significant difficulties because of rapid clogging with particulate matter and restriction of water flow.

It is the intent of this risk assessment to quantify the probability of escape of larvae from a land-based abalone culture system using flow-through seawater in the absence of an effluent filter. The assessment relates to the risks of a spawning event, which is affected by the volume of water used, but independent of the number of abalone in the farm and their density.

METHOD

A quantitative risk model (Vose 2000) was constructed using Microsoft® Excel, with the Palisade® @Risk add-in. However, because of the changing risks associated with the growth and development of abalone during the growing period, relevant parts of the growth and production system were also modeled. The model tracks abalone growth and associated aquaculture events daily.

Abalone production is based on a grow-out raceway fed by seawater, the flow rate of which increases as the abalone grow. Initially, approximately 0.2 megaliters (ML) of water per day is used, increasing to 40 ML per day for the 2 mo before harvest. A linear relationship between size and water flow is assumed: Flow Rate = Age (days) * 0.04 ML/day to day 1010, then 40 ML thereafter.

Indications from Purdom (1980) are that growth in fish is linear under optimal conditions, restrained by food, temperature, and sexual maturity. Social interaction has an effect in free swimming fish, but it is anticipated that such interaction is minimal in abalone. Hahn (1989) also showed that growth in length is relatively linear for abalone over a wide size range. Sexual maturity in greenlip abalone is generally after reaching 90 mm, so the constraints of feed and temperature remain the major ones, although precocious maturation occurs in abalone farms. Under farmed conditions, feed should be supplied *ad libitum* and temperatures maintained at or around optimum. Thus, a linear growth rate between 0.2 and 70 mm, over about 1,000 days is used. The growth expression is:

$$\text{Size (mm)} = \text{Age (days)} * 0.07.$$

Considerable attrition is noted in farmed abalone, with survival to maturity being very low. Large losses before settlement have been noted. Shepherd et al. (2000) observed settlement rates between 0.02–1.2% for *H. rubra*, and 0.1–6.5% for *H. laevigata* in experimental stock enhancement trials in South Australia. At the request of the Department of Fisheries, two linear death rates were used. In this situation, mortalities reach 95% by the time abalone are 5 mm (approximately day 127 of the model) and a further 50% mortality by the time abalone reach 88 mm. Simple linear regression lines were used for this purpose.

Abalone are harvested at approximately 70 mm in length, some 20 mm short of the anticipated size for sexual maturity. However, abalone have been reported to spawn when only 25 mm in length. Synchronous spawning may occur in abalone, although Hahn (1989) reports that spawning is poorly synchronized in some species. Egg production is from 0.5×10^6 to 3×10^6 per abalone, with larger shellfish producing more eggs. The relationship between size and spawn production is considered linear. Throughout this model, assumptions are made that favor the production of larvae and their escape, so as to avoid underestimating the risk. Thus, abalone as small as 15 mm are permitted to spawn in the model. The quantity of spawn (eggs) produced is calculated as:

$$\text{Spawn (millions)} = \text{length in mm} * 0.023809524 + 0.142857143.$$

Discharge water from the grow-out tanks is fed into a settling pond, which is believed to remove up to 80% of solid material. Although more accurate figures would be desirable, this percentage is an upper limit, with the minimum and means probably being 30 and 65%. There is a negative correlation between the flow rate of seawater through the farm and the efficiency of the settling pond: Proportion settling in the pond is: flow (ML) * (-0.0125628) + 0.8. The effectiveness of the settling pond was evaluated by running the model with zero settling.

From the settling pond, effluent is discharged through a pipeline to a subsurface outlet in the sea. This outlet is located at the maximum practical distance from the seawater inlet for the facility. Discharge is required to be over sand, to minimize the chance of any abalone larvae that escape of finding a suitable (rocky) habitat on which to settle. However, the effect of discharge over sand is not directly modeled, rather a probability that such larvae will survive and settle is used. Water from the subsea discharge pipe is expected to plume rather than disperse evenly into the sea, thereby maintaining a higher level of suspended particles for some distance from the outlet.

The model uses a random number generator to determine if a spawning event occurs during a growing cycle. It is assumed that spawning is an unexpected event that may occur once before harvest. The likelihood of spawning is set as a probability, using a beta-pert distribution. This type of distribution has been chosen, because it offers the capacity to specify minimum, maximum, and most likely values, and the curve is such that the extremes are not favored, and the bulk of the values generated cluster around the most likely value. The shape of the beta-pert curve is one that can be grasped intuitively, appearing as a bell-shaped curve, with or without a skew. The values for the distribution are: Minimum: 0.001; Most Likely 0.005; Maximum 0.0095. That is, there is a 1 in 200 chance of a spawning event occurring, but this may be as low as 1 in 1,000, or as high as (approximately) 1 in 100. These data have been provided from production experience. Although spawning is most likely to occur with larger abalone in the third year of the growing period, the model allows spawning on any day once abalone reach 15 mm. (This may seem very low, but gonad maturation occurs very early for some species; e.g., *Haliotis roei*) The day on which the spawning event occurs is randomly set between the time abalone reach 15 mm, to the end of the growing period.

When a spawning event occurs, a proportion of abalone present in the grow-out tank is able to spawn as females. This is also represented as a beta-pert distribution, with the following values: Minimum 0.05; Most Likely 0.1; Maximum 0.3. Proportions calculated in this manner were subsequently used to determine the number of individuals reaching the next stage, as a binomial probability.

Although a number of environmental variables interact at the time of spawning to influence fertilization, and the window of opportunity for fertilization may be short, is assumed that all spawn are fertilized—the worst case scenario. (In practice, any lag between males and females spawning in high flow rate tanks will impede fertilization.)

There is always a concern that "something drastic could go wrong"—the unexpected, rare event that throws the whole system into disarray, such as a meteor crashing directly into the abalone farm. In this model, the possibility of a rare event is incorporated in the form of a total washout of all particulate matter from the grow-out tanks; that is, whatever fertilized spawn is present gets washed straight out to sea without the benefit of a settling tank. The likelihood of such a rare event is a beta-pert distribution with the following parameters: Minimum 0.0000001; most likely

0.000001; Maximum 0.000005. That is, the event is most likely to occur with a 1 in a million probability, but could be as high as 5 in a million, or as low as 1 in ten million. This parameter is included simply to allow for the occurrence of the most extreme adverse event.

Any fertilized eggs (larvae) that escape the system are subject to several events: settlement, survival through the first year, and survival to sexual maturity. Although biologic events, these are treated as probability distributions as follows. Survival to settlement (Shepherd et al. 2000) as a beta-pert distribution: Minimum 0.0002; Most likely value 0.02; Maximum 0.08. Survival for the first year—a uniform distribution between 8 and 16%. Survival from the first year to spawning as a beta-pert distribution: Minimum 0.1; most likely value 0.2; Maximum 0.5. (It should be noted that Shepherd et al. (2000) modeled survival of larvae released directly onto a reef. They also found that survival depended on the density of abalone already on the reef. Our model assumes that any larva escaping from the farm will be carried to a reef area as if it was being released for reseeding. Clearly, this is a worst case scenario.) An abalone reaching maturity and then spawning is considered the end point of the model.

Outputs from the model are:

- total fertilized spawn (larvae) discharged;
- number of abalone surviving in the wild to spawn; and
- probability of a spawning event in aquaculture, and subsequent survival to spawn in the wild.

That is, if a spawning event occurs, and there is no filter, how many larvae escape, how many survive to spawn again, and what probability can be associated with such events occurring?

The model was run for 1,000 iterations, each iteration representing a full grow-out cycle (approximately 3 y). A random number seed is generated internally by @Risk, and this is allowed to vary between runs of the model. Consequently, results vary in detail between runs, but not in order of magnitude. Computationally, the model is a matrix of 17 variables calculated each day for 1,100 days (i.e., 18,700 individual variables determined on each iteration of the model), of which some 9,000 are generated as @Risk statistical distributions. This matrix is treated as an Excel lookup table, and outputs are computed by accumulating looked up values over the total number of iterations. Hence, outputs are not single values, but aggregations of data that are presented as means with upper and lower 95% confidence intervals, where appropriate. Limitations imposed on the model by capacity of @Risk to handle large numbers restricts maximum sizes used in some calculations. This was managed by performing such calculations on a per megaliter of water basis. For example, the use of binomial sampling is limited to population sizes of less than or equal to 32,767—a number far smaller than the expected number of spawn produced by abalone. For the calculation of outputs, the total volume of water is taken into account.

Where appropriate, sensitivity of output variables to the inputs was analyzed using the facility available in @Risk. Suitable input variables are day of spawning, proportion of abalone spawning, and probability of a spawning event, the main drivers of the model. Other variables are not suited to this process, because they are calculated independently each day of the growing cycle (about 1,000 days), and consequently, each daily probability contributes to a very small component of the final output.

The modeled abalone farm is stocked with five million juvenile abalone, of two millimeter (2 mm) length.

TABLE 1.

Outputs from risk model, with a settling pond.

Output	Mean Value	Lower 5% Confidence Interval	Upper 95% Confidence Interval
Total spawn discharged	13,184	3,920	26,800
Abalone surviving to spawn again	10	0	40
Probability of spawning event and survival to spawn in the wild	3.7×10^{-6}	6.1×10^{-7}	9.5×10^{-6}

RESULTS

Details of Output Variables Are Presented in Table 1.

The number of spawn discharged is variable. However, the mean value is under 20,000, with an upper confidence limit of the order of 30,000–40,000. Of these, very few survive, with around 10, but fewer than 100, expected to reach sexual maturity and subsequently spawn again. The likelihood that there will be a spawning event in the grow-out tank, and larvae will escape, developing to sexual maturity, is very low, in the order of 4 in a million, but may be as high as 1 in 100,000. These results include the possibility of a rare, but catastrophic event, as described previously.

The effect of the settling tank, although detectable, was small. The effect of removing the settling tank from the model is given in Table 2. Output graphs for the data in Table 2 follow (Figs. 1–3).

The impact of a "rare event" is small. Because the rare event operates in the same manner as removing the settling pond, the occurrence of a rare event, if it happened at the time of spawning, would be to increase the number of larvae escaping and reaching maturity. Because of the very low probability of a rare event, it does not affect the very low probability that larvae would escape and establish in the wild.

Sensitivity Analysis

As indicated in Tables 1 and 2, the model demonstrates that the presence of a settling pond reduces the quantity of larvae escaping if a spawning event occurs. However, because the effectiveness of the settling pond is not perfect, and its effectiveness decreases in efficiency as flow rates increase, the settling pond does not greatly affect the probability of larval escape.

TABLE 2.

Outputs from risk model, without a settling pond.

Output	Mean Value	Lower 5% Confidence Interval	Upper 95% Confidence Interval
Total spawn discharged	20,796	8,382	38,520
Abalone surviving to spawn again	17	0	80
Probability of spawning event and survival to spawn in the wild	4.0×10^{-6}	6.5×10^{-7}	9.1×10^{-6}

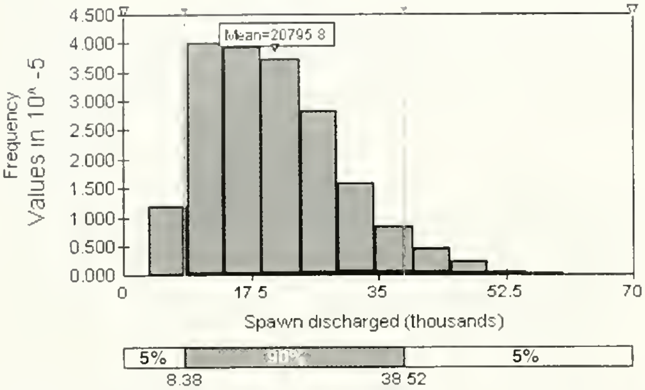

Figure 1. Distribution (frequency) histogram for total spawn discharged. Horizontal bar indicates percentiles.

The built-in facility of @Risk to determine the correlation of input variables to output variables indicates a correlation between total spawn discharged, and the input variables day of spawning (r = 0.8) and proportion of abalone spawning (r = 0.41). Survival of escaped larvae to spawn again subsequently is correlated to day of spawning (r = 0.2) and the proportion of abalone in the growing tank spawning (r = 0.16). Probability of a spawning event in the growing tank, and subsequent survival to spawn again in the wild, is also correlated to the day of spawning (r = 0.40) and probability of a spawning event (r = 0.3).

CONCLUSIONS

The model constructed and described here is a hybrid of risk and biologic models. Biologic components (growth of abalone, deaths, water flows) drive the development of abalone in culture, and risk components drive the events of interest; that is, spawning, settling, escaping, and maturing. Where available, published data have been used to determine probabilities. However, the relative newness of the abalone culture industry is such that much data is either lacking, or dependent on limited production experience.

In regard to the initial question of the importance of a filter to prevent the escape of larvae should a spawning event occur, the incorporation of a filter would seem to be a low utility procedure. The likelihood of a spawning event leading to establishment of abalone in the wild is very small (in the order of 10^{-5}–10^{-6}). The consequences of a spawning event would seem to be likewise small, with very few abalone surviving to spawn again. This result is in accord with practical experience. Most attempts to outplant hatchery-reared juvenile abalone on reefs have failed (Burton & Tegner 2000). It should be remembered that the data used in this model are considered pessimistic; that is, overestimates of the input values, and the outputs can likewise be considered pessimistic. It will require additional research to quantify the variables of concern better. It may also be of benefit to investigate improving the efficiency of settling ponds, to further reduce the numbers of abalone escaping should spawning occur.

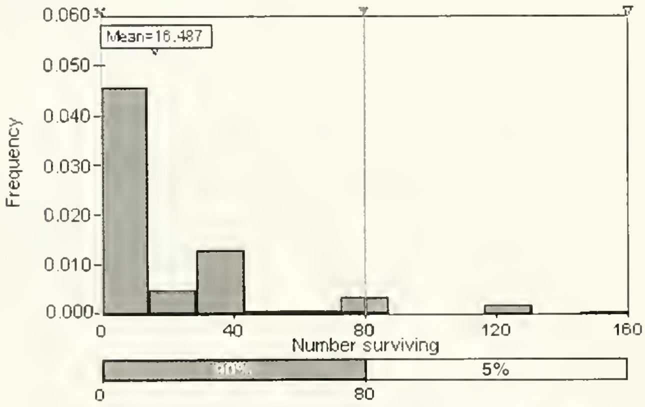

Figure 2. Distribution (frequency) histogram of abalone surviving to spawn in the wild. Horizontal bar indicates percentiles.

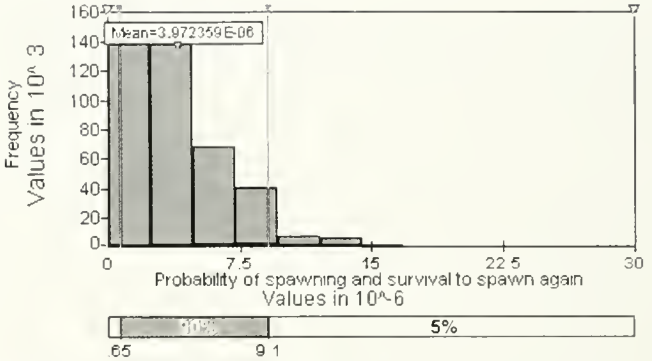

Figure 3. Distribution (frequency) histogram of the probability of a spawning event and survival of abalone to spawn in the wild. Horizontal bar indicates percentiles.

The nature of the model, using a large matrix as a lookup table tends to mask the effects of input variables. This occurs because an input variable may be referred to once in a chain of "events" over a large range (in this case, 3 y, or about 1,000 day-events). The model itself has some 9,000 input variables, which refer back either directly or by way of another variable, to the biologic and stochastic variables that provide the basic inputs for the models. It is difficult to determine relationships between inputs and outputs under these circumstances. However, for the primary driving variables, day of spawning, probability of a spawning event, and the proportion of abalone spawning, positive correlations with output variables were observed. In view of the nature of the model, such correlations strongly suggest close relationships between the outputs and the input parameters, despite traditional statistical thinking on the nature of correlations.

These correlations suggest that it would be beneficial to collate observations associated with spawning events in cultured abalone and to determine what range of triggers influence such an event, with the goal of manipulating these triggers to control or prevent spawning in culture.

Based on the results of this modeling exercise, the source of broodstock for land-based farms is of little importance in terms of genetic impact on wild populations. However, the model does not address disease risks and fine filtration (100 micron absolute) has been applied to systems in Western Australia to reduce disease risks associated with use of stock from interstate.

Similarly, settlement ponds did not greatly influence the risk of larval escape, but this is not their primary purpose. Settlement ponds are used primarily to reduce nutrient release into the pristine coastal areas usually selected as abalone farming intake locations.

ISOLATION AND CHARACTERIZATION OF MICROSATELLITE LOCI IN THE PACIFIC ABALONE, *HALIOTIS DISCUS HANNAI*

QI LI,[1] CHOULJI PARK,[2] AND AKIHIRO KIJIMA[2]*

[1]*Fisheries College, Ocean University of Qingdao, Qingdao 266003, China;* [2]*Education and Research Center of Marine Bio-resources, Graduate School of Agricultural Science, Tohoku University, Onagawa, Oshika 986-2242, Japan*

ABSTRACT Four microsatellite loci, designated *Hdh1321*, *Hdh78*, *Hdh1761*, and *Hdh1457*, were isolated from the Pacific abalone, *Haliotis discus hannai*, using an enrichment method based on magnetic/biotin capture of microsatellite sequences from a size-selected genomic library. Primers designed to amplify via polymerase chain reaction the microsatellite loci were used to screen 30 individuals from a natural Pacific abalone population in Onagawa Bay, Miyagi Prefecture, Japan. The four microsatellite loci were all polymorphic, with an average of 14.3 alleles per locus (range 7–20). The mean observed and expected heterozygosities were 0.48 (range 0.30–0.97) and 0.79 (range 0.60–0.92), respectively. Significant deviations from Hardy-Weinberg expectations were observed at three loci as a result of homozygote excess. The expected heterozygosity values were considerably higher than those previously found for allozymes (range 0.101–0.125), suggesting that these microsatellite loci should provide useful markers for studies of trait mapping, kinship, and population genetics.

KEY WORDS: microsatellite loci, Pacific abalone, *Haliotis discus hannai*, genetic variability

INTRODUCTION

The Pacific abalone, *Haliotis discus hannai*, is distributed along the coastal waters of East Asia, where it is one of the most valuable and popular fisheries resources. Although cultured seeds of the Pacific abalone were produced 20 years ago, the development of abalone culture has long been hampered by the problems of low growth rate and mass mortality during seed production (Hara & Sekino 2001). To resolve these problems and improve animal breeds for aquaculture production, many genetic studies on growth-related traits and temperature tolerance have been performed in the Pacific abalone (Wilkins et al. 1980, Okumura et al. 1981, Hara 1990, Kobayashi et al. 1991, 1992, Kobayashi & Fujio 1994, 1996, Furutono et al. 1995, Kijima et al. 1995, Kawahara et al. 1997, 1999). Allozyme analysis suggested the presence of homozygote excess and inbreeding depression (Kijima et al. 2002); however, genetic control of the target traits in *H. discus hannai* remains unclear. To find genetic markers associated with loci that control economically important traits to assist in selective breeding programs, the development of molecular markers is needed. For this purpose, allozymes are not appropriate because there are too few of them and they are not sufficiently variable (Kijima et al. 1992).

Microsatellites are tandemly repeated arrays of short nucleotide motifs found in all prokaryotic and eukaryotic genomes analyzed to date (Zane et al. 2002). Because they are evenly dispersed throughout genomes, usually characterized by high length polymorphism, and generally inherited in a Mendelian fashion, microsatellite markers have been widely used for genomic mapping, linkage analysis, pedigree analysis, and population genetics of biologic resources (Schlotterer et al. 1991, Knapik et al. 1998, Holland 2001).

The traditional approach to obtain microsatellites is to create a size-selected genomic library in a plasmid or phage vector and then screen clones using oligonucleotide probes containing different repeat motifs. For microsatellite repeats that are less abundant in the genome, it is difficult to isolate them using the method. Recently, different approaches have been developed to enrich for microsatellites (Zane et al. 2002). One method is based on selective hybridization, a protocol that is commonly used in enrichment procedures (Ostrander et al. 1992, Kandpal et al. 1994, Kijas et al. 1994, Refseth et al. 1997, Zane et al. 2002). In the present study, we report the first isolation of microsatellite loci in *H. discus hannai* by magnetic bead hybridization selection and assess polymorphism at microsatellite loci in individuals from a natural population.

MATERIALS AND METHODS

DNA Extraction from Abalone

For constructing a genomic DNA library, high-molecular weight DNA was extracted from a live Pacific abalone from Onagawa Bay, Miyagi Prefecture, Japan. The foot muscle was removed from the abalone and ground with dry ice in a mortar. About 100 mg of the tissue was digested overnight at 37°C in 0.7 mL of lysis buffer (6 M urea, 10 mM Tris-HCl, 125 mM NaCl, 1% SDS, 10 mM EDTA, pH 7.5) and 35 μL of proteinase K (20 mg/mL). The reaction mixture was extracted with phenol:chloroform (1:1), precipitated with isopropanol, and dissolved in TE (10 mM Tris-HCl, 1 mM EDTA, pH 8.0). DNA was treated with DNase-free RNase (20 μg/mL) at 37°C for 1 h, and purified again using a phenol/chloroform extraction.

Digestion of Genomic DNA, Size Fractionation, and Ligation of Adapters

Extracted DNA was digested with *Hae*III, *Dra*I, and *Hinc*II using 100 U each for 50 μg of abalone DNA. The digested DNA (5 μg) was electrophoresed on a 2.5% NuSieve GTG agarose gel (FMC Bioproducts), and fragments of 400–800 bp were excised and purified using a Qiagen column (QIAquick Gel Extraction Kit, QIAGEN). The fragments (1 μg) were ligated with 200 pmol of an *Eco*RI-*Not*I-*Bam*HI adapter (TaKaRa) using a DNA Ligation Kit (TaKaRa), then collected by ethanol precipitation, and resuspended in 20 μL of H_2O.

Magnetic Isolation of Target Sequences and Adapter Polymerase Chain Reaction (PCR)

One 0.6-mL tube of the Streptavidin MagneSphere® Paramagnetic particles (Promega) was washed according to the manufacturer's instructions, resuspended in 300 μL of 5× SSC (1× SSC = 150 mM NaCl, 15 mM sodium citrate), and mixed with 300 pmol of biotinylated oligoprobe: 5′-$(CA)_{12}$GCTTGA-biotin. The six-base noncomplementary region at the 3′ end was used to prevent the probe, copurified with target DNA during magnetic isolation, from acting as primers in subsequent adapter PCR (Gardner et al. 1999). The beads and probe were incubated for 15 minutes at room temperature, then washed three times in 5× SSC and resuspended in 100 μL of hybridization solution (0.5 M NaCl, 4% polyethylene glycol 8000) at 56°C (Gardner et al.1999). The fractioned DNA (20 μL) was mixed with 80 μL of the hybridization solution, denatured by incubating at 95°C for 5 min, added quickly to the beads, and incubated at 56°C for 20 min. The beads were then washed four times at room temperature in 200 μL 2× SSC followed by four times at 30°C in 200 μL 1× SSC. Immobilized DNA fragments were eluted from the beads in 50 μL 0.15 M NaOH at room temperature for 20 min. The beads were then removed, and the supernatant was neutralized by the addition of 5.5 μL 10× TE, 3.25 μL 1.25 M acetic acid. DNA was purified by a Qiagen column (QIAquick PCR purification kit, QIAGEN) and eluted in 50 μL of TE buffer. PCR amplification was performed in 50 μL volumes containing 5 μL of the released DNA, 1.25 U of AmpliTaq Gold (Perkin Elmer), 5 μL of GeneAmp 10× PCR buffer (Perkin Elmer), 0.2 mM dNTP mix, 1.5 mM $MgCl_2$, and 0.6 μM of the adaptor sequence primer, 5′-CGGCGGCCGCGGATCC-3′. Reactions were denatured at 95°C for 11 min before 35 cycles of 94°C for 1 min, 63°C for 1 min, and 72°C for 1 min, followed by a 5 min, 72°C final extension. PCR products were purified using a QIAquick PCR purification kit (QIAGEN).

Cloning of the PCR-Amplified DNA Fragments

The purified PCR products were digested with *Not*I, inserted into the *Not*I site of the pBluescript II SK(+) vector (Stratagene), and the recombinant plasmid vector was transformed into XL1-Blue MRF′ supercompetent cells (Stratagene) following the manufacturer's protocol. Recombinant clones were selected by plating on LB media containing ampicillin (100 μg/mL), IPTG (100 μL of 10 mM stock solution) and X-Gal (100 μL of 2% stock solution).

PCR Screening of Microsatellite-Containing Clones

A small portion of a white colony was transferred to 10 μL of 10 mM Tris-HCl (pH 8.5) with a toothpick, incubated at 95°C for 10 min, and then used as template (1 μL) in the PCR with two vector primers (T3 and T7) and the nonbiotin-labeled $(CA)_{12}$ primer (Gardner et al. 1999). Each 10-μL reaction mixture contained 0.25 U of AmpliTaq Gold (Perkin Elmer), 1× the supplied buffer (Perkin Elmer), 0.2 mM dNTP mix, 1.5 mM $MgCl_2$, and 0.2 μM of each primer. Screening amplifications were performed as follows: 11 min at 95°C followed by 35 cycles of 1 min at 94°C, 1 min at 57°C, and 1 min at 72°C, followed by 5 min at 72°C. PCR products were electrophoresed on 1.5% agarose gels. Inserts producing two or more bands were considered likely to contain a microsatellite locus. Positive plasmid DNAs were purified using Qiaprep spin columns (QIAGEN), and then double sequenced on a Shimadzu DSQ-2000L DNA sequencer (Shimadzu) using ThermoSequenase cycle sequencing kit (Amersham) in combination with the universal forward (5′-CGCCAGGGTTTTCCCAGTCACGAC-3′) and reverse (5′-GAGCGGATAACAATTTCACACAGG-3′) primers, respectively. PCR primers for each microsatellite locus were designed using the OLIGO software package (National Biosciences Inc.).

Assessment of Polymorphism in Microsatellite Loci

Primer pairs were tested on a random sample of 30 Pacific abalones from Onagawa Bay. Abalone DNA was extracted by the method as described above. PCRs were performed in 10-μL volumes containing 0.25 U of AmpliTaq Gold (Perkin Elmer), 1× PCR buffer, 0.2 mM dNTP mix, 1.5 mM $MgCl_2$, 1 μM forward FITC-labeled primer and reverse primer, and about 100 ng template DNA. The PCR conditions for all loci were 11 min at 95°C followed by 35 cycles of 1 min at 94°C, 1 min at the annealing temperature listed in Table 1, and 1 min at 72°C, with a final extension of 5 min at 72°C. Amplification products were resolved via 6% denaturing polyacrylamide gel on a Shimadzu DSQ-2000L DNA sequencer equipped with DSQ-SA program (Shimadzu), and a pBluescript II SK(+) sequencing reaction was co-electrophoresed as a size marker.

tations (HWE) were calculated using GENEPOP 3.1 software (Raymond & Rousset 1995).

RESULTS

Isolation of Microsatellites in H. discus hannai

An enriched library of 350 white colonies was screened using the PCR-based technique, and 84 clones were identified by the presence of two or more bands on the agarose gel. Sequencing the 84 clones gave 46 loci containing microsatellites arrays with a minimum of five repeats, primarily $(CA)_n$, but some in combination with other tetra- or pentanucleotide array motifs. Primer pairs were designed for 10 of the 46 sequences with long, uninterrupted repeats and adequate unique regions flanking the microsatellite array. Of the 10 primer sets developed, four loci were successfully amplified with polymorphisms (Table 1).

Genetic variability of Microsatellites in H. discus hannai

Figure 1 shows the alleles of microsatellite loci *Hdh1321*, *Hdh78*, *Hdh1761*, and *Hdh1457* identified in six Pacific abalone individuals. The presence of minor peaks below the major amplification product ("stutter") was observed. At locus *Hdh1761*, the peaks of longer alleles tended to be smaller than those of shorter alleles. Primer sequences, repeat motif, annealing temperature, number of alleles, amplified product size range, the observed (H_O) and expected (H_E) heterozygosities for the four microsatellite loci are summarized in Table 1. The four microsatellite loci were all highly polymorphic, whereas the degree of variability was different at each locus. *Hdh1321* had the highest number of alleles (20), whereas number of alleles at *Hdh78*, *Hdh1761*, and *Hdh1457* was 7, 18, and 12, respectively. The expected heterozygosity ranged from 0.60 at *Hdh78* to 0.92 at both *Hdh1321* and *Hdh1761*. Significant deviations from HWE for the observed heterozygosities were observed in the *Hdh78*, *Hdh1761*, and *Hdh1457* ($P < 0.01$). Allele frequencies of the four microsatellites for samples from Miyagi Prefecture are shown in Table 2. At loci *Hdh78* and *Hdh1457*, the frequencies of major alleles 267 and 563 were 0.617 and 0.500, respectively. At loci *Hdh1321* and *Hdh1761*, allele frequencies were overall low, with the most common alleles being 0.150 and 0.167, respectively.

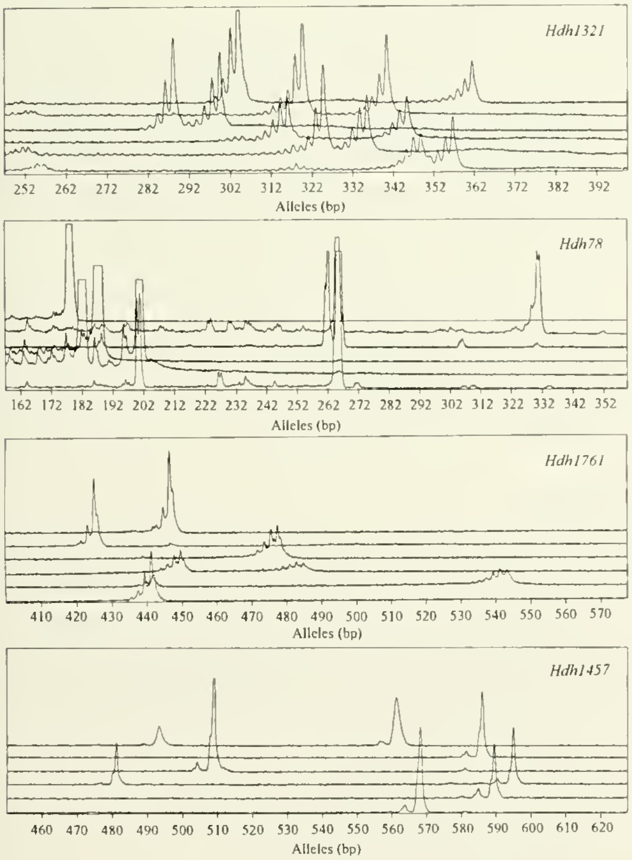

Figure 1. Alleles of microsatellite loci *Hdh1321*, *Hdh78*, *Hdh1761*, and *Hdh1457* identified in six Pacific abalone individuals from a natural population in Miyagi Prefecture.

DISCUSSION

The enrichment efficiency seen here (13.1%) is similar although lower than that reported by Gardner et al. (21%, 1999). By the colony hybridization method, the percentage of positive clones containing microsatellite repeats was 0.52–0.66% in the European flat oyster (Naciri et al. 1995), 0.1% in the quagga mussel (Wilson et al. 1999), and an average of 1.96% in molluscs (Zane et al. 2002). Compared with traditional methodologies, the enrichment procedure using the magnetic bead hybridization selection is more efficient.

The presence of the microsatellite stutter bands seen at all four microsatellite loci is a typical artifact of PCR amplication of microsatellite loci (Johansson et al. 1992). This phenomenon is due to slipped strand mispairing during PCR (Weber 1990). In this study, although the variability observed in the microsatellite loci (average 14.3 allele per locus) is possibly underestimated because of small sample size (30 individuals), it was still much higher than that of allozymes in the Pacific abalone population (Kijima et al. 1992). They surveyed 18 allozyme loci using 445 Pacific abalone individuals in six groups from coastal waters of Japan, and found the average number of alleles per locus in allozymes was 2.01 (range 1.89–2.17). The average expected heterozygosity in total populations was 0.116 (range 0.101–0.125). The high level of length variation found here is similar to that found in *H. discus discus* and other abalone species (Huang & Hanna 1998, Kirby et al. 1998, Miller et al. 2001, Sekino & Hara 2001).

Significant deviations from HWE occurred for the observed genotype frequencies at loci *Hdh78*, *Hdh1761*, and *Hdh1457* because of homozygote excess. The departure from HWE with an excess of homozygotes may be the result of one or more of the following reasons. (1) Large allele "dropout" artifacts in the PCR amplification process: At locus *Hdh1761*, we observed that large allele bands tended to be less intense than small alleles. In heterozygous individuals, preferential amplification of a smaller allele over a larger allele would result in the mis-scoring of heterozygotes for homozygotes even though larger alleles may indeed exist. The problem of large allele dropout during PCR has been well documented for humans (Day et al. 1996), Minke whales (Van Pijlen et al. 1995), and chinook salmon (Banks et al. 1999). (2) Small sample size: As microsatellite DNA has a rapid mutation rate, resulting large number of alleles, a large sample size is needed for accurate reflection of genotypic frequencies (Ruzzante 1998). This sample size was suggested to be at least 50 individuals per population for microsatellite loci studies. (3) Presence of null alleles: Null alleles of microsatellite regions, which occasionally

fail to yield an amplification product, may arise through mutations such as point mutations in the primer annealing site (Callen et al. 1993, Pemberton et al. 1995). Kijima et al. (1997) have found null alleles at allozyme loci in the Pacific abalone by mating experiment. If null alleles are present but not accounted for, the resulting scoring error of heterozygotes for homozygotes can create an apparent excess of homozygotes in population studies (Jones et al. 1998). (4) Inbreeding effects: Extensive heterozygote deficiency has also been reported at allozyme loci in natural populations of the Pacific abalone (Fujino 1978, Fujio et al. 1986). Hara and Kikuchi (1992) showed an excess of homozygotes in all natural populations of *H. discus hannai* collected from nine different sampling sites, suggesting extensive inbreeding. The excessive homozygotes for microsatellite loci were also described for *H. rubra*, *H. discus discus*, and *H. kamtschatkana* populations (Huang et al. 2000, Miller et al. 2001, Sekino & Hara 2001). (5) Presence of size homoplasy: Size homoplasy is the co-occurrence of alleles that are identical in state (PCR products of the same size) without being identical by descent (Ardren et al. 1999). Mistaking homoplasy for homology can lead to underestimation of the genetic divergence within and among population (Taylor et al. 1999). Microsatellite allele size homoplasy has been confirmed in various animal species (Estoup et al. 1995, Viard et al. 1998, Ardren et al. 1999, Taylor et al. 1999); however, was not reported for abalones. Further studies of natural populations and controlled crosses of *H. discus hannai* will help to clarify this deviation from HWE.

The high variability of the microsatellite markers identified in this study will make them excellent tools for paternity testing, population studies, and the linkage analysis of genes related to traits with economic significance in the Pacific abalone.

ACKNOWLEDGMENTS

The study was supported by grants from the Japan Society for the Promotion of Science (No. P00335), Agriculture, Forestry and Fisheries Research Council of Japan, and National Natural Science Foundation of China (No. 30170735).

ABSTRACT Withering syndrome (WS) has been associated with catastrophic declines in black abalone populations in southern and central California. In an effort to identify the etiological agent of WS and to characterize the progression of this disease, we initiated a transmission study in which abalone from Ano Nuevo Island, a location free of WS, shared aquaria with animals from Vandenberg Airforce Base, a location where WS is epizootic. The mean incubation period of WS (time to develop overt signs of the disease) was 245 days with a mean time to death after development of clinical signs of 42 days. Median time to death was 41 wk in the experimentally exposed Ano Nuevo Island abalone and 16 wk in the positive control Vandenberg abalone. Cumulative mortality was significantly different between the negative control (unexposed) Ano Nuevo Island abalone (25% mortality) and both the exposed Ano Nuevo Island abalone (85% mortality; $P = 0.0001$) and the positive control Vandenberg abalone (100% mortality; $P = 0.0001$). In addition, significant differences in prevalences of a recently described Rickettsiales-like procaryote (RLP), "*Candidatus* Xenohaliotis californiensis," were observed between negative control animals (no RLPs) and those with WS (both the experimentally exposed Ano Nuevo Island and Vandenberg abalone were infected with RLPs; $P < 0.001$). All abalone infected with the RLP had signs of WS, including decreased condition indices, foot muscle atrophy, and digestive gland degeneration ($P < 0.05$). No correlation between intensity of RLP infection and degree of WS was observed ($P > 0.05$), suggesting a complex relationship between the RLP and clinical disease in black abalone. Despite this, these data in conjunction with a lack of observation of any other significant pathogens in the abalone provides evidence that the RLP infecting abalone ("*Candidatus* Xenohaliotis californiensis") is the etiological agent of WS.

KEY WORDS: withering syndrome, black abalone, *Haliotis*, rickettsiales, "*Candidatus* Xenohaliotis californiensis"

INTRODUCTION

Withering syndrome (WS) has been associated with catastrophic declines in black abalone populations in southern and central California (Haaker et al. 1992; Steinbeck et al. 1992, Friedman and Haaker unpublished data). Initial studies identified a previously undescribed coccidian parasite, *Margolisiella* (=*Pseudoklossia*) *haliotis* (Friedman 1991; Friedman et al. 1995, Desser & Bower 1997), in black abalone with WS that was subsequently determined to be nonpathogenic as evidenced by field and laboratory studies (Friedman et al. 1993, 1997). VanBlaricom et al. (1993) documented WS on San Nicolas Island in April of 1992. These researchers a observed Rickettsiales-like procaryote (RLP) that was recently described as a new taxon and has been given the provisional status of "*Candidatus* Xenohaliotis californiensis" (Friedman et al. 2000). Two of six abalone with clinical WS harbored RLPs, whereas apparently healthy animals were devoid of the RLP. The authors indicated that Rickettsiales-like bacteria were commonly observed in marine invertebrates and that the pathogenicity of these organisms was unknown. Gardner et al. (1995) also observed RLPs in association with WS in black abalone from San Nicolas and San Clemente Islands in southern California. Healthy abalone from Ano Nuevo Island in central California were not infected with RLPs, suggesting an association between the RLP and WS. Friedman et al. (1997) examined the association between the RLP, degeneration of the digestive gland, and mortality in a laboratory study. No clear associations between intensity of RLP infection and either condition of the digestive gland or time to mortality were observed. Recently, Moore et al. (2000) observed a significant relationship between the intensity of RLP infection and degree of WS in cultured red abalone. These conflicting data indicate further examination of the role of the RLP in WS is warranted. This study was designed to examine the transmissibility of WS and to determine the relationship between RLP infection and WS in black abalone.

MATERIALS AND METHODS

Animals

Healthy black abalone were collected on March 28, 1995 from Ano Nuevo Island, where WS had never been observed. Black abalone with WS were collected from Vandenberg Airforce Base (Vandenberg) and Cayucos on April 24, 1995. Abalone were transported to the Pathology Quarantine Facility at the Bodega Marine Laboratory, where they were placed in an 88-L aquaria and received ambient (8–10°C), flow-through, full-strength seawater. *Macrocystis pyrifera* was collected from Bodega Bay and was surface sterilized by soaking in a tamed iodine solution (Prepodyne: Westagro, Kansas City, MO) for 15 min followed by a freshwater rinse. Animals were fed *M. pyrifera* twice per week. All abalone were tagged and the following data were collected: maximum length, foot length and total volume (TV), and total weight (TW). Animals were bled from the pallial sinus with a tuberculin syringe and a 26-gauge, 0.5-inch needle and the density, cell-type, and condition of circulating hemocytes was determined using a hemocytometer. Visual condition of the abalone was assessed according to the following scale: (3): healthy abalone with a foot and viscera that fills the entire shell volume; (2): visible mantle retraction and moderate atrophy of the foot muscle; and (1): severe atrophy of the foot muscle.

Histology

Selected tissues were placed in Invertebrate Davidson's solution (Shaw & Battle 1957) for 24 h and processed for routine paraffin histology. Deparaffinized 5-μm sections were stained with hematoxylin and eosin (Luna 1968) and viewed by light microscopy. The intensity of RLP infection was quantified using the following logarithmic scale at 200× magnification: (0): no bacterial foci; (1): 1–10 foci per field; (2): 11–100 foci per field; and (3): >100 foci per field (Friedman et al. 1997). Infection intensity was quantified in both the postesophagus (PE) and digestive gland (DG), and an overall infection intensity was calculated by summing the intensity in the PE and DG (range of 0–6 possible) (Moore et al. 2000). Intensities were examined according to tissue type to determine whether the location of infection was correlated with animal health. Unless otherwise specified, the term RLP infection refers to overall infection intensity. Condition of the digestive gland and foot muscle were assessed using the (1)–(3) scales of Friedman et al. (1997), in which normal was scored as (3), moderate (up to 30%) alteration from normal was scored as (2), and tissue that was severely (>30%) altered was scored as (1). Three specific morphologic changes that characterized observed alterations in digestive gland architecture were individually scored according to the following (1)–(3) scale: (1) normal architecture; (2) moderate (up to 25%) degeneration (characterized by an increase in connective tissue between digestive tubules, the primary tissues responsible for secretion of digestive enzymes and nutrient absorption in abalone) (Voltzow 1994), transport duct metaplasia, or inflammation; and (3) abundant (>25%) transport duct metaplasia, an increase in connective tissues between degenerating tubules, or inflammation.

Transmission Experiment

Groups of 12 abalone from Ano Nuevo Island were randomly placed in each of two negative control (NC) and two experimental aquaria (EA). Groups of 12 abalone with WS (EWS) were randomly added to each of the two experimental aquaria and to each of the two positive control aquaria (PC) (Fig. 1). Animals were maintained on ambient seawater for the first 3 mo of the study. During this time temperatures ranged between 8–10°C ($\bar{X}$ = 9.53°C) for the first 4 wk, 11–15°C ($\bar{X}$ = 12.89°C) for the following 4 wk and 10.5–15°C ($\bar{X}$ = 12.47°C) for the third month. After this time, the animals were acclimated over a 2-wk period to 18 ± 1°C, the temperature at which the abalone were maintained for the remaining 34 wk of the 46-wk study. Physical measurements and hemocyte counts were assessed approximately every 8 wk over the course of the experiment. All moribund abalone or mortalities were sampled as above, including shell weight (SW) and shell volume (SV), and selected tissues (foot, digestive gland, PE, and kidneys) were processed for histology. The intensity of RLP infection and condition of the digestive gland and foot muscle were quantified as described above. The condition of the abalone was also assessed upon death using the body weight condition index of Friedman et al. (1997) = [(TW − SW)/TW]. In addition, the percentage of live tissue volume relative to the entire volume of the animal was determined = [(TV − SV)/TV].

Statistical Analysis

The Fisher's exact test was used to test the independence of exposure to WS and mortality; abalone were grouped as exposed or unexposed and as alive or dead. Chi square contingency table analysis (X^2) was used to test independence between exposure to WS and measured health parameters. Abalone were grouped as exposed (laboratory or field exposed) and unexposed. The following health parameters or responses were grouped as normal (scores of 3 for animal condition and that of the digestive gland and foot and 0 for RLP presence), whereas those with signs of WS and RLP infection were grouped as abnormal. Observed versus expected frequencies in each category were compared using 2 × 2 contingency table analyses. The Fisher's Exact test was used when fewer than five observations were observed in any cells. These analyses

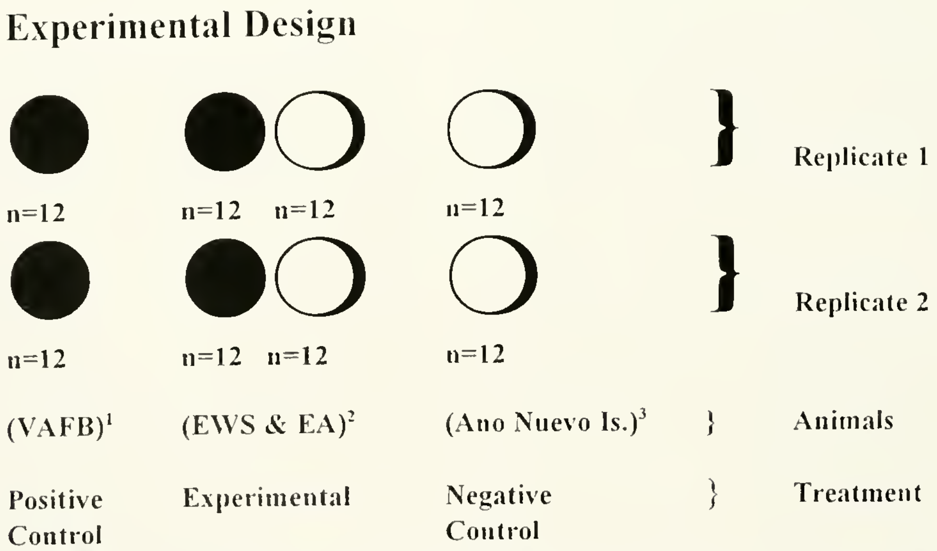

Figure 1. Experimental Design. The dark circles represent black abalone with WS collected from the field (Vandenberg Airforce Base or Cayucos (VBCS)). The open circles represent healthy, naive (no exposure to WS before study) black abalone from Ano Nuevo Island. [1]Animals with WS collected from Vandenberg Airforce Base and Cayucos in the positive control treatments. [2]Animals from VBCS (EWS) or Ano Nuevo Island (EA) with and without WS, respectively, in experimental treatments. [3]Animals in the negative control treatments without WS that were collected from Ano Nuevo Island.

were also used to test the independence of RLP infection and WS. Animals were grouped as infected and uninfected and as above for survival and health parameters. In a separate analysis to further assess the independence of specific lesions and RLP infection intensity animals were grouped as low overall infection levels (0–3) and high overall infection levels (4–6) and the response (e.g., metaplasia) was grouped as present or absent. Spearman rank correlation coefficients were calculated and tested for a (linear) relationship between intensity of RLP infection and condition of the digestive gland and foot, condition indices, density of circulating hemocytes, cumulative mortality, and time of exposure. Stepwise forward and backward regression models were used to predict the intensity of RLP infection in exposed abalone from the following variables: condition of the digestive gland and foot, weight condition index, visual condition assessment, and duration of exposure. Multiple logistic regression analysis was used to predict presence of RLP infection by using combinations of the five independent variables listed above.

RESULTS

All abalone from the PC treatment and all except three animals in the experimental treatment (EWS and EA) that died in this study had visible signs of WS, including weakness, weight loss, and visible atrophy of the foot muscle (Fig. 2). The two EA abalone in the experimental aquaria that died during the first week of the study lacked visual and histopathological signs of WS, RLP infections, or visible injuries. A third abalone from the experimental treatment that died during the 21st week of the study was too decomposed for gross or histologic examination. The six NC abalone that died during the experiment and 18 NC survivors sampled upon termination of the study did not have visible or microscopic signs of WS (Figs. 3 and 4). Both Vandenberg/Cayucos (PC and EWS) and Ano Nuevo Island (EA) abalone with clinical WS had histopathological and hematological signs of this disease, including degeneration and inflammation of and/or metaplastic changes in the digestive gland, depletion of muscle bundles in the foot, (Figs. 3–5), and the presence of necrotic cells, cellular debris, and small hemocytes (~4.5 μm) with a large nucleus to cytoplasmic ratio within the hemolymph. In addition, all PC and EWS animals and all except the two EA abalone that died during the first week of the study were infected with the RLP, whereas none of the NC animals were infected. Other than the nonpathogenic renal coccidian, *Margolisiella* (=*Pseudoklossia*) *haliotis*, no other parasites were observed in any of the abalone examined in this study. In this study, the incubation time for clinical WS is defined as the duration between initiation of the study and development of gross clinical signs such as mantle retraction or visible atrophy of the foot muscle. The mean incubation period for the EA abalone was 245 days ($n = 21$) with a range of 154–301 days. The duration between onset of visible signs of WS and mortality averaged 42 days ($n = 21$) with a range of 6–113 days. The two abalone that died during the initial week of the study from handling stress and the single animal that died at 21 wk did not show signs of WS or were too decomposed for assessment of WS, respectively, and were not included in these calculations. Cumulative mortality approached 100% in the PC aquaria, 85% of the EA animals in the experimental aquaria, and 25% in the NC aquaria (Fig. 6). A significantly higher proportion of abalone died upon exposure to WS (22/24) relative to unexposed animals (6/24; $P < 0.0001$, Fisher's exact test). Median time to mortality was significantly different between the exposed EA (41 wk) and PC (16 wk) abalone ($P < 0.0001$, Mann-Whitney test). As only a few NC abalone died during the study, median time to death was not calculated for this group.

A significantly higher proportion of abalone exposed to WS (EA and PC) had reduced condition indices, morphologic changes, and RLP infections than did unexposed animals (NC). Reduced condition indices were observed in 18/24 EA and 19/24 PC abalone, whereas only 3/24 NC animals lost condition ($P = 0.002$ and $P < 0.001$, respectively, X^2 test). Morphologic changes were observed in the digestive gland of 20/21 EA and 17/24 PC abalone, whereas only 1/24 NC abalone had an abnormal digestive gland architecture ($P < 0.001$, X^2 test). Of these, degeneration was observed in 14/21 EA and 6/10 PC animals, metaplastic changes in 9/21 EA and 4/10 PC abalone, and inflammation in 6/21 EA and 1/10 PC abalone, whereas 1/24 of the unexposed animals only had mild digestive gland degeneration. Pedal atrophy was observed in 15/21 EA, 17/24 PC, and only 1/24 NC abalone ($P = 0.001$ and $P < 0.001$, respectively, X^2 test). Infections with "*Candidatus* Xenohaliotis californiensis" were observed only in EA (22/21) and PC (24/24) treatments ($P < 0.001$, X^2 test and $P < 0.001$, Fisher's exact test). As above, significantly higher proportions of animals with RLP infections died and had clinical signs of WS than did unexposed abalone ($P < 0.001$, X^2 test).

Spearman rank correlation coefficients for relationships between intensity of RLP infection of individuals in each WS-exposed group (EA, EWS, and PC) versus visual condition, condition indices, condition of the foot and digestive gland, and density of circulating hemocytes were low and ranged between −0.275 and 0.486 for the Ano Nuevo Island animals and −0.0175 and 0.0567 for Vandenberg animals. Except for metaplasia and overall

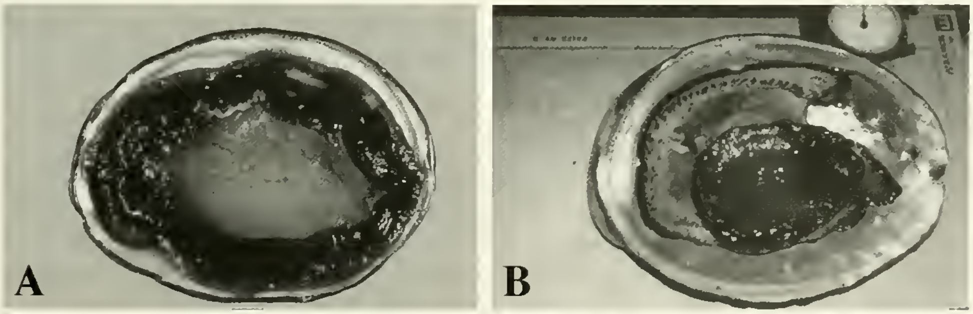

Figure 2. Black abalone with and without WS. A, Healthy animals from Ano Nuevo Island from a negative control treatment. B, An (EA) abalone from Ano Nuevo Island that contracted WS from infected black abalone in an experimental treatment.

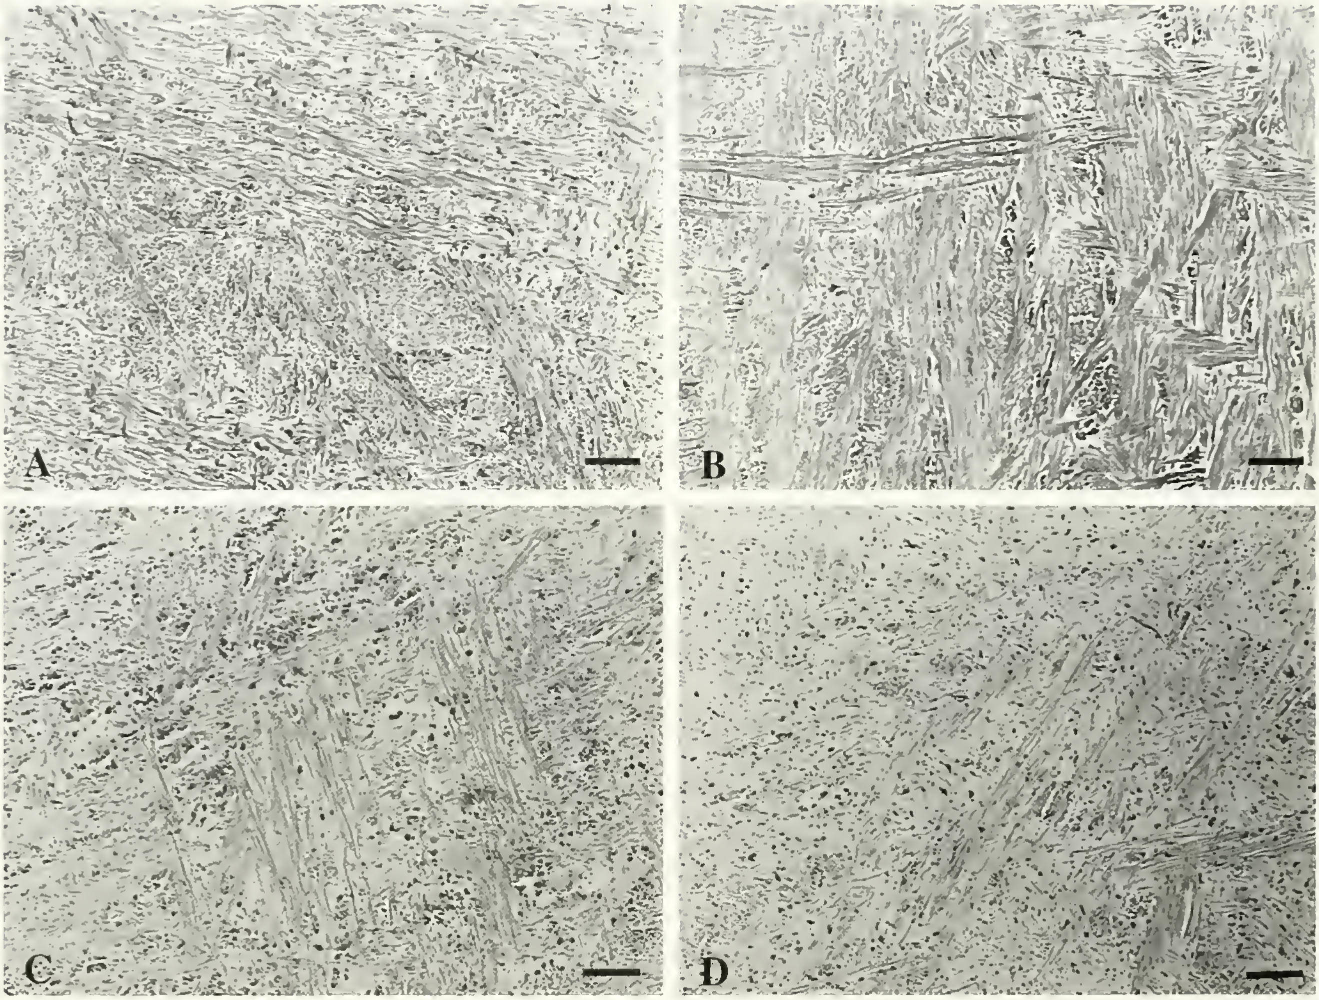

Figure 3. Microscopic anatomy of the foot muscle of black abalone with and without WS. The foot muscle of an uninfected animals are illustrated in A (Vandenberg abalone) and B (Ano Nuevo Island abalone). Note that dense bundles of muscle fibers comprise most the foot. The pedal muscle atrophy of an abalone that contracted WS in the field (C) is also observed in those that acquired WS in this laboratory study (D). Note the severe reduction in muscle fibers and increase in visible connective tissue in affected individuals. Hematoxylin and eosin, bar = 150 µm.

RLP burden in the EA abalone ($P < 0.05$), all coefficients were nonsignificant ($P > 0.05$). This relationship was also mirrored in X^2 analysis in which a higher proportion (8/9) of EA abalone with high overall RLP burdens (scores of 4–6) had metaplastic changes as the sole or partial response to RLP infections than did those with low (scores of 0–3) infections (1/7, $P < 0.01$). Several of the PC abalone were too necrotic to assess specific lesions in the digestive gland, a tissue that degrades more quickly than other tissues (Friedman, personal observation), and resulted in small samples sizes for this specific analysis. Intensity of RLP infection in laboratory EA abalone was predicted from the duration of exposure (time) with weight condition index, visual condition, condition of the foot and digestive gland, and time as independent variables in the model ($P = 0.0156$, Forward and Backward stepwise regressions). No prediction of presence of RLP infection could be made using Multiple logisitic regression analyses using all possible combinations of the five independent variables used in this study ($P > 0.500$). We did observe a significant correlation between hemocyte numbers and weight condition index of the EA abalone ($P = 0.0469$), PC abalone ($P = 0.0016$) and NC abalone ($P = 0.0015$). Correlation coefficients, however, were low to moderate and ranged between 0.2668–0.5612.

DISCUSSION

The present study describes the transmission of WS from black abalone with WS to previously healthy black abalone held in the same aquaria. The similarity in physical, histopathological, and hematological characteristics of WS between black abalone exposed to WS in the laboratory and field, combined with a lack of these signs in the negative control animals, confirmed that the experimental abalone contracted WS in this study (Haaker et al. 1992, VanBlaricom et al. 1993, Gardner et al. 1995, Shields et al. 1996, Friedman et al. 1997). These data also suggest that WS is directly transmissible between sympatric abalone by cohabitation.

WS is a chronic, slow-progressing malady in which clinical signs appear in the final stages of the disease. The presence of advanced microscopic morphologic changes throughout the pedal muscle and digestive gland of affected abalone supports this conclusion (Figs. 2–5). Our data also suggests a long incubation period for WS (~35 wk) followed rapidly by mortality (~42 days) under the conditions used in this study. As shown in Figure 6, once the animals developed clinical WS, the slopes of the mortality curves from the experimentally (EA) and field-exposed (PC) animals were very similar. However, median survival times between

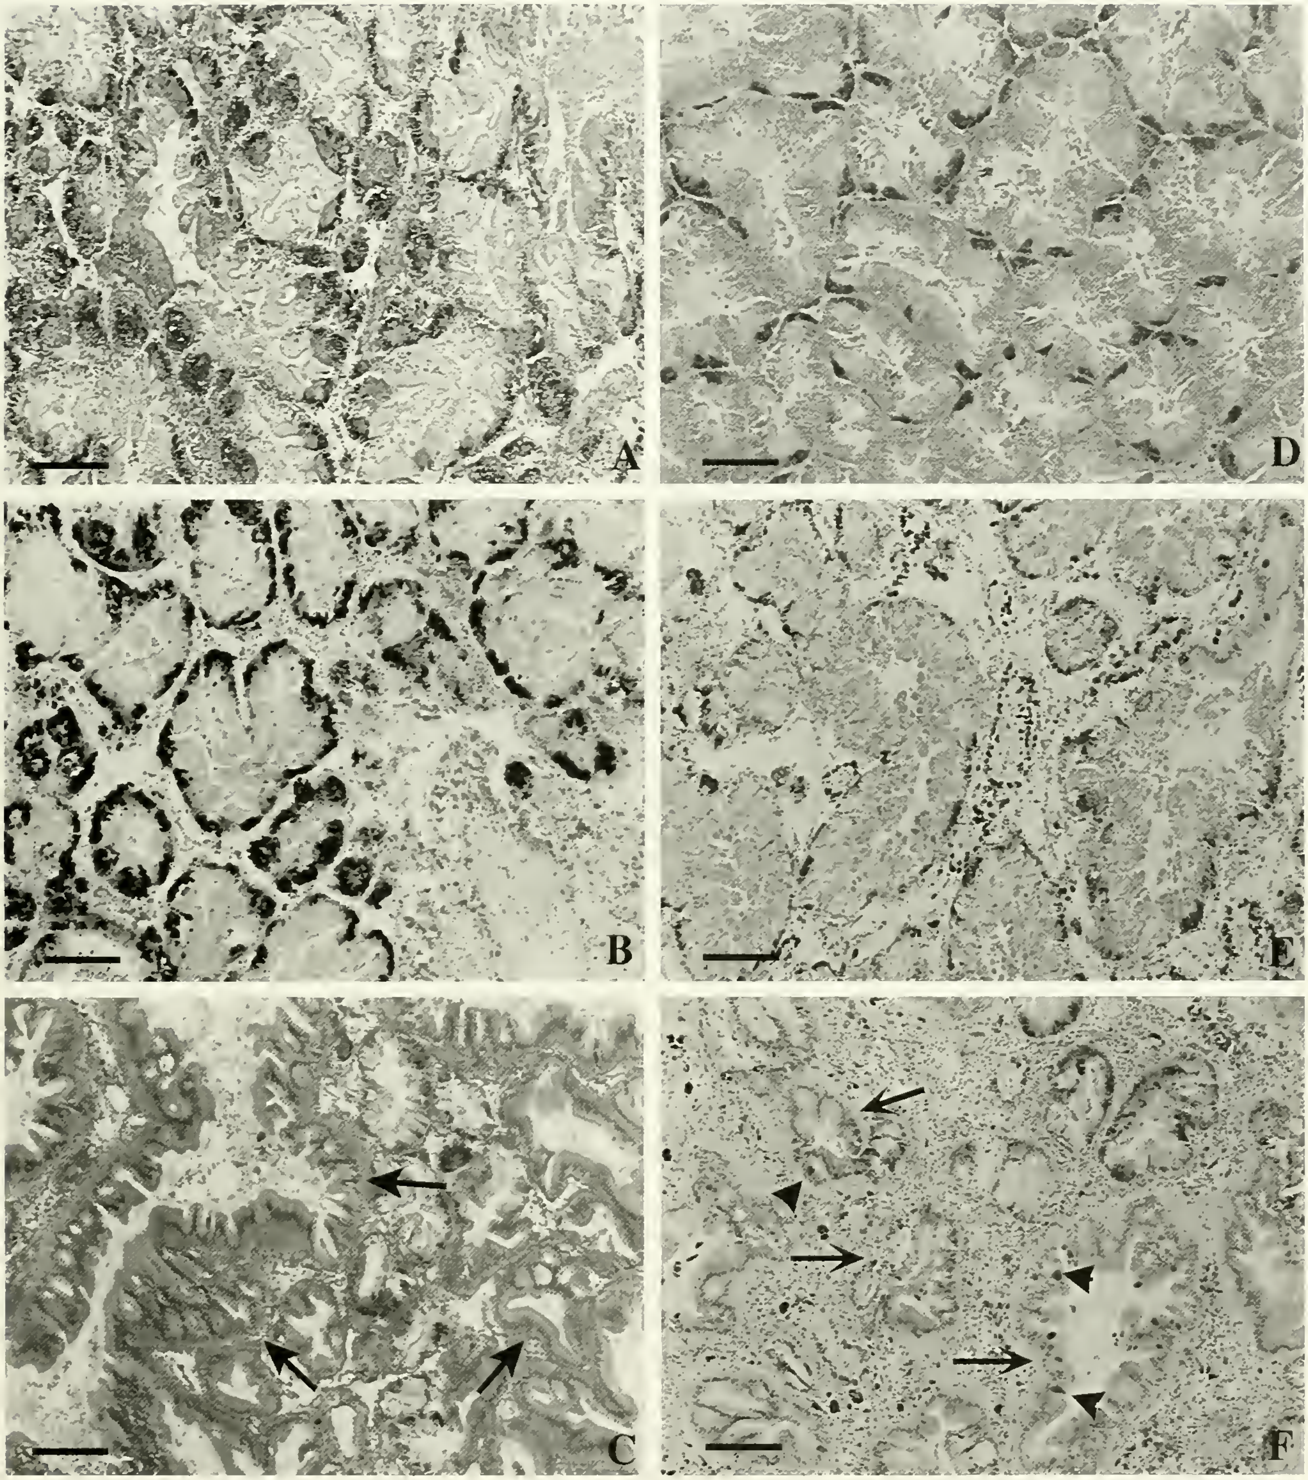

Figure 4. Microscopic anatomy of the digestive gland of black abalone with and without WS. The digestive gland of unexposed abalone from both Vandenberg (A) and Ano Nuevo Island (D) is composed primarily of terminal tubules and little transport/absorptive duct epithelia, whereas those of abalone that contracted WS in the field (B, C) and laboratory (E, F) show a reduction in numbers of terminal tubules and an increase in connective tissue and transport/absorptive duct epithelia. The digestive gland of some abalone with WS is characterized by an atrophy and loss of terminal tubules (B, E), while other individuals respond to RLP infection (arrow heads) with a transport/absorptive duct metaplasia (arrows; C, F). Hematoxylin and eosin, bar = 150 μm.

these two groups were quite different (41 wk for Ano Nuevo and 16 wk for Vandenberg/Cayucos animals) and may be due to a variety of factors. The Ano Nuevo Island EA abalone was uninfected before initiation of the study, whereas the Vandenberg and Cayucos PC abalone were in varying stages of WS. In addition, differences in susceptibility may exist between abalone from these geographically distant locations. In an earlier study in which asymptomatic but previously exposed black abalone were col-

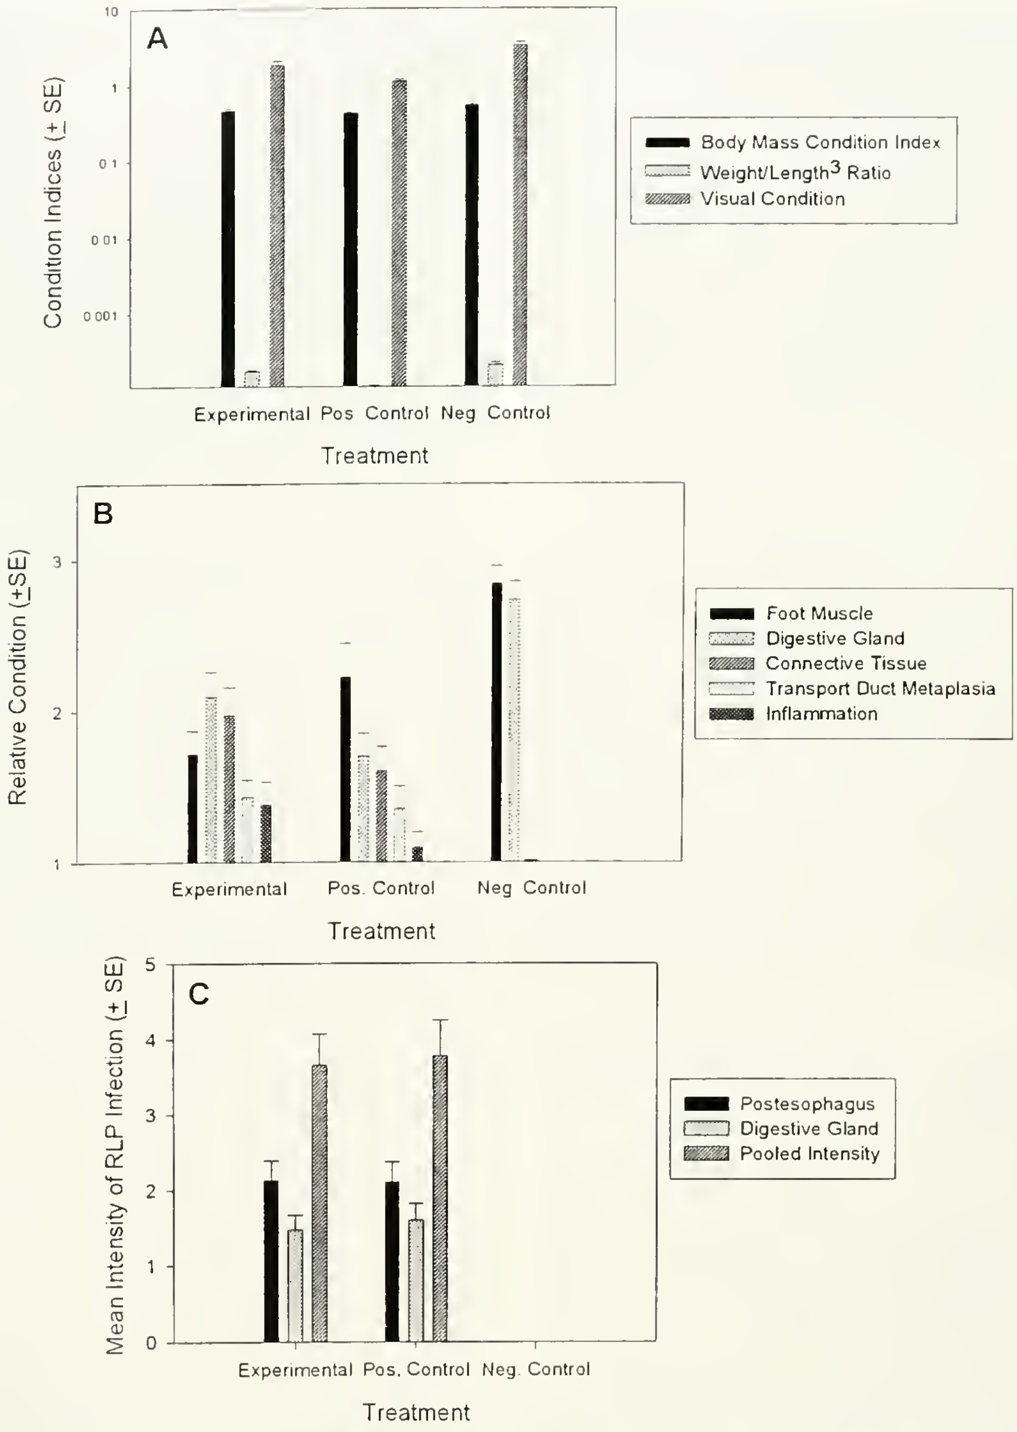

Figure 5. Microscopic morphologic changes of black abalone that acquired WS in the field (Pos. Control) or in the laboratory (Experimental) relative to unexposed (Neg. Control) animals. A, Animal condition; B, relative condition of the foot muscle and digestive gland, C, RLP intensity of infection. Each bar represents the mean of 12 abalone in each of two replicate treatments ± standard error (SE).

lected from Vandenberg and held at 18°C, the initiation of mortality at 15 wk was similar to that observed in the PC and EWS abalone in the current study and also supports a long incubation period for WS (Friedman & Fan 1998).

The observation of RLPs in the EA Ano Nuevo Island animals and not in the NC Ano Nuevo Island animals (Fig. 5) suggests that this bacterium, like WS, is horizontally transmitted by cohabitation and is the etiological agent of this disease. This is further supported by a lack of observation of any pathogens besides "*Candidatus* Xenohaliotis californiensis" in any abalone examined in this study. Transmission of this RLP is thought to be via a water-borne/fecal-oral route because of the presence of bacterial foci in the digestive epithelium and the observation of both intact and lysed RLP foci in lumina of the digestive tract (unpublished observations). Mortalities of the European Saint-Jacques scallop, *Pecten maximus*, have been associated with a branchial RLP infection (Le Gall et al.

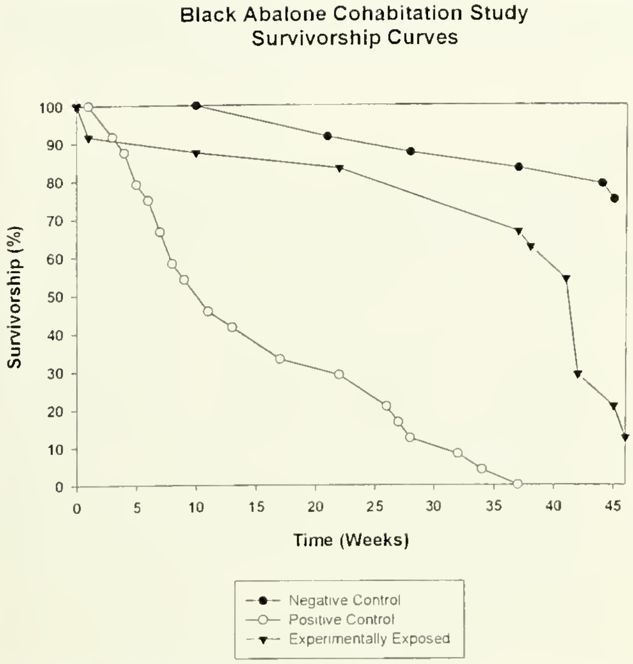

Figure 6. Survivorship curve of abalone in the cohabitation study. The closed circles represent the negative control animals, the open circles represent positive control animals, and the closed triangles represent the (EA) Ano Nuevo Island animals in the experimental treatment.

1988, 1991). Transmission of this scallop-pathogenic RLP via horizontal, water-borne transmission has also been documented (Le Gall et al. 1991). Field and laboratory studies suggested that transmission of the scallop RLP occurred between ~5–28 wk of exposure (Le Gall et al. 1991). Additional field studies reported heavy RLP infections in scallops during the winter months followed by mortalities in the spring (Le Gall et al. 1991), suggesting a relatively long incubation period for the scallop rickettsial disease as we have observed for the RLP-induced WS in this study.

The relationship between the RLP and WS in black abalone is complex as evidenced by higher proportions of mortality and clinical WS in groups of abalone either exposed to WS-affected animals or infected with the RLP. With one exception, a lack of significant correlation existed between intensity of RLP infection and WS in both the experimental and PC animals coupled with a lack of ability to predict intensity of RLP based on gross or histologic signs that characterize WS (regression models). The single significant positive correlation between overall intensity of RLP infection and degree of metaplasia in the EA abalone that responded, in part, with this morphologic change suggests that sustained high RLP burdens may lead to metaplasia in black abalone as has been observed in red abalone (Moore et al. 2000). This relationship was not observed in the small number (10) of PC abalone in which the presence or absence of metaplasia was quantified; the small sample size may account for an inability to detect a relationship. However, when the overall DG condition (alteration from normal, including all three specific morphologic changes) was assessed in the EA and PC, these relationships were not observed. This lack of correlation between RLP infection and DG overall condition in black abalone may relate to the host response to RLP infection (primarily degeneration of digestive tubules) (Figs. 4 and 5) combined with the high turnover rate of the target tissue (digestive epithelia) infected by the WS-bacterium relative to the bacterium's growth rate. Significant correlations between intensity of RLP infection and degree of WS have recently been observed in both field and laboratory studies using wild and cultured red abalone (Moore et al. 2000, Friedman, unpublished observation). The authors also suggested that differences in correlations between intensity of RLP infection and disease in red and black abalone might relate to species differences in host response to infections. Red abalone respond to the RLP infections predominantly by a metaplastic change in which digestive gland tubules are replaced by transport duct epithelium (Moore et al. 2000). Black abalone respond to RLP infection by a combination of digestive tubule degeneration and, to a lesser extent, transport duct metaplasia (Gardner et al. 1995, Friedman et al. 1997) (Figs. 4 and 5). Both of these tissue changes result in a loss of key functional tissue in the digestive gland, the terminal tubules (Voltzow 1994), which may lead to starvation and account for the utilization of foot muscle as an energy source followed by death as observed in abalone with WS (Friedman unpublished data.). As the RLP infects transport duct epithelia and not terminal digestive tubules, this may result in an increase in RLP intensity of infection in red and not in black abalone as the infections progress and clinical disease develops. Figure 5, however, does illustrate alterations in condition indices and changes in the condition of the foot and digestive gland only in abalone with RLP infections. This provides further evidence that the RLP is the etiological agent of WS. RLPs have been associated with atrophy and degenerative changes in other invertebrate species (Min & Benzer 1997).

Infections with RLPs have been reported in a variety of molluscs and crustaceans, including the sea scallop, *Placopecten magellanicus* Gmelin (Gulka & Chang 1984a), the blue mussel, *Mytilus edulis* Linné (Gulka & Chang 1984b), the manila clam, *Tapes japonica* Adams and Reeve and the Japanese scallop, *Patinopecten yessoensis* (Elston 1986), the European flat oyster, *Ostrea edulis* Linné (Friedman et al. 1989), the black abalone, *Haliotis cracherodii* Leach (VanBlaricom et al. 1993), and the penaeid shrimp, *Penaeus marginatus* Randall (Brock et al. 1986). These infections varied greatly in tissue specificity (nonspecific to highly specific), length of incubation period, and pathogenicity, ranging from no apparent harmful effects to lethal effects in the host (Gulka & Chang 1984a, Brock et al. 1986, Frelier et al. 1993, Gardner et al. 1995, Bower et al. 1996). In addition, the pathogenicity of a specific RLP has been shown to vary between host species (Brock et al. 1986). As in these studies, which document that RLPs are pathogenic for marine invertebrates, our data provides evidence that "*Candidatus* Xenohaliotis californiensis," the recently identified RLP observed in abalone in California, is the etiological agent of WS. Future studies that examine the interaction between host gastrointestinal cells and the RLP may provide insight into the cellular physiology of the host and the physiology and disease mechanisms of the bacterium.

C. de R. L. Av. Ryerson 117, 22820 Ensenada, Baja California, México*

ABSTRACT The yellow abalone *Haliotis corrugata* and the blue abalone *Haliotis fulgens* are caught in Baja California. Emerging diseases are affecting the fishery of abalone in several countries around the world. To determine the health status of the yellow and the blue abalone in Isla de Cedros and Islas San Benito in Baja California, México, a histopathological survey of commercial stocks of these species was conducted. The results showed the presence of bacterial foci in epithelial cells of the digestive tract resembling to the intracellular bacterium "*Candidatus* Xenohaliotis californiensis," considered to be the etiological agent of the Withering Syndrome (WS). The prevalence was higher in the blue abalone than in the yellow abalone, 100% and 63%, respectively; and their presence was not correlated with the external signs of WS. These bacteria were found in WS symptomatic and nonsymptomatic abalone. Protozoans and copepods were found between the branchial filaments, with a maximum prevalence of 79% and 37%, respectively; gregarines were also found with a prevalence of 29%. With the exception of the intracellular bacterium, the other organisms seem to be innocuous for the studied abalone.

KEY WORDS: abalone, *Haliotis fulgens*, *Haliotis corrugata*, histopathology, Rickettsia, withering syndrome

INTRODUCTION

Abalone production in Baja California (México) was 365 metric tons in 1998, reaching a value of about 36 million US dollars. The abalone fishery has been one of the main sources of economic resources in the Peninsula of Baja California. Currently, there are more than 1,300 direct employees involved in this activity (Ponce et al. 1998). Two species comprise 97% of this fishery, the blue abalone *Haliotis fulgens* and the yellow abalone *Haliotis corrugata*. Other abalone species included in this production are the black abalone *Haliotis cracherodii*, the red abalone *Haliotis rufescens*, and the white abalone *Haliotis sorenseni* (Ramade et al. 1998). During the last few years, an important decrease in the production has been recorded, which has been related to overfishing, inefficient application of management regulations, and environmental fluctuations that have favored the development of some diseases (Haaker et al. 1992, Vanblaricom et al. 1993, Olivas-Valdéz & Cáceres-Martínez 2002). In 1984, dramatic mortalities of California black abalone were recorded after the occurrence of El Niño. Lately, it has been suggested that the agent responsible for those mortalities was an intracellular bacteria from the order Rickettsiales (Gardner et al. 1995), tentatively named "*Candidatus* Xenohaliotis californiensis" (Friedman et al. 2000, Moore et al. 2000, Friedman et al. 2002). External signs in the abalone include reduction of the foot muscle in relation to shell size, loss of adherence capacity, and death. Because of the foot muscle appearance, these symptoms are called withering syndrome (WS) (Haaker et al. 1992). It has been suggested that very high temperatures may increase the mortality of abalone affected by the WS (Friedman et al. 1997). Other parasites that have been recorded in abalone species are the protozoan *Margolisiella* (= *Pseudoklossia*) *haliotis*, which infect the kidney and was first associated with the WS (Friedman et al. 1995), and the eukaryotic protist *Labyrinthuloides haliotidis*, which is pathogenic to juvenile abalone of *H. kamtschatkana* and *H. rufescens* (Bower 1987). Metazoan parasites such as the nematode *Echinocephalus pseudouncinatus* have been detected in *H. corrugata*, *H. fulgens*, and *H. cracherodii* (Milleman 1963). Damage to the host by these parasites varies and some of them cause severe mortalities (Bower et al. 1994).

Studies of the parasites and symbionts in abalone from México are scarce. These studies revealed a trematode belonging to the family Opecolidae in *H. fulgens* (Romero 1996), a boring clam in *H. fulgens* and *H. corrugata* (Álvarez-Tinajero et al. 2001), and the parasitic load of *H. rufescens* from a culture facility (Cáceres-Martínez & Tinoco-Orta 2001). The present study was conducted as part of a health evaluation of a commercial catch of *H. fulgens* and *H. corrugata* from Isla de Cedros and Islas San Benito, Baja California.

MATERIALS AND METHODS

In the first sampling (November 1997), 19 individuals of *H. corrugata* and 16 individuals of *H. fulgens* were obtained from Punta Norte, north of Isla de Cedros; in March 1998, 26 *H. fulgens* were studied from Islas San Benito; finally, in June 1998, 21 *H. corrugata* and 14 *H. fulgens* were obtained from San Agustín, south of Isla de Cedros (Fig. 1). Abalone species were obtained from commercial catches (mean size of 145 mm ± 1.73 SD) during commercial season when abalones are not in the reproductive stage. The external appearance of the abalone was recorded from a visual examination using a modification of the WS scale of Friedman et al. (1997) as: (0) no external symptoms, (1) from 1 to 10% reduction of the foot muscle in relation to the shell, (2) from 11 to 20% reduction of the foot muscle, (3) from 21 to 30% reduction, and finally (4) from 31 to 50% reduction of the foot muscle.

The visceral mass of the abalone was fixed whole in the Davidson's fixative (Shaw & Battle 1957) for at least 24 h. Seven transverse sections that contained portions of the digestive tract (pos-

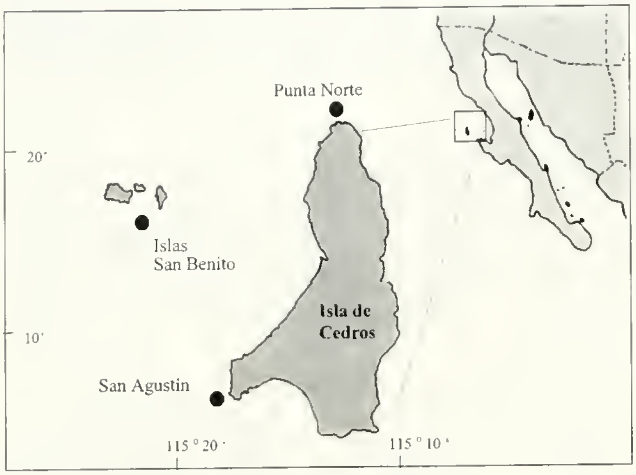

Figure 1. Map showing the sampling sites in Isla de Cedros and Islas San Benito, Baja California, México.

terior esophagus included), kidney, gonad, muscle, epipode, and gills were processed for histology. Sections of 5 μm were stained with iron hematoxylin and eosin (Gray 1954). The rickettsia-like prokaryotes (RLPs) infection intensity was estimated considering the number of bacterial foci in each histologic preparation at 200× magnification, which were enumerated using a modification of the scale of Friedman et al. (1997): (0+) no RLP, (1+) 1 to 10 RLP, (2+) 11 to 100 RLP, (3+) 101 to 1000 RLP, and (4+) >1000. Moreover, following the criteria of Friedman et al. (1997), the appearance of the digestive gland was marked as (1) normal tissues (see Antonio et al. 2000), (2) moderate tissue degeneration, and (3) severe tissue degeneration. Protozoa in the digestive tract and gill branchiae were counted in each histologic preparation. Prevalence of the other organisms was estimated as (number of infested abalone/number of abalone examined) × 100. The Mann-Whitney U Test was used to compare differences in the intensity of organisms per abalone species and the Spearman rank order correlation test was used to determine the relationship between degeneration of the digestive gland, intensity of RLP, and external signs of WS (Zar 1984).

RESULTS

RLPs

The RLPs were found in *H. fulgens* and *H. corrugata* in the three study sites. These bacteria infected the epithelial cells of the digestive tract, including the posterior esophagus, stomach, digestive diverticula, and intestine (Fig. 2a and b). The RLPs formed colonies inside a large vacuole in the cytoplasm of the infected cells. These colonies varied in shape from round to elongated and their size ranged from 17.5 × 10.8 μm to 24.3 × 10.2 μm. The host cell nucleus was displaced to the limit of the cytoplasm, the host cell became hypertrophied, and in a heavy infection there was a metaplasia of the epithelium within the digestive gland. Some host cells were disrupted and bacterial colonies were expelled to the lumen of the digestive tract (Fig. 2a).

Table 1 shows the RLP intensity of infection in *H. fulgens* and *H. corrugata* per studied site. The yellow abalone from Punta Norte showed a RLP prevalence of 63.2%; of these, 52.6% had a severe infection (3+ to 4+), including a moderate degeneration (2) of the digestive gland in 47% of the animals, whereas the remaining 52.6% of the abalone did not show signs of degeneration of the digestive gland. Blue abalone from the same area showed a RLP prevalence of 43.7%, with severe infection (3+ to 4+) in 31.3% of the animals. Only 12.4% of the infected abalone showed a moderate degeneration of the digestive gland (2). The results showed a higher grade of infection in yellow abalone than blue abalone, but this was not significant statically (U Mann-Whitney, $P = 0.33$). There was no significant correlation between the degree of degeneration in the digestive gland and the intensity of infection by RLP in the yellow and blue abalone species (Spearman rank order correlation $r = -0.19$, $P = 0.93$ and $\mathbf{r} = 0.34$, $P = 0.18$, respectively). This correlation was neither significant between the external signs and degeneration degree of the digestive gland (Spearman rank order correlation $r = 0.36$, $P = 0.12$ and $r = -0.23$, $P = 0.37$).

The blue abalone from Islas San Benito showed a RLP prevalence of 96.2%, and the infection was severe (3+ to 4+) in 92.4% of infected abalone. In 56.2% of these abalone the digestive gland was normal whereas the remaining 43.8% showed a moderate

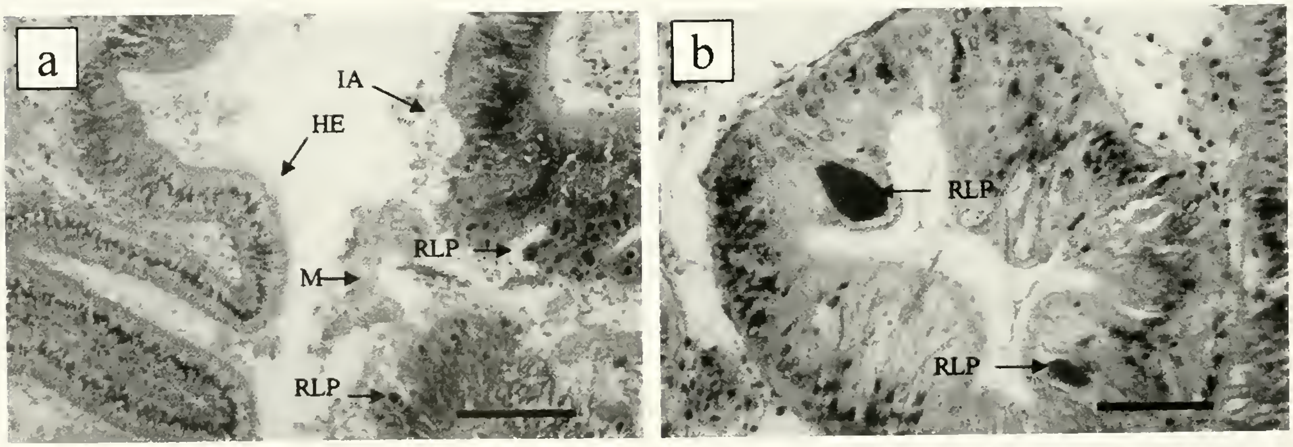

Figure 2. (a) RLP in the intestinal epithelium. An RLP-infected area is shown where the epithelium of the post-esophagus has lost its structure by hypertrophy of infected cells and rupture (IA). The epithelium in front is in normal condition (HE). There is mucus or cellular debris (M) in the intestinal lumen. Scale bar = 40 μm. (b) RLP in digestive diverticula. The hypertrophy of infected cells is compressing the neighbor cells. Scale bar = 20 μm.

degeneration (2). There was no significant correlation between the presence of RLP and degeneration of the digestive gland (Spearman rank order correlation $r = 0.34$, $P = 0.08$) or between WS external signs and the degeneration degree of the digestive gland (Spearman rank order correlation $r = 0.33$, $P = 0.08$).

The yellow abalone from San Agustín showed a RLP prevalence of 61.9% and the infection intensity was medium (2+) in 42.8% of the organisms. In relation to the degeneration of the digestive gland, 57.1% of the infected organisms had a moderate degeneration (2), 14.28% had a severe degeneration (3), and 28.6% had a normal digestive gland. There was no significant correlation between the RLP intensity and degeneration degree of the digestive gland (Spearman rank order correlation $r = -0.03$, $P = 0.86$). However, a sign correlation was observed between the external signs of WS and the degree of digestive gland degeneration (Spearman rank order correlation $r = 0.75$, $P < 0.001$). The blue abalone from the same area showed a RLP prevalence of 100%, with severe infections (3+ to 4+) in 57.2% of these abalone. Of the severely infected abalone, 28.5% showed a moderate degeneration of the digestive gland, 14.28% showed severe degeneration, and 57.14% showed a normal appearance of the digestive gland. In both species, the correlation between the RLP intensity and degeneration of the digestive gland was not significant (Spearman rank order correlation $r = 0.08$, $P = 0.75$), but it was significant between the WS external signs and the degeneration of the digestive gland (Spearman rank order correlation $r = 58.36$, $P < 0.001$). The infection prevalence from San Agustín was significantly higher in the blue abalone (U Mann-Whitney $P < 0.01$) but not from Punta Norte (Table 1).

Table 2 shows the percentage of both abalone species with external signs of the WS. At the microscopic level, all these organisms showed some tissue disorders, such as an increase in connective tissue between digestive tubules; lack of gonadal maturation and in a few occasions duct metaplasia or inflammation. The foot muscle showed a reduction in muscle fibers and loss of muscle bundle orientation, increase in connective tissue and infiltration by hemocytes. There was no correlation between the WS external signs and the presence of RLP in tissues (Table 3); in some individuals with WS external signs, infection by RLP was not detected (Fig. 3).

Ciliated Protozoan

A ciliated protozoan (Fig. 4a) was found in the mantle cavity and gill filaments of the yellow and blue abalone. The unidentified ciliates measured 26.5 μm × 12.7 μm. No histologic disorders or lesions were associated with these organisms. Prevalences were low in both species with 10.5% of the yellow and 6.3% of the blue abalones from Punta Norte (Table 4, Mann Whitney U, $P = 0.66$). Prevalences were higher at the other two locations where over 40% of the blue abalone from Islas San Benito and over 70% of both yellow and blue abalones from San Agustín were infested (Table 4, Mann Whitney U, $P = 0.25$).

Copepods

Copepods were found among the filaments of the gill where some compression and infiltration of hemocytes in the tissue was detected (Fig. 4b). The mean size of the copepods was 200 μm × 50 μm. Copepod prevalence in the yellow abalone from Punta Norte was 36.5%, there were no copepods in blue abalone from this locality. Copepod prevalence in blue abalone from Islas San Benito was 34.6%. The yellow abalone from San Agustín showed a prevalence of 19.0%, in the blue abalone only one copepod was recorded. There were no significant differences of copepod intensity between both abalone species (pooled data, U Mann-Whitney $P = 0.34$).

Gregarines

Low prevalences of trophozoites of a gregarine protozoan (Fig. 4c) were observed in the branchial epithelium, esophagus epithelium and kidney of the blue abalone (Table 4). The organisms measured 22 μm × 14μm and no host reaction against this protozoan was observed. Prevalences ranged between sites from 0 to a high of 28.7% (Table 4). The limited number of data precluded the use of a statistical test for comparison.

DISCUSSION

Cáceres-Martínez and Tinoco-Orta (2001) and Culver and Richards (1992) mentioned that the WS was observed in the black (*Haliotis cracherodii*) green (*H. fulgens*) and red (*H. rufescens*) abalone from Baja California, México; however, this is the first record of RLP infecting the tissues of *H. fulgens* and *H. corrugata*. The histologic appearance, shape, size, and targeted cells are similar to that of the intracellular bacterium "*Candidatus* Xenohaliotis californiensis" causing the WS in *H. cracherodii* and *H. rufescens* in California, (Friedman et al. 2000). Further characterization is needed to confirm this hypothesis, therefore molecular methods for RLP detection are necessary (Andree et al. 2000, Antonio et al. 2000).

The absence of a relationship between the intensity of RLP infection with the external signs of WS and the degeneration degree of the digestive gland in both abalone species was previously observed in studies on WS in black abalone (Friedman et al. 1997, Friedman et al. 2002). Moreover, Cáceres-Martínez and Tinoco-Orta (2001) found changes of the digestive gland (metaplasia) in red abalone infected by RLP but also in noninfected organisms. Only in San Agustín was the relationship between the WS external signs and the degeneration of the digestive gland significant. Friedman et al. (1997) and Friedman et al. (2002) showed that the WS disease agent requires a long incubation period before the external symptoms become apparent. This could help us to explain this contradictory result. Another possibility is the existence of subspecies or strains of RLP, some pathogenic and other nonpathogenic. Moreover, the external signs of the WS are not exclusive of this disease, other diseases or starvation conditions may result as external symptoms similar to those of the WS (Milleman 1963, Dixon et al. 1991); also, differences in susceptibility between abalone species and individuals are possible. Friedman et al. (2002) noted "studies that examine the interaction between host gastrointestinal cells and the RLP may provide insight into the cellular physiology of the host and the physiology and disease mechanisms of the bacterium."

Vanblaricom et al. (1993) also found a suctorian protozoan in gill squashes from the black abalone *H. cracherodii*, both in healthy specimens and in organisms affected by the WS. Ciliated protozoa are common in marine invertebrates, and most of them are considered as commensals (Lauckner 1983). Our histopathological results did not show any host response to the protozoa, and the low numbers suggested a lack of potential for a health problem.

To our knowledge, this is the first record of a copepod associated with abalone species. Copepoda and mollusk associations have been widely studied, *Mytilicola intestinalis* and *Pseudomyicola spinosus* are two of the most studied copepods associated with bivalve mollusks. These copepods may produce severe damage to the epithelial cells of the digestive tract, they may produce encapsulations in the connective tissue of the digestive gland, and they may produce obstruction and rupture of reproductive follicles (Sindermann 1990, Olivas-Valdéz & Cáceres-Martínez 2002). In this study, no evidence of copepods inside of the abalone digestive tract was found, but some inflammation in the gills of abalone was observed in some cases. Their prevalence suggests a symbiotic association but more studies are needed for determining a kind of interaction between the copepods and the host.

In the blue abalone, we recorded the presence of gregarines in the renal tissue and no histologic evidence of reaction of the host against the protozoan was observed. Some authors (Vanblaricom et al. 1993) found similar protozoa in the black abalone, *Haliotis cracherodii* from California and from Baja California, México. In both studies, no evidence of pathogenic activity was found. A similar gregarine infection has been observed in mussels, oysters and other marine bivalves, in some cases the infection has been associated with a focal, benign inflammatory response, without significant health effects (Bower et al. 1994).

AKNOWLEDGMENTS

The authors thank Rafael Muñoz Gallardo and Amado Castro from the Cooperative Pescadores Nacionales de Abulón for an agreement with CICESE for the financial support of this work.

ABSTRACT The effect of the 1997–98 El Niño on the snail Astraea undosa population along the Baja California western coast on biomass changes in June 1997 and July 1998 was evaluated. In 1998, dead snails >40 mm basal diameter were collected and their basal diameter measured. Individual weight and density (snails/10 m^2) decreased significantly in 1998 from those registered in 1997, with an average 47% decrease in biomass. We discuss the possible causes of those changes as a function of the disappearance of the Macrocystis pyrifera forest and of an extended period of positive anomalies of the sea surface temperature that were present previous to July 1998.

KEY WORDS: El Niño 1997–98, snail, *Astraea undosa*, biomass, Baja California.

INTRODUCTION

The 1997–98 El Niño has been considered the most intense of the twentieth century (Kerr 1998, McPhaden 1999). It was detected along the Baja California western coast through positive anomalies of the SST >3°C. In July 1998, we observed dying as well as dead snails *Astraea undosa* (Wood) in the intertidal zone and in fishing banks. No kelp forests *M. pyrifera* (Agardh) were found in Bahía Tortugas from October 1997 to April 1998 (Ladah et al. 1999). This species together with *Eisenia arborea* (Aresch) are the food source and habitat of *A. undosa*, *A. turbanica* (Dall), and other species of herbivores of commercial interest such as the abalone *Haliotis fulgens* (Philippi) and *H. corrugata* (Wood) (Guzmán del Próo et al. 1991).

In July 1998 we monitored the *A. undosa* populations located on the Baja California peninsula western coast to evaluate the effect of the 1997–98 El Niño. This region carries the highest abundance of *A. undosa*, where >80% of its catch is obtained (Gluyas–Millán et al. 2000). The size structure of live and dead snails, average size and weight, density and biomass of July 1998, were contrasted with those obtained from the same fishing banks in June 1997. We assumed that the sampled snails in July 1998 reflect the effect of the 1997–98 El Niño.

MATERIALS AND METHODS

The study area is located between Punta Eugenia (27°51′N–115°04′W) and Bahía Asunción (27°08′N–114°17′W) (Fig. 1). The area was divided into three zones and three fishing banks were selected out of each one (Table 1). We believe the selected geographical area was adequate because it is the main area of abundance of *A. undosa* in its distribution range along the Baja California western coast, and also because of the accessibility of the sampling places, and because this is where the main snail fishing banks are located. Monitoring was done in June 1997 and in July 1998 in the same places. As an environmental indicator of the 1997 to 1998 El Niño conditions we used the SST monthly anomalies of 1996 to 1998 from the deviations of the monthly average of the ten-year period before 1997 for the Bahía Tortugas area. The SST values were extracted from NOAA COADS records (Comprehensive Ocean and Atmospheric Data Set) for the Bahía Tortugas area.

The corners of the polygons that comprise the area fishing banks were estimated using a GPS receiver (Garmin model 45XL) (Table 1). The monitoring in June 1997 and July 1998 consisted of conducting up to 10 dives at each fishing bank (a, b, c), using a Hooka diving equipment at depths between 5 and 20 m. In each dive, all snails inside a 10-m^2-sample unit (SU) were taken and the basal diameter (BD) of each snail was measured, grouping them in intervals of 5 mm to obtain the size frequency distribution. A subsample was obtained by randomly selecting up to five snails of each size interval and measurements were made of the BD of the shell (±1 mm) and the weight (±1 g) of the adductor muscle to estimate the biomass.

The area of each fishing bank was transformed to SUs. Snail density for each fishing bank was stratified according to the snail number frequency distribution in each SU (Cochran 1978). The number of density intervals (DI) was determined with the Sturges rule (Daniel 1984).

An estimate of the population total abundance of snail was obtained according to the estimators of the random stratified sampling technique (Schaeffer et al. 1987, Conquest et al. 1996):

Average population estimate was

$$\bar{y}_{st} = \frac{1}{N} \sum_{i=1}^{L} N_i \bar{y}_i$$

Total abundance population estimate was

$$N\bar{y}_{st} = \sum_{i=1}^{L} N_i \bar{y}_i$$

Where N = total number of SU, N_i = SU number in the fishing bank$_i$, L = number of density intervals, i = density interval average.

From the total population abundance estimation, the biomass was calculated by size interval with the following relationship:

$$BIT = (\alpha T^{\beta}) * \left(\sum_{i=1}^{L} N_i \bar{y}_i \right) * \Phi_T$$

where BIT = size interval biomass, α and β = weight-size relationship parameters, $(\sum_{i=1}^{L} N_i \bar{y}_i)$ = biomass in snail numbers, Φ_T

III c	Isla San Roque	75,000

= relative frequency accumulated by size interval from total snails measured.

The total biomass for all the size intervals was estimated by:

$$Bt = \sum_{T} BIT$$

To determine the empty shells of snails from individuals that died in 1998, and that did not come from the commercial catch of that year or earlier, observations of presence-absence of fauna and flora epibiotics were made inside the shell. Additionally, we know that the snails are not killed in the fishing banks, and furthermore the snail-fishing season was suspended in 1998, except in Bahía Tortugas and Isla Natividad. The latter is 7.5 km NW off Punta Eugenia (Fig. 1).

RESULTS

In July 1998 we observed that *A. undosa* snails at depths of 5 to 20 m were dying. In addition empty shells were found in the intertidal zone, and few *M. pyrifera* stalks between Punta Eugenia and Bahía Asunción. July 1998 was preceded by a period of intense warming, the SST rose to 26°C (Fig. 2A). SST positive anomalies >3°C persisted from September 1997 to January 1998 (Fig. 2B) and the *M. pyrifera* forests disappeared in Bahía Tortugas. The June 1997 monitoring was not preceded by conditions of intense warming (Fig. 2A, B), and the snails showed normal conditions, the appearance of the adductor muscle was not flabby as in July 1998; dead snails were not observed, and the *M. pyrifera* forests were present.

Dead snails in the intertidal area in July 1998 showed remains of viscera, a flabby adductor muscle, the opercula fixed to the muscle, and absent epibiotic fauna and flora in the shell internal surface. This indicates that these snails were not the product of fishing and that they had recently died.

In each sampling zone in July 1998, the range and the size frequency distribution of the living as well as of the dead snails were similar ($P > 0.05$, KS-test) (Fig. 3): indicating the 1997–98 El Niño affected proportionally those snails whose BD was >40 mm. This result is reinforced when contrasting the size frequency distribution of 1997 and 1998 (Fig. 3), which showed no significant differences ($P > 0.05$, KS-test). This suggests that the effect of El Niño 1997 to 1998 was not selective for snails >40 mm BD.

In 1997 and 1998 the mean BD of the live snails by zone was not significantly different ($P > 0.05$, t-test) (Fig. 4). This confirms the previous results that indicate an effect on the population without size selectivity. The mean individual weight, density, and biomass were significantly greater in 1997 than in 1998 (Fig. 4) ($P < 0.05$, t-test). This shows a negative effect on individual weight and density of the snail and in consequence the 1998 biomass decreased. The magnitude of the biomass was variable among the zones because of the different area sizes (Table 1). The biomass decreased 47% on average in 1998 as compared with that registered in 1997. Because of this decrease, the commercial catch season was suspended in 1998 in most of the study area.

Observations made in June 1998 of the *A. undosa* stomach contents indicated important proportions of silt and crustose cor-

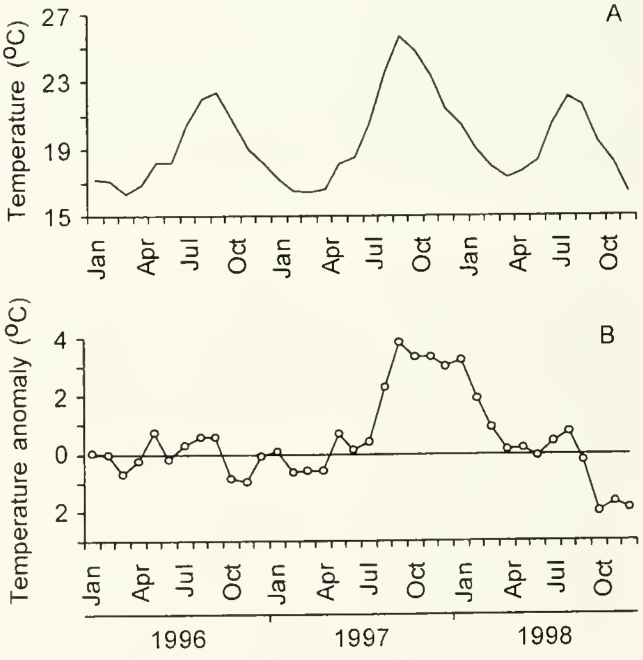

Figure 2. (A) Monthly sea surface temperature (SST), and (B) SST anomalies from 1996 to 1998. Data obtained from NOAA COADS records of the Bahía Tortugas area.

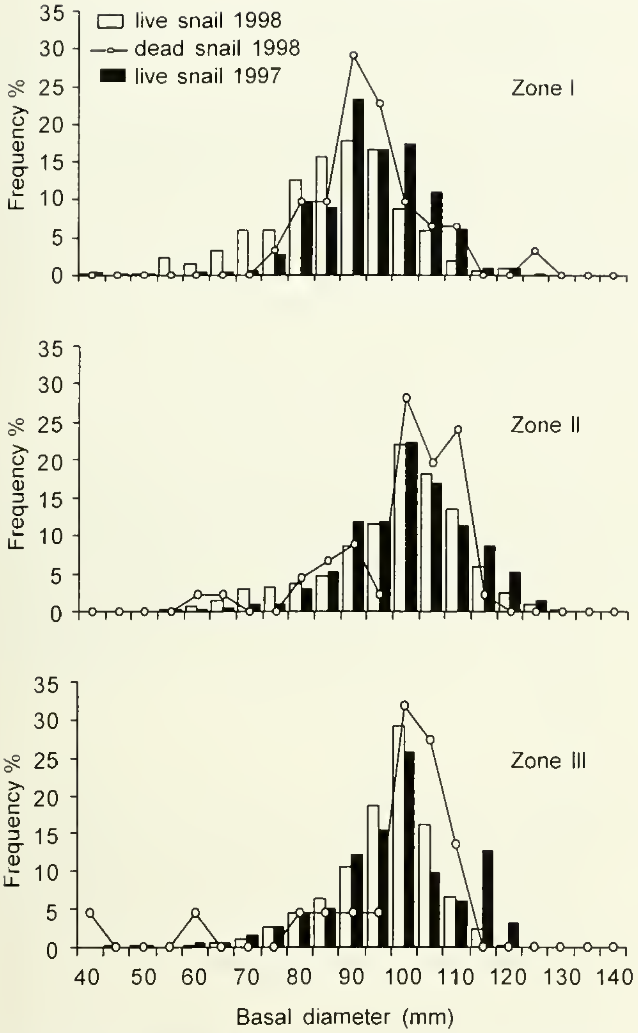

Figure 3. Size frequency distribution of the snails *Astraea undosa* from the Baja California western coast in June 1997 and July 1998.

alline algae (*Lithothamnium* or *Lithophylum*), articulated coralline algae (*Bossiella orbigniana* [(Manza) Johans], and *Corallina officianalis* [L.]). They were the predominant flora then and are of temperate and subtropical affinity (Guzmán del Próo et al. 1991). These algae covered a great extension of the rocky surface at all the levels of the sampling depths. In June 1997 the diet components were varied, and we observed in the snail stomachs an important proportion of *M. pyrifera*, which was still present in the area (Raúl Reyes Tisnado, pers. com.). It was not possible, however, to quantify the stomach contents.

DISCUSSION

Though the 1997–98 El Niño was detected from summer 1997 in the northern Pacific Ocean (Liu et al. 1998, Connolly & Roughgarden 1999), its impact on the *A. undosa* population along the Baja California western coast was not evident until the summer of 1998, when it became obvious that the biomass of snails had decreased and dead snails were seen. These events were also reported at La Bocana, 70 km south of Isla San Roque (Daniel Aguilar Osuna, pers. com.).

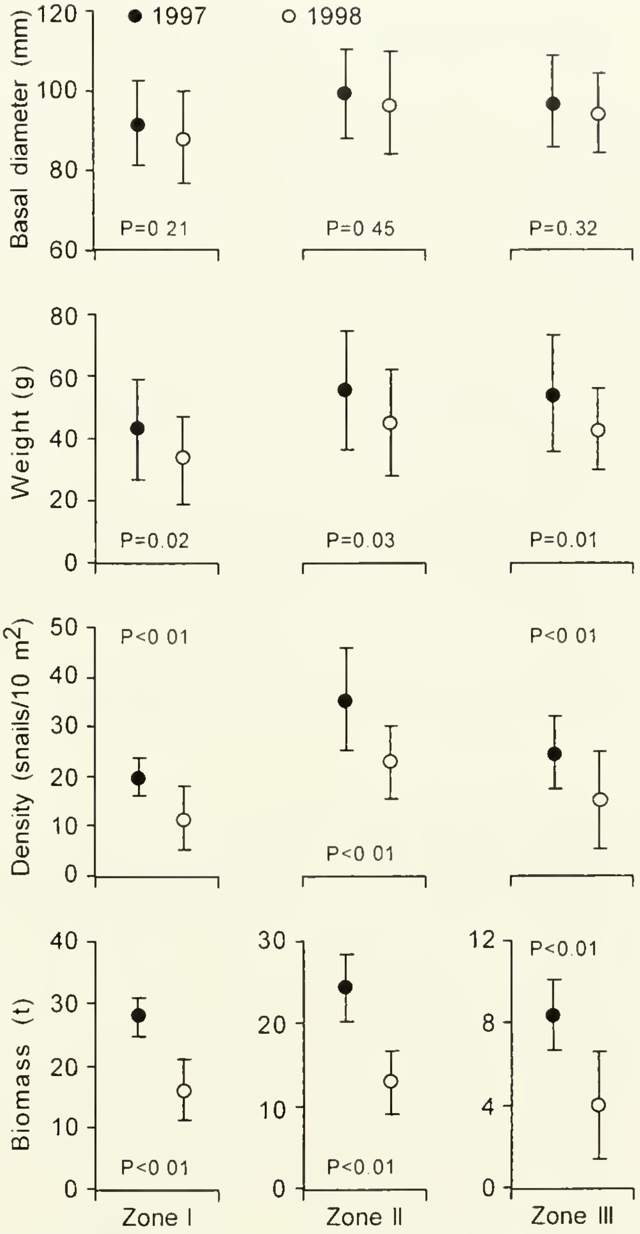

Figure 4. Average and standard deviation of the basal diameter (mm), individual weight (g), density (snails/10 m^2), and biomass (t) by sampling zone of the snail *Astraea undosa* from the Baja California western coast in June 1997 and July 1998.

The results and the observations suggest that the observed mortality and the diminished biomass that occurred in 1998 were caused by weakness and starvation because of the absence of *M. pyrifera*, and a possible long-warming period temperature effect that contributed to the disappearance of kelp forest (Ladah et al. 1999). Nearly all snails >40-mm BD are mature individuals, because the minimum reproductive size is attained at 58-mm BD (Belmar-Pérez et al. 1991). Those snails would be >2-years-old according to the BD-age relationship reported by Gluyas-Millán et al. (2000). The individuals <40 mm-BD are in the cryptic phase (Gluyas-Millán et al. 1999, Gluyas-Millán et al. 2000) and they were not observed in the study period.

The biomass decrease of the *A. undosa* population from 1997 to 1998 was the result of both an increased natural mortality and decreased individual weight and can be attributed to two factors: 1) The prolonged disappearance of the forests of *M. pyrifera* from October 1997 to April 1998 (Ladah et al. 1999) affected the habitat and the food availability of *A. undosa*. This alga is one of the main food sources of *A. undosa* (Guzmán del Próo et al. 1991) and also provides protection against predators; and 2) The physical factors associated with 1997–1998 El Niño had a density-independent influence because their potential effect in each member population >40-mm BD is the same regardless of population size (Sissenwine 1984). Therefore, the increase of SST and the change of the predominant diet components could have affected the mollusk physiology and consequently its growth efficiency.

The decrease of the 1998 snail biomass resulted in an important economic loss for the fishing sector. Because of the low yields and the poor quality of the adductor muscle fishing ceased at most of the fishing banks. These fishing yields decreased from 166 t in 1997 to 44 t in 1998.

El Niño negative effects have been documented in the eastern Pacific Ocean on the productivity, abundance and distribution of invertebrates, the recruitment failure of some fish, and the devastation of the *M. pyrifera* forests (Lenarz et al. 1995, Teagner & Dayton 1987, Ladah et al. 1999). There are also positive effects in the recruitment of the balanus *Balanus glandula* and *Chthamalus* spp. along the California coast attributed to an increase of the transport toward the coast (Connolly & Roughgarden 1999).

For *A. undosa* along the Baja California western coast, the 1997–1998 El Niño negatively affected its survival. The effects of this on the structure and function of the *M. pyrifera* forest ecosystem where *A. undosa* is an important species, cannot be ignored, even when the consequences of these impacts on the structure and function of the ecosystem are difficult to quantify (Gislason et al. 2000). Moving from population to the ecosystem level increases complexity and we lack the general rules to help us predict changes in the abundance of the interacting species (Lawton 1999). However, the annual evaluations of the *A. undosa* biomass from the National Institute of Fishing (INP-Mexico) will allow the evaluation of the recovery of *A. undosa* associated with the *M. pyrifera* forests.

ACKNOWLEDGMENTS

The authors thank Ramón Hernández, from CRIP-La Paz, for his collaboration during the monitoring. We also thank the technicians and members of the following fishing cooperatives for their support in the collection of the biologic material: SCPP "Bahía Tortugas", SCPP "Emancipación" and SCPP "California San Ignacio". CQV was supported by COFAA-IPN and CONACYT-México. Thanks to Dr. Ellis Glazier who edited the English-language text, and two anonymous reviewers for advice and editorial help.

ABSTRACT Based on the information from catches in Contoy, QR, Mexico (February–December 1993), the reproductive cycle of the spotted pink shrimp, *Farfantepenaeus brasiliensis*, is described. Population size structure shows that fishery exploitation affects small sizes. Females were more numerous than males, particularly during months of greatest reproductive activity. The period for ripe females period occurs from February to August, peaking in March and April. Main recruitment offshore follows from this spawning population. The estimated size at first reproduction averaged 148 mm. According to this estimation, 65–80% of the females have not been able to reproduce at least once before being caught. We observed a significant relationship (Pearson $P = 0.05$) between the larger size shrimps and a proportionally larger number of ripe females with depth from February to August. Based on catch-per-unit-effort indices (CPUE) of ripe females, we propose the region located between 21°40′ to 22°10′N and 86°30′ to 86°50′W, at depths of approximately 25 to 40 fathoms (33 to 59 m) as the main spawning area for the spotted pink shrimp, *F. brasiliensis* in the northeast region of Contoy, QR, Mexico.

KEY WORDS: spotted pink shrimp, reproductive dynamics, maturity, sex ratio

INTRODUCTION

The spotted pink shrimp, *Farfantepenaeus brasiliensis* Latreille 1817, is a commercially important species in Mexico where the main fishery is located in the Mexican Caribbean along the coast of the state of Quintana Roo. This important commercially area is near the northern end of the species geographic distribution which extends from Florida, USA, to the Rio Grande do Norte in Brazil (Pérez-Farfante 1969, 1988).

In the Mexican Caribbean, *F. brasiliensis* is the target of a trawl fishery. Landings also consist of rock shrimp, *Sicyonia brevirostris*, which is of lesser commercial importance and represents approximately 55% of the total catch. Recorded production of spotted pink shrimp is low compared with the penaeid shrimps harvested in the Gulf of Mexico (*F. aztecus, F. duorarum and Litopenaeus setiferus*). However, fishery exploitation of the spotted pink shrimp represents an important regional activity accounting for more than 45% of the crustacean production of the state (Anonymous 1995).

The annual landings of spotted pink shrimp have declined since 1984–1987, when maximal production was attained (309–474 Metric tons), falling to less than 200 tons during recent years. Similar to other tropical penaeid stocks (Gracía et al. 1997), the spotted pink shrimp, *P. brasiliensis*, has reached its maximal sustainable exploitation levels, or even surpassed them, posing serious problems for the resource. Despite its regional importance, the spotted pink shrimp fishery has not been described adequately, and the available literature about its biology and ecology is scarce. There have been some previous studies about growth (Arreguín Sánchez 1981a), gonad development (Sandoval-Quintero and Gracia 1998), general distribution (Porras-Ruiz et al. in prep.) and some fishery aspects (Arreguín Sánchez 1981b, Soto-Aguirre in prep.), but information about main population processes is still lacking.

Basic information on the reproductive biology of this species is needed to establish adequate management policies to sustain this resource. This study presents data on the temporal pattern of reproductive activity and distribution of females of *F. brasiliensis* in different stages of gonadal maturation in relation to depth.

STUDY AREA

The *F. brasiliensis* fishery in Quintana Roo, Mexico operates for most of the year, except for the closed season which occurs around August and September since 1994. The main fishing location is on the continental shelf of the Yucatán Peninsula, northeast of Contoy Island, between 21°27′ to 22°18′N and 86°34′ to 87°01′W (Porras-Ruiz et al. in prep.). The marine bottom is sandy, with large coralline formations that limit the operation of trawlers to regions locally called "blanquizales" which are free from rocks and corals. It is reported that *F. brasiliensis* is also distributed over coralline bottoms, hence part of the population is not subjected to fishing gears (Soto-Aguirre in prep.).

MATERIAL AND METHODS

Spotted pink shrimp were collected from the fishing area of Contoy from February to December 1993 onboard shrimp trawlers. The monthly information obtained consisted of: sampling coordinates, depth and duration of each of the tows, total length of the shrimp (TL, measured from the tip of the rostrum to the tip of the telson, at a 0.5 mm precision), sex, and gonadal stage of females by visual inspection according to a gonad color key based on a dissecting analysis (Silva Neto et al. 1982, Sandoval-Quintero and Gracia 1998). The calculated appropiate minimum size of the monthly sample taken from the commercial catch was 90 individuals (Daniel, 1987), at a confidence level of 95% ($P = 0.05$). Sex ratio for each month was analyzed through a χ^2 independence test (Méndez et al. 1984).

Periods of greatest reproductive activity during the year as demonstrated from the commercial catch were determined from an analysis of gonadal development of females. Females were grouped according to maturation stage as non-ripe (I and II) or ripe (III and IV) to avoid misclassification of gonadal stage determination. The last two stages indicate proximity of the spawning period, and can only be distinguished precisely by histologic sectioning of the gonads (Sandoval-Quintoro and Gracia 1998).

We used catch-per-unit effort (CPUE) as an index of abundance of these stages to analyze variations in the proportion of non-ripe and ripe females, estimating it monthly from each tow in the following manner: $[\mathrm{CPUE}_{\mathrm{I,M}}] = (n/t)(\%\mathrm{I,M})$, where n = number of females in the sample, t = duration of trawl (hr) and %I,M = percentage of non-ripe (I) or ripe (M) females, expressed in terms of total number of females per hour towed.

Size at first maturity was defined as mean total length of females when 50% had reached maturity. The relationship between size distribution and depth was analyzed through a linear regression analysis (Zar 1974, Bhattacharya & Johnson 1977). We calculated the correlation coefficient (r) to determine whether there was a statistical association between the gonad stage and depth for those months in which the variables were not independent (Everitt 1977). Localities were classified arbitrarily according to whether they yielded >50% non-ripe or ripe females.

RESULTS

Population Size Structure

Total length for entire study ranged from 35 to 205 mm both sexes, with females typically reaching greater maximum lengths than males (Fig. 1). Both sexes size distribution was unimodal during most of the months. When two modes were found they corresponded to large females and small males groups.

Male and female size distribution varied along the period studied (Table 1). Usually female modal sizes were greater than 140 mm TL. Female average total length varied from 129 mm (inmature females) to 166 m (ripe females). Male average lengths varied from 116 to 133 mm TL. Modal frequencies were close to the average in most of the months. May and September modes suggest the presence of two cohorts (Fig. 1).

Sex Ratio

Sex ratio varied in the months sampled (Table 2). Females prevailed in the months of March to May and in July. Males prevailed in February and August and from October to December. The χ^2 test for independence revealed significant differences (χ^2_{obs} = 276.8; χ^2_{tab}, 0.05 = 18.307) in the sex proportions during the year.

Size of First Reproduction

The size at which 50% of the females are mature was estimated as 148 mm TL (Fig. 2). However, mature females with a minimum size of 95 mm were found in February and March, while a minimum size of 105 mm was observed in April. In the other months, minimum sizes of mature females ranged from 110 to 125 mm TL.

Distribution of Females on the Fishing Ground

A significant correlation (Pearson $P < 0.05$) between increasing mean size of spotted pink shrimp females and increasing depth of capture (Table 2, Fig. 3) was found from February to August. In most cases the relationship was positive, except in August when large females were found at shallower depths.

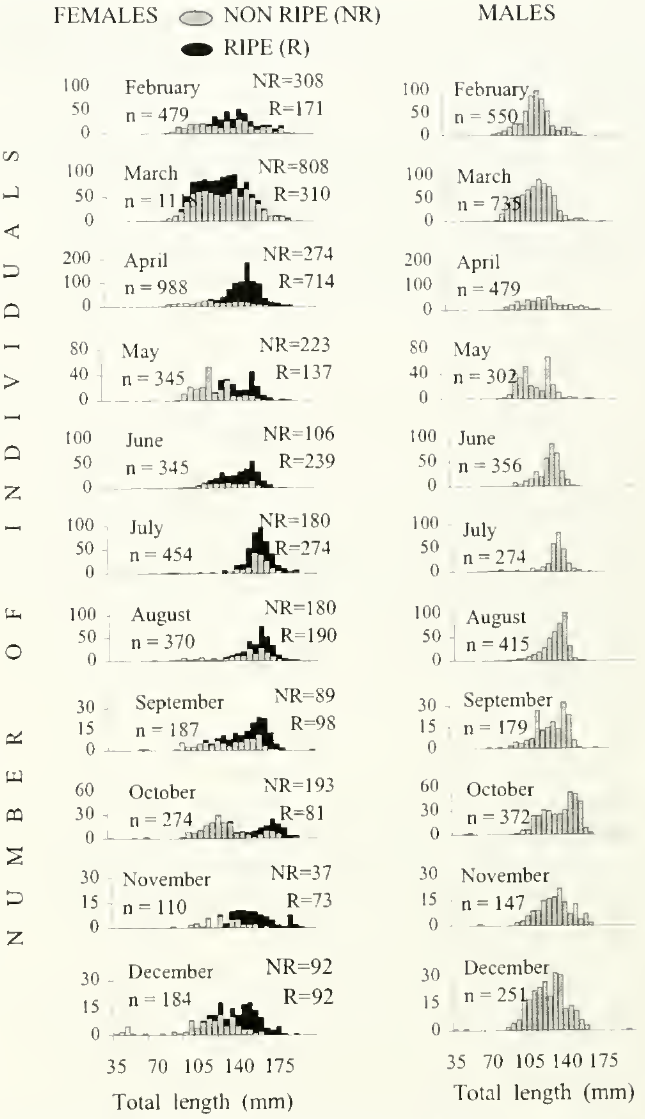

Figure 1. Size structure of the spotted pink shrimp, *F. brasiliensis*, stock from February to December 1993.

The degree of ripeness of the females and the depth showed a significant linear relationship (Pearson $P \leq 0.05$) from February to May and during July and August. April, May, July, and February yielded positive correlations between the degree of ripeness and depth. The inverse condition was observed in March and August.

During all months, except March, at least one area was found in which more than 50% of the females were ripe. From February to June ripe females were more widely distributed. In March, no area had high percentages of ripe females; however, the CPUEs in some of the areas were among the highest (17, 20, 28 ripe females/hr towed) along with those observed in April (13–20 ripe females/hr towed).

Sites with larger CPUE for non-ripe females occurred in February (8–15 and 15–20 non-ripe females/hr towed) and March (35, 45, 52 non-ripe females/hr towed). During other months, these values ranged from 1–13 non-ripe females/hr towed.

One main area which contained ripe females (more than 50%) during almost all months was delimited (Fig. 4). Based on this we propose that the main spawning area within the general fishing ground is located at 21°40′ to 22°10′N and 86°30′ to 86°50′W. In subarea B, determined only for April, with depths of 25 to 40 fathoms (approximately 42–67 m), the CPUE was estimated at 13

TABLE 1.

Female and male size distribution.

	Average Size	Maximum Size	Minimum Size	Mode	Size Range 95%	Observations
Immature females	129–157	195	35	110–160	85–195	
Ripe females	146–166	205	95	130–170	115–180	February and March mean length 130 and 136 mm (recruits)
Males	116–133	200	35	110–145	80–170	May and September, two modes
Both sex	124–147	205	35	120–160	80–185	July, August and October, two modes

to 20 ripe females/hour towed. Subarea C located between 20 to 35 fathoms depth (approximately 33–59 m) was also present for most of the year with a CPUE of 2 to 11 ripe females/hr towed.

Reproductive Periods

Ripe females were present throughout the whole year, indicating that reproduction may be continuous. The highest percentages were found in the months of April (72.3%), June (69.3%), and November (66.4%) (Fig. 5a). Female percentages registered in May and July to October were lower (less than 50%) than the previous months. These differences are also related to the catch of this species within the year, which reaches a maximum in April (Soto-Aguirre in prep.). Catches yield a relatively high number of females in April, suggesting that the greatest reproductive activity occurs during this month.

If we analyze the reproductive activity using CPUE as an index of abundance (ripe females/hr towed), the pattern obtained differs from that of percentages (Fig. 5a and 5b), mainly on the last part of the year. Ripe females are better represented in March and April, with a CPUE of 8.3 ripe females/hr towed, indicating that these months are most important in terms of reproduction. June, also considered as an important month for reproductive activity in terms of percentage of mature females, had lower CPUE values of 5.6 females/hr towed. February, May, July, and August, varied from 4.6 to 4.8 ripe females/hr towed. November registered as important in terms of percentage of ripe females had one of the lowest values based of CPUE. From September to December the number of females decreased from 3.2 to 1.6 ripe females/hr towed (Fig. 5c).

TABLE 2.

Coefficient correlations (r) of female pink spotted shrimp (n) size and depth, and monthly sex ratio (calculated on the basis of females) in the Contoy fishing ground.

Month	r	n	Sex Ratio (Male/Female)
February	0.246*	479	1.17

December	−0.073	184	1.38

* Significant at 5% level.

DISCUSSION

Ninety-five percent of the spotted pink shrimp catches consisted of organisms that ranged from 80 to 185 mm TL, which suggests that shrimp are recruited at small sizes about 80 mm TL. This agrees with the emigrating size (80–100 mm TL) of juveniles of other penaeid shrimps from the nursery areas in the Gulf of Mexico (Bielsa et al. 1983, Gracia 1989a, Gracia & Soto 1990, Gracia 1995). Juveniles of *F. brasiliensis* seem to leave the nursery areas at 67–84 mm TL according to data recorded in coastal lagoons near the study area (May 1999).

Sex Ratio

In general, the months with the greatest ratio of males/females are within the main reproductive period (February to August). In contrast, the months of October to December, which are not considered as part of the main reproductive period, had a higher proportion of males (1.33–1.38 per female). Guitart and Hondares (1980) also found a difference in the female/male ratio of *F. duorarum* and *F. aztecus* in the Campeche Bank.

Female Spatial Distribution Pattern

Some relationships between size of females and gonad stage were found; however, no consistent pattern was observed. Several authors have reported that mature female shrimp migrate toward deeper regions during the spawning time (Bielsa et al. 1983, Brusher et al. 1972, García and Le Reste 1986, Gracia 1992). This may be the case for *F. brasiliensis*, since the reproduction period established in this paper (February to August) coincides with a significant relationship of size and gonad stage with depth.

The best correlation between size of females and depth of catches was observed during March and April that are the months of greatest reproductive activity. If we also consider that female size can be related to maturity, one could expect a similar behavior

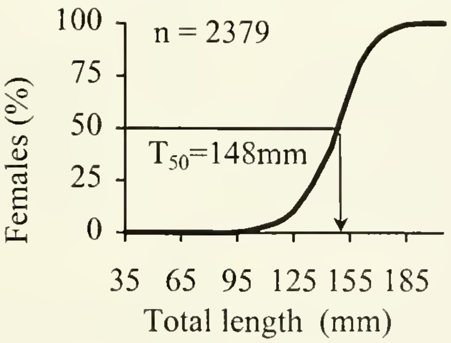

Figure 2. Size of first maturity of *F. brasiliensis* with the criterion of 50%.

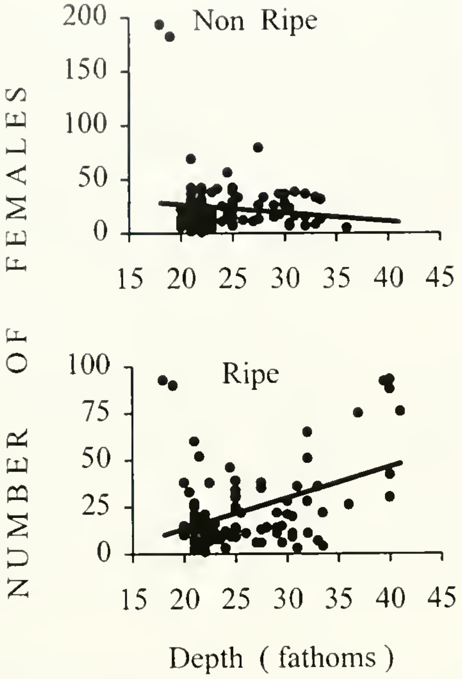

Figure 3. Number of ripe and non-ripe females of *F. brasiliensis* vs depth.

for the relationship between ripeness and depth. This was found for April but did not occur in March, when no significative correlation was observed. This correlates well with the fact that March is a month of marked recruitment to the fishing ground (Porras-Ruiz et al. in prep.) which can mask this relationship.

In August, when smaller organisms were found at greater depths, the relationship of size and depth depicts a negative slope. This finding is related with the second recruitment period of the population towards the fishing grounds (Soto-Aguirre in prep.) during summer. In general terms, the results suggest that there may be a relationship of size and female gonad stage with depth of the fishing ground, especially during reproduction periods.

Nonetheless, monthly variations of non-ripe and ripe females ocurrence in the fishing ground suggest an area of recruitment with small shrimp troughout the year (21°30′ to 21°50′N and 86°30′ and 86°40′W) and a spawning area (21°40′ to 22°10′N and 86°30′ to 86°50′W) at depths of 20 to 40 fathoms (approx. 33–67 m) which can be useful as reference areas for the fishery.

This study suggests that the reproductive period for pink spotted shrimp occurs throughout the whole year, but the highest reproductive activity in terms of number of ripe females occurs from February to August, peaking in March and April. According to García and Le Reste (1986), variation in reproductive activity of shrimps is typically linked to seasons of the year, with two reproductive peaks. Other authors (Crocos and Kerr 1983, Crocos 1987a and b, García 1988) have also observed a bimodal pattern in egg

production, as well as abundance of larval stages of various penaeid species (Rothlisberg et al. 1987). Gracia (1989a) reports that the *L. setiferus* population of the Campeche Sound presents two reproductive peaks of variable magnitude: the most important one occurs late spring and early of summer and a second less intensive period occurs in autumn.

We observed only one reproductive peak during spring for *F. brasiliensis*. However, it will be necessary to determine whether this reproductive pattern is typical of the spotted pink shrimp or whether it is related to environmental factors or high fishing effort levels that might have suppressed the second reproductive peak during the year evidenced only from ripe female percentage. Spawning becomes unimodal, even for species that reproduce all year round, when they occur near the temperate limits of its geographical distribution (Dall et al. 1990). The study area is located in a tropical latitude, so it could be expected that *F. brasiliensis* would fit better to a spawning bimodal pattern.

Protracted spawning period allows a high reproductive potential for *F. brasiliensis* and also allows a protracted recruitment through the year. This behavior agrees with the opportunistic reproductive strategy proposed for white shrimp *L. setiferus* by Gracia (1989a). Maintaining a high reproductive potential year-round could permit pink spotted shrimp to cope with environmental fluctuations, thereby adopting an opportunistic strategy to make good use of microscale variations, mainly in nursery areas which constitute a critical stage (Gracia 1989a, 1991). Unfortunately, in spite of its importance, no data are available on this stage which can confirm the presence of postlarvae year round or that can give details about the behavior of *F. brasiliensis* in the nursery areas.

On the other hand, shrimp spawning during the main peak reproductive period seems to have a high importance with respect to the relative contribution to the fishery recruitment. The main shrimp recruitment that occurs in February-March arises from female population left at the end of the fishing season of the previous year (November–December). This may suggest that the decimated spawning population at the end of the year is more important for stock renewal than the large female population of younger small-sized females present during March and April. This behavior conforms to a common pattern of penaeid shrimp spawning in which some of the individuals of a cohort breed at earlier ages and then have a massive spawning at about 10–12 mo of age (Crocos 1987a and b, Gracia 1989a). During this time a large proportion of the spawning stock is removed by the fishery. Other shrimp species like *P. merguiensis*, *P. semisulcatus*, *L. notialis*, and *L. setiferus* (Rothlisberg et al. 1985, Mathews et al. 1987, Lhome and García 1984, Gracia 1989a) present this type of reproduction where the main recruitment originates from a minor spawning stock. The success of these spawnings are related to envinronmental factors which propitiate postlarvae recruitment to the nursery areas, affect juvenile survival and subsequent recruitment offshore (Gracia 1991).

On the other hand, pink spotted shrimp size caught by the fishery is reducing, which can also influence the reproductive dynamics of the stock. Gracia (1989b, 1995) points out that considering shrimp reproductive strategy, where the recruitment is highly variable due to environmental conditions, the protection of juvenile stages has greater influence on increasing population fecundity than protecting spawning population. For *F. brasiliensis* females, 60 to 85% of the catches consist of sizes with a total maximum length of 140 to 150 mm. The size for the first reproduction averages 148 mm TL and the high fishing mortality, suggest that most of the females have no chance of reproducing at least once before being caught. This may induce recruitment over-

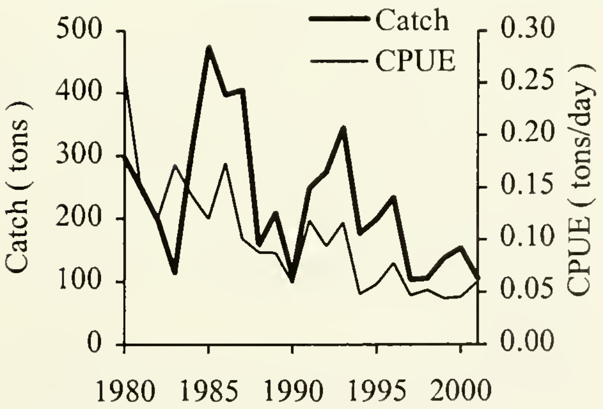

Figure 6. Catch variations of *F. brasiliensis* in Contoy, Q. Roo

fishing and lead to serious problems for the recovery of the population.

This could be one of the reasons for the decreasing shrimp production which shows a sustained negative trend since 1980. Both annual shrimp yield and commercial CPUE have shown a steady decreasing trend to around 20% of maximum records (Fig. 6). It has been reported that shrimp can support exploitation levels which can reduce spawning stock in a wide range up to around 20% of virgin biomass without affecting seriously the recruitment (Gracia 1996). However, it also has been demonstrated that a depleted spawning stock could reduce recruitment and decrease yield. Fishery statistics seem to indicate that this is the case and maximum sustainable yield of the resource has been surpassed affecting the reproduction rate and hence recovery of the population.

A closed season during August–September was implemented to protect spotted pink shrimp and also rock shrimp *S. brevirostris*. The fishery regulation was mainly designed to reduce fishing pressure on *F. brasiliensis* spawning stock. This seems reasonable because location of the main spawning area, as well as the periods of highest reproductive activity, coincide with the areas and periods of greatest fishing activities on *F. brasiliensis*, which could impact negatively this critical stage for the population renewal. However, according to our data, this closure does not fill this objective, as it does not protect the more important spawning at the end of the year or the more abundant ripe female population earlier in the year. Neither does this regulation reduce growth overfishing as it does not protect the main recruitment period of pink spotted shrimp. A more effective regulation would be to close the fishery between November–December to protect the remaining and more important spawning stock. A measure like this would be more important to enhance spawning potential if a second closure is considered in March–April. A combination like this could help to reduce fishing effort on main spawners and pre-spawners of red spotted pink shrimp which could result in a higher reproductive potential.

Information provided in this study could serve as a basis to design management strategies which can help to improve spawning stock and shrimp yield. It is clear that a closure oriented to improve spawning potential of spotted pink shrimp should be directed to the more important spawning stock; however, other combinations of fishery regulations can also be done.

ACKNOWLEDGMENTS

This study was done as part of the program "Turtles Excluding Devices" (DETs, for its acronym in Spanish) implemented by the National Institute of Fishery, SEPESCA. Technician participation is greatly appreciated.

INFLUENCE OF THE REPRODUCTIVE CYCLE ON THE BIOCHEMICAL COMPOSITION OF DEEP-SEA DECAPOD *PARAPENAEUS LONGIROSTRIS* (LUCAS, 1846) IN THE PORTUGUESE SOUTH COAST

R. ROSA* AND M. L. NUNES

Departamento de Inovação Tecnológica e Valorização dos Produtos da Pesca, IPIMAR Avenida de Brasília, 1449-006 Lisboa, Portugal

ABSTRACT The reproductive cycle and biochemical composition of the muscle, ovary, hepatopancreas (HP) of *Parapenaeus longirostris* were studied during a period of one year (October 2000–September 2001) in the Portuguese south coast. Gonado-somatic index (GSI) increased significantly in May and June and during the maturation process, suggesting that spawning may start in late spring or summer. Hepato-somatic index (HSI) also increased throughout the ovarian maturation, suggesting that the HP resources are not depleted. Ovarian lipid levels increased with maturation, but no concomitant decrease occurred with HP lipids. The muscle showed very low lipid levels and higher percentages of polar lipids than ovary and HP. On the other hand, these two tissues presented higher proportions of neutral lipids, mainly triacylglycerols (TAG). Because both ovarian and HP cholesterol increased with maturation, the mobilization of HP cholesterol stores to the build-up of ovarian cholesterol was not clear. Protein and glycogen contents in the muscle, ovary, and HP did not vary as a function of ovary maturity stage. Among the different tissues analyzed, the glycogen is mainly stored in the HP and to a lesser extent in the muscle. In both ovary and HP, the major fatty acids were 16:0, 18:1(n-7), 18:1(n-9), 20:5(n-3), and 22:6(n-3), and significant increases in the levels of monounsaturated fatty acids (MUFA) were observed in the ovary during sexual maturation, which indicates that these compounds act as the major sources of energy during embryonic and early larval development.

KEY WORDS: biochemical composition, *Parapenaeus longirostris*, reproductive cycle

INTRODUCTION

The deep-water rose shrimp *Parapenaeus longirostris* (Lucas 1846) is the second most valuable species caught by the Portuguese crustacean trawl fleet, operating mainly along the south coast of Portugal (Caramelo et al. 1996). It has a wide geographical distribution in the Eastern Atlantic, from the north of Spain to southern Angola, as well as in the Mediterranean and its adjacent seas (Pérez-Farfante 1982). Its growth, reproduction, morphometry, and fecundity have been studied by Ribeiro-Cascalho and Arrobas (1983, 1984, 1987) and Ribeiro-Cascalho (1987) in the south Portuguese waters. However, there are no biochemical data associated with the reproductive biology of *P. longirostris*.

Knowledge of the biochemistry and metabolism processes that occur during the reproductive cycle are essential for a complete understanding of reproduction. Biochemical changes during maturation, moulting, and reproduction in gonads, hepatopancreas, and muscle have been examined for a number of crustacean species (Pillay & Nair 1973, Guary et al. 1974, Gehring 1974, Galois 1984, Castille & Lawrence 1989, Mourente & Rodriguez 1991, Palacios et al. 2000). Many of these studies concentrated on lipid dynamics. The accumulation and mobilization of these organic reserves constitutes one of the most significant metabolic events in the physiology of crustaceans (Teshima et al. 1989). Carbohydrates are important in the Krebs cycle, in glycogen storage, in chitin synthesis, and in formation of steroids and fatty acids (New 1976). Synthesis of several proteins, including peptide hormones, enzymes, high-density lipoproteins (HDLs), and glycoproteins is especially important in maturation and reproduction (Yehezkel et al. 2000). These two biological processes are also regulated by terpenoid, peptide, and steroid hormones (Quackenbush 1986), and a particular consideration in steroidogenesis is the metabolism of the steroid precursor, cholesterol. Crustaceans are not capable of *de novo* synthesis of the steroid ring (Van den Oord 1966, Teshima & Kanazawa 1971), and the dietary intake of cholesterol or mobilization of previously consumed cholesterol reserves is required to support production of steroid hormones (Middleditch et al. 1980).

The purpose of the present study was to follow the biological changes (gonad and hepatosomatic indices) and the biochemical composition of the muscle, ovary, and hepatopancreas (HP) of *P. longirostris* over a one-year period and link these to the shrimps' reproductive cycle.

MATERIAL AND METHODS

Samples

The research was performed over a period of one year, between October 2000 and September 2001. Monthly samples (30–40 shrimps taken from a commercial trawl vessel catches—*Costa Sul*) were collected in Algarve (Portuguese south coast). The fishery of *Parapenaeus longirostris* was mainly between 200 and 300 m. All the specimens analyzed (a total of 452) had a carapace length between 20–28 mm. For each shrimp, the following parameters were recorded: sex, total weight, gonad and HP weight, and maturity stage (only for females). The maturity stage was based on Ribeiro-Cascalho (1987). Females were classified as immature (S1: ovary thin and transparent or translucid white, very small and with no signs of granulation); maturing (S2: thick ovary, yellowish or greenish); and mature (S3: stout ovary, olive green or bluish green colored). Gonad (GSI—gonad wet weight/ body wet weight ×100) and hepatosomatic indices (HSI—hepatopancreas weight/ body wet weight × 100) were only calculated for females. To study the seasonal biochemical changes in the muscle, the monthly samples were pooled in triplicate taking sex into account. To elucidate how biochemical composition may be associated with maturation process (namely, oogenesis), females tissues (muscle, ovary, and HP) were pooled in triplicate taking maturation stage into account.

Proximate Chemical Composition and Lipid Class Analysis

Water, protein, fat, and ash contents were determined according to AOAC procedures (1998). Total lipids were extracted using the Bligh and Dyer (1959) method. Lipid classes were resolved by analytical thin-layer chromatography (TLC) on plates coated with 0.25 mm silica gel G and developed with hexane: diethylether: acetic acid (65:35:1 by volume). The developed plates were sprayed with 10% phosphomolybdic acid in ethanol. Lipid class identification was made by comparing with standards (Sigma, St. Louis, MO). Quantification was performed using a scanner and the software Quantity One (version 2.4) from PDI, Inc. (New York).

Total Lipid Fatty Acid Analysis

The percentage distribution of fatty acids was based on the experimental procedure of Lepage and Roy (1986) modified by Cohen et al. (1988). The fatty acid methyl esters were analyzed in a Varian 3400 gas chromatograph, equipped with an autosampler and fitted with a flame ionization detector. The separation was carried out with helium as the carrier gas in a fused silica capillary column Chrompack CPSil/88 (Middleburg, The Netherlands) (50 m × 0.32 mm inner diameter [id]), programmed from 180–200°C at 4°C/min, held for 10 min at 200°C, and heated to 210°C for 14.5 min, with a detector at 250°C. A split injector (100:1) at 250°C was used. Fatty acid methyl esters were identified by comparison of their retention times with those of Sigma chromatographic standards. Peak areas were determined using the Varian software (Sunnyvale, CA).

Cholesterol and Glycogen Analyses

The quantification of cholesterol content was based on the experimental procedure of Naemmi et al. (1995) modified by Oehlenschläger (1998). The cholesterol was analyzed in a Hewlett-Packard 5890 gas chromatograph. The separation was carried out with helium as the carrier gas in a column HP5 (Wilmington, DE) (30 m × 0.5 mm id). The temperatures of the oven, injector, and detector were 280°C, 285°C, and 300°C, respectively. Cholesterol was identified and quantified by comparing with standards (Sigma) from which a standard curve was prepared. Glycogen concentrations were determined according to Viles and Silverman (1949). Glycogen was measured by the anthrone-reagent method, and the absorbance read at 620 nm. A calibration curve was prepared using glycogen (Sigma, St. Louis, MO) as a standard.

Statistical Analysis

Data were analyzed using a one-way and a two-way analysis of variance (ANOVA), after the assumptions had been met (normality and homogeneity of variances were verified by Kolmogorov–Smirnov and Bartlett tests, respectively). When data did not meet the assumptions of ANOVA, the nonparametric ANOVA equivalent (Kruskal–Wallis test) was performed. Whenever significance was accepted at $P < 0.05$, the Tukey (parametric) and Dunn (nonparametric) multiple comparison tests were used (Zar 1996).

RESULTS

Biological Changes

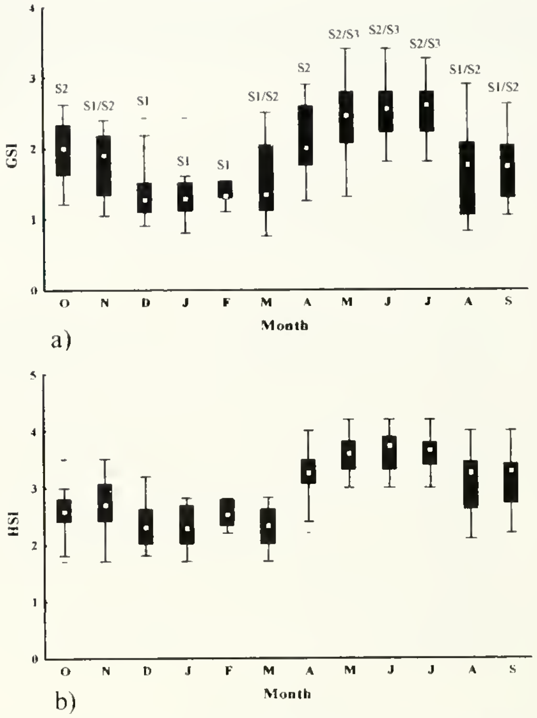

Figure 1. Box plots of the monthly distribution of gonadosomatic index (GSI) (a) (with the indication of the dominant maturity stages found in each month) and hepatosomatic index (HSI) (b) of *Parapenaeus longirostris* females.

The seasonal (intra-annual) patterns of the GSI and HSI observed in *Parapenaeus longirostris* females ($n = 325$) can be seen in Figure 1. GSI and HSI are the highest in May, June, and July.

Proximate Chemical Composition, Cholesterol, and Glycagen Contents of Muscle, Ovary, and Hepatopancreas

The biochemical composition of the muscle of *Parapenaeus longirostris* exhibited seasonal variations in the water, protein, and lipid contents (Fig. 2). The water content ranged from 72.9–75.7% in females and 73.6–75.5% in males, revealing significant temporal variations. The protein content ranged from 20.1–22.3% in females, and 19.5–21.3% in males. The statistical analysis revealed a significant increase from November/December to April/May in both genders (Females: $F_{11,24} = 4.63$, $P < 0.05$; Males: $F_{11,24} = 4.25$, $P < 0.05$). The lipid content ranged from 0.1–0.5% in females and 0.1–0.4% in males, exhibiting a considerable rise in the spring. The ash levels varied between 1.8–2.1% in females and 1.9–2.3% in males. The cholesterol content in the muscle ranged from 56.1–72.3 mg/100 g in females and 50.5–67.9 mg/100 g in males (Fig. 2), exhibiting significant seasonal variations between winter and summer months (Females: $F_{11,24} = 4.55$, $P < 0.05$; Males: $F_{11,24} = 4.09$, $P < 0.05$). The glycogen content varied from 0.8–2.6 mg/100 mg in females and from 1.2–2.8 mg/100 mg in males (Fig. 2) (Females: $F_{11,24} = 4.32$, $P < 0.05$; Males: $F_{11,24} = 4.25$, $P < 0.05$), being the highest between March and May for both genders.

The protein content of the muscle, ovary, and HP of the females as a function of ovary maturity stage showed no significant variations (Table 1). Statistical differences were obtained when comparing the different tissues; the protein content varied from 20.6–22.3% in the muscle, 42.1–45.3% in the ovary, and from 8.5–9.7% in the HP. The cholesterol content increased significantly from S1

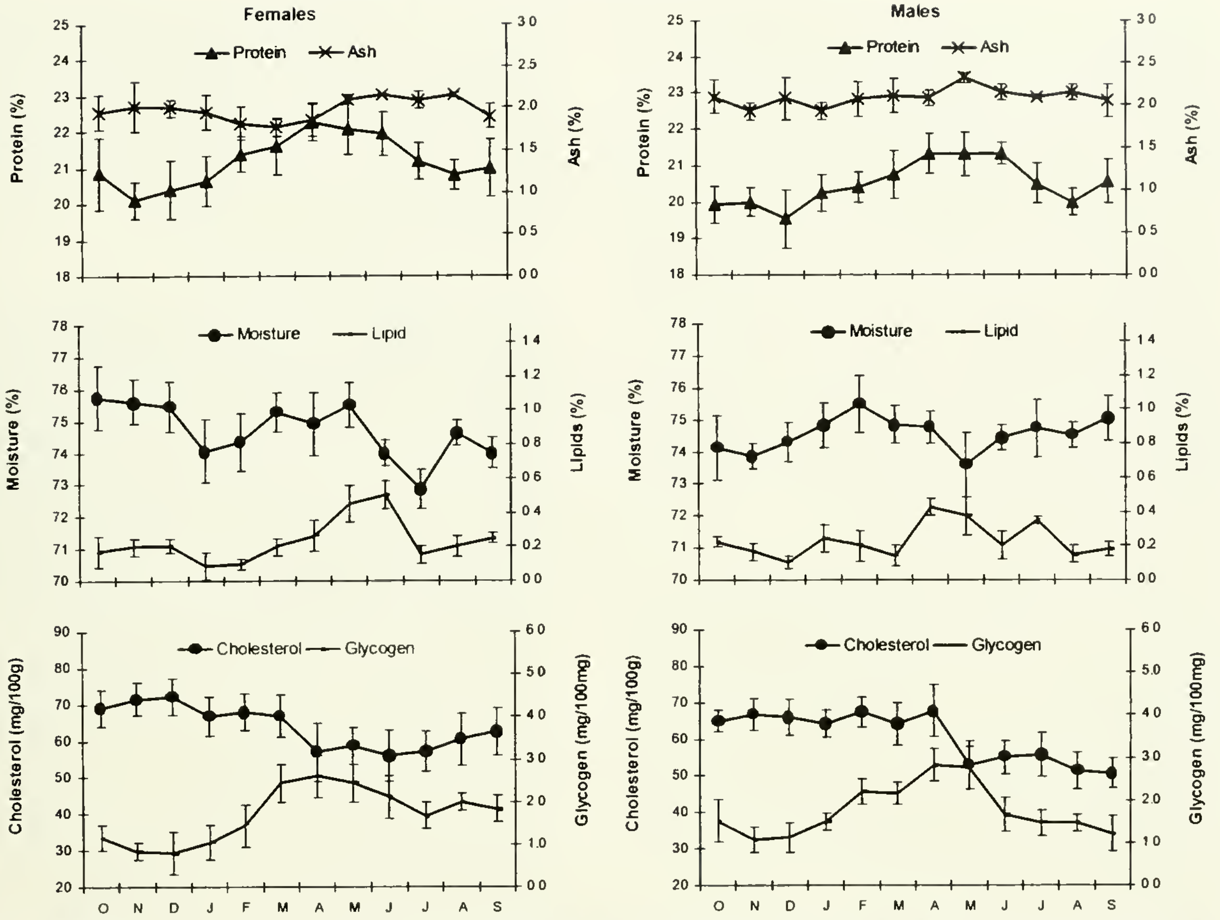

Figure 2. Monthly variations in proximate chemical composition (% wet wt.), cholesterol (mg/100g wet wt.), and glycogen (mg/100mg wet wt.) contents in the muscle of *Parapenaeus longirostris* females and males (values are means of three pooled samples ± SD).

to S3 (62.3–73.5 mg/100 g) in the ovary and from S1 to S3 (150.2–181.9 mg/100 g) in the HP. In the muscle, this content decreased significantly from S1 to S3 (70.0–56.7%) (Table 1). On the other hand, muscle, ovary, and HP glycogen content did not show significant variations throughout the maturation process (Table 1).

Lipid Class Distribution Among Female Tissues

To elucidate how lipids may be associated with maturation and reproduction processes, lipid content was determined in the muscle, ovary, and HP of females as a function of ovary maturity

TABLE 1.

Variations in protein (% wet wt.), glycogen (mg/100 mg wet wt.), cholesterol (mg/100 g wet wt.), total lipids (mg/100 mg dry wt.), lipid class content (% total lipids) in the muscle, ovary, and hepatopancreas of *Parapenaeus longirostris* females at different stages of ovarian development.

Values are the means ± SD of three pooled samples. Different superscript letters within rows represent significant differences ($P < 0.05$).

stage (Table 1). The lipid levels did not vary significantly in the muscle (from 2.9–3.4 mg/100 mg), but in the other tissues showed significant variations; namely, between S1 and S3 (ovary: 19.8–29.1 mg/100 mg; HP: 37.8–48.3 mg/100 mg).

Different patterns of distribution of the polar and neutral lipids, (expressed as % total lipids) among the muscle, ovary, and HP can be found throughout the maturation period (Table 1). Neutral lipids were dominated by triacylglycerols (TAG), which are by far the largest fraction in the ovary and HP. TAG increased significantly from stages 1 to 3 (ovary: 40.5–58.7%; HP: 53.6–71.7%). The free fatty acids (FFA) percentage decreased during the maturation process, and the neutral lipids, diacylglycerols (DAG), and monoacylglycerols (MAG) showed no clear trends in the different tissues. Similar trends of variation were shown by the other classes. In the muscle, the polar lipids attained higher percentages, because phospholipids (PL) reached about 25% during the maturity process. Significant differences in PL percentages were also detected between the ovary and HP.

Total Fatty Acid Composition of Female Tissues

The fatty acid composition in the muscle of females at different stages of ovarian development is shown in Table 2 (only the quantitatively most important fatty acids are represented in the table). Saturated fatty acids (SFA) content ranged from 6.9–7.1 mg g^{1} dry weight. The most predominant was 16:0, attaining 4.6–4.7-mg g^{-1}. The monounsaturated fatty acids (MUFA) content ranged from 6.8–8.0 mg g^{-1}. Most of this content was present as 18:1. Polyunsaturated fatty acids (PUFA) were the major group attaining the highest values in stage 3 (12.2 mg g^{-1}) because of the increase of ARA (20:4n-6), EPA (20:5n-3), and DHA (22:6n-3) in that period. These fatty acids accounted for almost 80% of the PUFA.

The fatty acid composition of the ovary and HP of females in relation to ovary maturity stage is also presented in Table 2. With respect to the SFA fraction, there were significant differences among the developmental stages. A similar trend was obtained in the most predominant saturated fatty acid (16:0). The MUFA fraction increased significantly during oogenesis and represented more than half of the total fatty acids. The significantly higher values of the MUFA in the ovary and HP compared to muscle were attributable to the significantly higher contribution of 18:1(n-9), 18:1(n-7), 20:1(n-9), and 20:1(n-7). PUFA ranged from 46.1–58.5 mg g^{-1} in the ovaries and from 72.9–90.0 mg g^{-1} in the HP. The major PUFA were ARA, EPA, and DHA, and significant differences were obtained between the tissues analyzed.

DISCUSSION

Oogenesis and primary vitellogenesis usually correspond to the juvenile and prepubescence phases, which are characterized by a slow increase in ovary weight. The onset of puberty is distinguished by a rapid deposition period, the secondary vitellogenesis (Adiyodi & Adiyodi 1970, Aiken & Waddy 1980). In this study, the maturation of *P. longirostris* ovary, indicated by GSI, seemed to show this basic phase pattern, with a slow increase up to the S2, followed by a rapid increase in S3. The temporal trend of GSI seems to be concordant with the seasonal spawning pattern observed by Ribeiro-Cascalho & Arrobas (1987) in Portuguese waters, which suggests two peaks of reproduction, one at the end of spring and another at the beginning of autumn in October.

On the other hand, the variations of HSI throughout the year and during the maturation process did not seem to corroborate the general pattern among the decapods; namely, the storage of organic reserves in the HP and the utilization of these reserves in the ovarian development (Gibson & Barker 1979, Kyomo 1988) or in the formation of a new exoskeleton (Adiyodi & Adiyodi 1970). The fact that both GSI and HSI increased with the ovarian maturation suggests that the HP resources are not depleted and, according to Tuck et al. (1997), if resources are mobilized from this organ, then these resources seem to be compensated by those gained from feeding.

The increase in lipid levels in the ovary occurs as a result of the maturation process. In fact, neutral lipids, particularly TAG, are the major energy source, and the predominant form of energy

storage in the adult, egg, and prefeeding larva (Xu et al. 1994, Nates & Mckenney 2000), comprising primarily 16:0 and omega-9 family fatty acids (Teshima et al. 1988). PL, DAG, and sterols are the other main lipid classes found in marine shrimps and are also associated with the maturation of oocytes (Teshima 1997, Ravid et al. 1999, Wouters et al. 2001).

The HP is the major lipid storage and processing organ for postembryonic stages (Voght et al. 1985), but during maturation the ovary becomes an additional center for lipid metabolism, including lipogenesis—TAG synthesis (Teshima et al. 1988). In the present study, and like some previous studies in decapods (Castille & Lawrence 1989, Cavalli et al. 2001), the increase in ovarian lipids is not accompanied by a decrease in HP lipids. Under these circumstances, the lipid requirements of the developing ovary seem to be more dependent on the ingestion of dietary lipids than on HP reserves.

The profile of fatty acids in the ovaries of *P. longirostris* is a reflection of the fatty acid requirement of this tissue or of what is required for transfer to the developing embryos after fertilization. Alava et al. (1993), Cahu et al. (1994), and Cahu et al. (1995) demonstrated the benefits of high levels of highly unsaturated fatty acids in the diet on reproductive parameters and on offspring quality of penaeid shrimps. In fact, the long-chain fatty acids are necessary for vitellogenesis of crustaceans (Middleditch et al. 1980, Millamena & Pascual 1990) and ARA and EPA are precursors of eicosanoids in marine animals (Lawrence et al. 1979, Sargent, 1995). The high values of MUFA in the ovary and HP are consistent with previous findings of Clarke et al. (1990) and Roustaian et al.(1999), which indicated that these compounds are the major sources of energy during embryonic and early larval development.

In the present study, the protein content of the ovary and HP did not vary significantly. On the other hand, the seasonal (intra-annual) variation of protein content of the muscle may be linked with changes in feeding activity. Muscle protein loss during starvation has been observed in other deep-sea decapod species (Dall 1981).

Because cholesterol is a precursor of steroid hormones (Kanazawa & Teshima 1971), the increase of ovarian cholesterol levels with maturation in the *P. longirostris* was not surprising. This increase can also be related to the role of cholesterol as precursor of ecdysteroids, as these compounds are known to increase during gonadal maturation (Wilder et al. 1991). Similar trends were observed in HP cholesterol, which differs from the results obtained by other authors (Adiyodi & Adiyodi 1970, Lautier & Lagarrigue 1988), where the decrease in HP cholesterol during vitellogenesis suggests that mobilization of HP cholesterol stores may contribute to the build-up of ovarian cholesterol. The explanation of our findings could be found in Teshima et al. (1988), which indicated that cholesterol is sequestered to the ovaries from the muscle stores. In fact, in the present study, the muscle cholesterol content decreased significantly from S1 to S3, and the seasonal variation of the cholesterol content also seems to confirm the conclusions of Teshima et al. (1988). On the other hand, because cholesterol stores within the HP and gonads are derived from the diet (Middleditch et al. 1980), because of the incapacity of *de novo* synthesis of the steroid ring, if the steroid resources are mobilized from the HP to the gonad, then the HP resources seem to be compensated by those gained from feeding.

Glycogen did not show significant variations throughout the maturation process, in contrast to what was stated by Kulkarni and Nagabhushanam (1979). Moreover, because carbohydrates have specific roles in the production of nucleic acids, are precursors of metabolic intermediates in the production of energy and nonessential amino acids, and as a component in ovarian pigments (Harrison 1990), they have to be especially important for the maturation process and for embryogenesis. Among the different tissues analyzed in this study, the glycogen is mainly stored in the HP and to a lesser extent in the muscle, but according to the studies by Hagerman et al. (1990) and Baden et al. (1994), on the decapod *Nephrops norvegicus* (Linnaeus 1758), the occurrence of glycogen depletion in the muscles, following hypoxia and starvation, suggests that the muscle contains a particularly important store of glycogen, because it is more readily accessible when there is a shift to anaerobic metabolism or when there is decrease in the feeding activity during winter. This can explain the seasonal variation of glycogen content in the muscle of *P. longirostris*, because the lowest values were obtained in the winter. Although there is no evidence of a decreasing feeding activity during this period of the year, the diet composition of *P. longirostris* should vary significantly between seasons like the other deep-sea crustaceans species (Cartes & Sardà 1989, Labropoulou & Kostikas 1999), because these changes correspond basically to the period of abundance of the different dietary group in the deep-sea environment (Cartes 1994).

In summary, it is evident that reproductive cycle has profound effects upon the biochemistry of *P. longirostris*. Reproduction and gonadal maturation have large associated energy costs attributable to the increase in biosynthetic work, which will support the lecithotrophic strategy (reliance on egg yolk nutrition) of the embryos and prefeeding larval stages. Moreover, these processes seem to be influenced or even synchronized with seasonal feeding activity or food availability. Despite not being mentioned or discussed in this study, moult cycle can also have an important effect in the biochemistry and physiology of decapod crustacea, manifested in changes in their physiological ecology and behavior. Lack of data on this matter in *P. longirostris* indicates that further work will be necessary to understand better the biochemistry and physiology of this species.

ACKNOWLEDGMENTS

The Foundation for Science and Technology (FCT) supported this study through a doctoral grant to the first author. The technical assistance of Angelino Martins is greatly appreciated. We express our gratitude to the crew of the trawler *Costa Sul*.

A COMPARISON OF GROWTH PERFORMANCE ACROSS THE SQUID GENUS *ILLEX* (CEPHALOPODA, OMMASTREPHIDAE) BASED ON MODELLING WEIGHT-AT-LENGTH AND AGE DATA

SERGIO RAGONESE,[1]* PATRIZIA JEREB,[1] AND EARL DAWE[2]

[1]*Istituto di Ricerche sulle Risorse Marine e l'Ambiente, IRMA-CNR, Via Vaccara 61, 91026 Mazara, Italy;* [2]*Department of Fisheries and Oceans, Science Oceans and Environment Branch, P.O. Box 5667, St. John's, Nfld., Canada, A1C 5X1*

ABSTRACT A new approach to study growth performance in squid is described, based on modeling the ratio of body weight to mantle length (BW/ML) as a function of age (squid "condition"). This approach has several advantages above traditional size-at-age modeling, including the concurrent use of two size indices, the fact that it is not constrained by theoretical considerations regarding the form of growth in absolute size, and that it is also less severely affected by sampling bias. It was tested on three species of the genus *Illex* using raw data sets for two species as well as BW/ML values calculated from sizes predicted by models available in the literature for all three species. Several experimental models were explored, but the specific logistic model was found to be the most suitable, especially when most of the life cycle was sampled. This model was successfully applied to all species and case studies, thereby elucidating common features of growth performance throughout the genus *Illex*. It provided similar or superior model fits when compared with corresponding models of length-at-age or weight-at-age. Comparisons within and among species indicated some effects that have also been suggested from independent length-at-age studies, including a positive effect of temperature on growth performance. This new approach also indicates a relationship between growth performance and sexual maturation.

KEY WORDS: squid, *Illex*, growth performance, age

INTRODUCTION

Three species of short-finned squids of the genus *Illex* (Teuthoidea, Ommastrephidae) are commercially exploited (Roper et al. 1998); *Illex illecebrosus* (Lesueur 1821), *I. argentinus* (Castellanos 1960), and *I. coindetii* (Verany 1839). The fisheries they support have recently gained increasing attention because of concerns regarding potential for overexploitation (Haimovici et al. 1998, O'Dor & Dawe 1998, Sánchez et al. 1998).

Effective squid fisheries management, however, is hampered by uncertainties concerning the life cycle. As is typical of most squid, *Illex* species show great and unpredictable variability in growth, maturation, and spawning patterns over very short time periods (Mangold 1987, Forsythe 1993, O'Dor & Lipinski 1998). Such great variability in life history parameters largely accounts for the great variability evident in size-at-size (e.g., weight-at-length) and size-at-age relationships observed in *Illex* sp. and the difficulty in applying length-frequency methods (Caddy 1991, Jereb & Ragonese 1995) conventionally used for estimating growth rates in other fisheries resources (Pauly & Morgan 1987). Recent direct ageing techniques based on squid statolith microstructure (Jereb et al. 1991; Jackson 1994), despite the inevitable existence of ageing bias (Pauly 1998, Gonzalez et al. 2000), indicate very high growth rates, even higher than those observed in fast growing pelagic fish such as the scomberoids (Longhurst & Pauly 1987, Jarre et al. 1991).

Despite the many studies of the past decade, there is no consensus on which model is the most suitable to describe squid growth. Among those used for various species and portions of the life cycle, the simple linear, power, log linear, piece-wise, exponential, seasonally oscillating von Bertalanffy, double exponential (or Gompertz), and logistic (Jackson 1994) have most frequently been applied. To date, five models have been used to describe absolute growth in either length or weight within the genus *Illex* (Table 1).

Until now, size-at-size and size-at-age relationships have been analyzed separately, despite the strong correlation existing between body mass and mantle length. Here, these relationships are analyzed jointly by relating body mass to mantle length and investigating trends in this ratio with age. The main purpose of our study was to combine two indices of size (both important factors in ecology and evolution studies; Peters 1983, La Barbera 1989) into a new index, which may better indicate variation in growth performance than either length or weight alone and thereby facilitate broad-scale comparison within and among species. Potential advantages of this approach include that variability surrounding models of weight-at-length on age may be lower than for more familiar models of size on age. Weight-at-length on age models may be simpler, more consistent, and provide better fits than single size variable on age models. They may also better reflect suitability of the biotic environment than growth in either length or weight alone.

The models we developed were applied to three congeneric squid species (*Illex* spp.) to test the utility of this approach for comparison of growth performance patterns.

MATERIALS AND METHODS

The weight-at-length index (WaL) is defined as the ratio of whole body weight (BW; g) to dorsal mantle length (ML; mm), i.e., WaL = BW/ML; it is, therefore, analogous to other more conventional condition indices, derived from the classic Huxley's allometric formula $y = ax^b$ (La Barbera 1989) and widely used in aquaculture and fisheries science (Dawe 1988, Bolger & Connolly 1989, Scott Cone 1989).

Two kinds of size-at-age databases were used (Tables 1 and 2). The first one consisted of original individual estimates of size (ML and BW) and age. Such data sets were available for two micro-cohorts of *I. coindetii* from the Strait of Sicily (Arkhipkin et al.

1998, Arkhipkin et al. 2000; Case A: Tables 1 and 2) and three micro-cohorts of *I. illecebrosus* from the Northwest Atlantic (Dawe & Beck 1997; Case E; Tables 1 and 2). *I. coindetii* samples were collected during an experimental depth-stratified random bottom trawl survey (stretched mesh size in the cod-end of 31 mm), whereas *I. illecebrosus* samples were collected from the Newfoundland inshore jig fishery during July to November 1990.

The second kind of database consisted of size values (ML and BW) at age predicted by the specific size-at-age models reported by sex for different hatching groups or populations (pooled over hatching groups) of *Illex* spp. in the literature (Tables 1 and 2). When only ML-at-age models were available (Case B), the corresponding BW-at-age data were roughly approximated from published BW-ML relationships obtained for the same season. There-

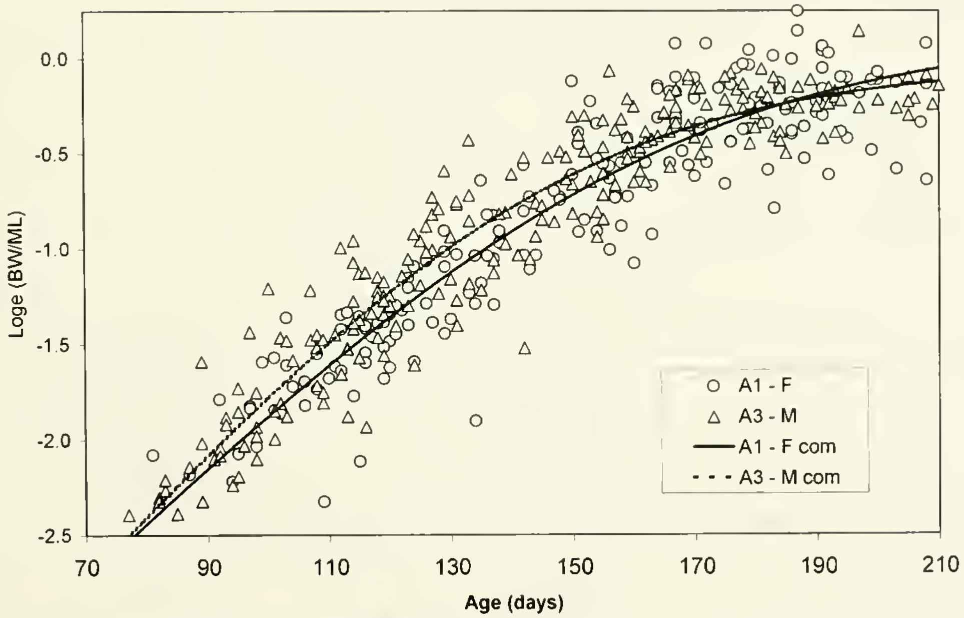

Figure 1. Individual $\log_e$ of body weight (BW) at mantle length (ML) ratio vs. age and computed (com) specified logistic model for A1 and A3 cases, *Illex coindetii* females (F) and males (M) of the Central Mediterranean (see Table 1 for case specifications).

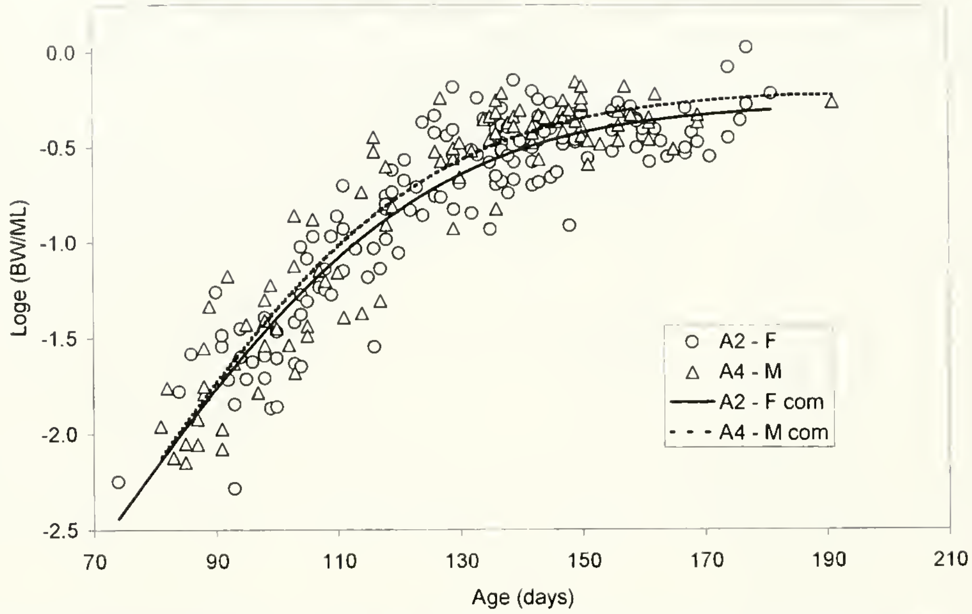

Figure 2. Individual $\log_e$ of body weight (BW) at mantle length (ML) ratio vs. age and computed (com) specified logistic model for A2 and A4 cases, *Illex coindetii* females (F) and males (M) of the Central Mediterranean (see Table 1 for case specifications).

fore, they have to be considered only as representing the form of growth.

To explore the most suitable models to apply, WaL-at-age scatter plots were analyzed by points interpolation with a model-fitting procedure (Systat 1992). A variety of available models were applied to the untransformed WaL and age data, as well as to data sets with the dependent variable only and with both variables transformed (using natural, base e, logarithms). This exploratory analysis indicated that the relationship of WaL on age (t) was best described by the power function in some cases (WaL $= at^b$) and by asymptotic models in other cases. Among the asymptotic models, the sigmoidal logistic model was preferred (Ratkowsky 1983).

Therefore, the following two models (applied to log transformed data to stabilize the variance and normalize the residuals) were tested:

the **allometric** model, hereafter referred to as the **log-log model**, which represents the linear transformation of the power model:

$$\log_e WaL = \log_e a + b\log_e t + e$$

and;

the **specific logistic** (Weatherley 1972):

$$\log_e WaL = A - \log_e(1 + e^{-B(t-C)}) + e'$$

where $\log_e$**a** and **b** are the intercept and the slope parameters respectively, **A** denotes the asymptote ($\log_e WaL_\infty$), **B** is the slope, **C** is the inflection point (days), **t** is the age (days), considered as the independent variable, and **e** and **e′** are the error terms.

A possible disadvantage of the specific logistic model is the apparent lack of a direct biologic interpretation for the asymptotic parameter (A). However, a direct biologic meaning may be found for the parameter C, which, when modeling growth in length, represents the inflection point at the end of the initial exponential growth phase and the beginning of the logarithmic growth phase. We investigate the possible relationship of the age at inflection point (i.e., the C parameter) with the approximate mean age of all mature animals of a specific group, as derived from the literature.

Model coefficients were estimated by the ordinary (Type I) simple least squares method, using both linear (Model i) and non-linear (Model ii; "Quasi Newton" and "Simplex") iterative procedures. The coefficient of determination (r^2) and the mean square errors (MSE) were used as approximate indices of goodness of fit. The former statistic, in particular, was used to compare results derived by modeling WaL with those derived by modeling ML and BW separately (original size models, Table 1). Probability levels for acceptance of significance of the regression coefficients and the overall regressions were fixed at $P < 0.05^*$ (significant) and $P < 0.01^{**}$ (highly significant). Statistical analysis, model fitting, and computations were performed using the package Systat (1992).

RESULTS

Models for Data Sets from Individuals

I. coindetii

The log-log transformation (Model i) was not successful in achieving linearity between WaL and age for *I. coindetii* from the Strait of Sicily, with the exception of females of the October to December group (A1). However, the scatter-plots of $\log_e$ transformed WaL values vs. age according to Model ii (Figs. 1 and 2), showed an acceptable homogeneity of variance. Male and female curves overlapped, but the two seasonal groups did not. October to December specimens (A1–A3) showed lower $\log_e$WaL values for a given age than did their May to July counterparts (A2–A4), suggesting a seasonal effect with higher growth performance of spring-summer group.

Considering cases A and Model i (Table 3), all regressions were significant, but the regression parameters were rather imprecise, as reflected by high standard errors. The Model i, therefore, did not properly fit the data sets, as already indicated by failure to achieve linearity. Improvement in both r^2 and MSE was achieved by fitting Model ii (Table 3). For both hatching groups and sexes convergence was rapid, and various starting values led to very similar final estimates of regression parameters, regardless of which non-linear fitting procedure was used. The precision of the regression parameters was acceptable. Model ii parameter values were similar between sexes of the May–July group (A2 and A4: Table 3, Fig. 2), whereas some sex effect was detected in the October to December group (A1 and A3, Fig. 1). In that fall to winter group, females exhibited higher asymptotic values than males and a small difference in the slope parameter and inflection points (Table 3, Fig. 1). Overall, *I. coindetii* specimens hatched in May to July showed a higher growth performance than their October to December counterparts.

I. illecebrosus

For this species (E cases), parameter estimation was achieved only using Model i (Table 3), except for the E2 case. The precision in the estimation of parameter A (Model ii) was very low in that case, however, as reflected by the ratio of that parameter to its standard error (0.27/0.71, i.e., 38% of the variation).

The Model i (log-log regression) coefficients (Table 3) indicate that the slopes were higher for May and April than for March, and higher for females than males.

Models for Data Sets of Predicted Values

Results obtained from fitting both models to the data sets of predicted values (all cases) are presented in Table 4. The consistently higher model fits (reflected by higher r^2 and lower MSE) than for models fitted to data sets of individuals (Table 3), reflects the much lower variance in the data sets of values predicted by other (single size-at-age) models than in raw empirical data sets. A comparison of specific logistic models among cases is shown for females (Fig. 3) and males (Fig. 4).

It is interesting to initially compare the A and E cases for which models were also fitted to the data sets based on individuals.

Case A: *I. coindetii*

The $\log_e$WaL-at-$\log_e$-age plots (Model i) were nearly linear for the October to December group (cases A1 and A3) and more strongly curvilinear, with an asymptotic trend, for May to July hatched squid (cases A2 and A4). The $\log_e$WaL-at-age plots (Model ii) showed a curvilinear trend in October to December specimens and a clear asymptote in May to July animals.

Application of Model (i) resulted in clear differences in models between seasonal groups and sexes. Model fits were better (higher r^2 and lower MSE) and slopes were higher for October to December than for May to July models and also for female than for male models (Table 4).

The application of Model ii (Table 4) resulted in rapid convergence and good agreement between empirical and predicted values. The asymptotic (A) and inflexion (C) parameters were higher in the October to December group; with the exception of the A parameter (which showed great variability), males and females within the each group showed very similar inflection and steepness parameters (Table 4).

Case E: *I. illecebrosus*

Linearity was not fully achieved by the log-log transformation and the application of Model i resulted in different parameter values among groups (cases E1 to E6; Table 4); however, the fit was good (high r^2 and low MSE) with only slight differences between sexes, except for E3 and E6 cases (higher slopes for females than males in the May-hatched group).

The $\log_e$WaL-at-age plots (Model ii) resulted in very similar (virtually coincident) curves for both sexes of the March (E1, E4) and May (E3, E6) groups while larger values of $\log_e$WaL-at-age were observed in females than in males of the April group, (E2, E5); the slopes consistently increased from March to May for both sexes, suggesting increase in growth rate throughout the spring.

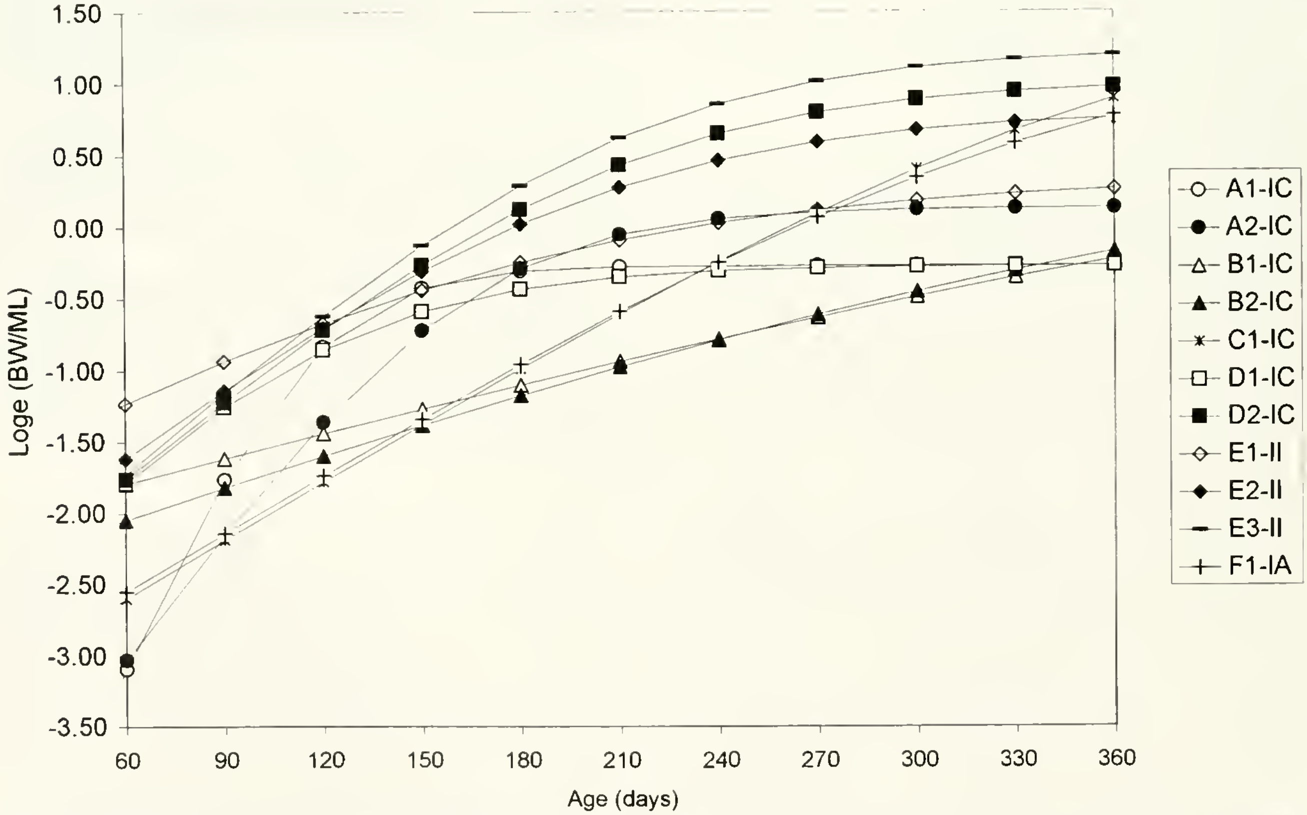

Figure 3. Log_e of body weight (BW) at mantle length (ML) ratio (based on predicted values, symbols) vs. age and computed specified logistic models (lines) for *Illex* females (see Table 1 for case specifications).

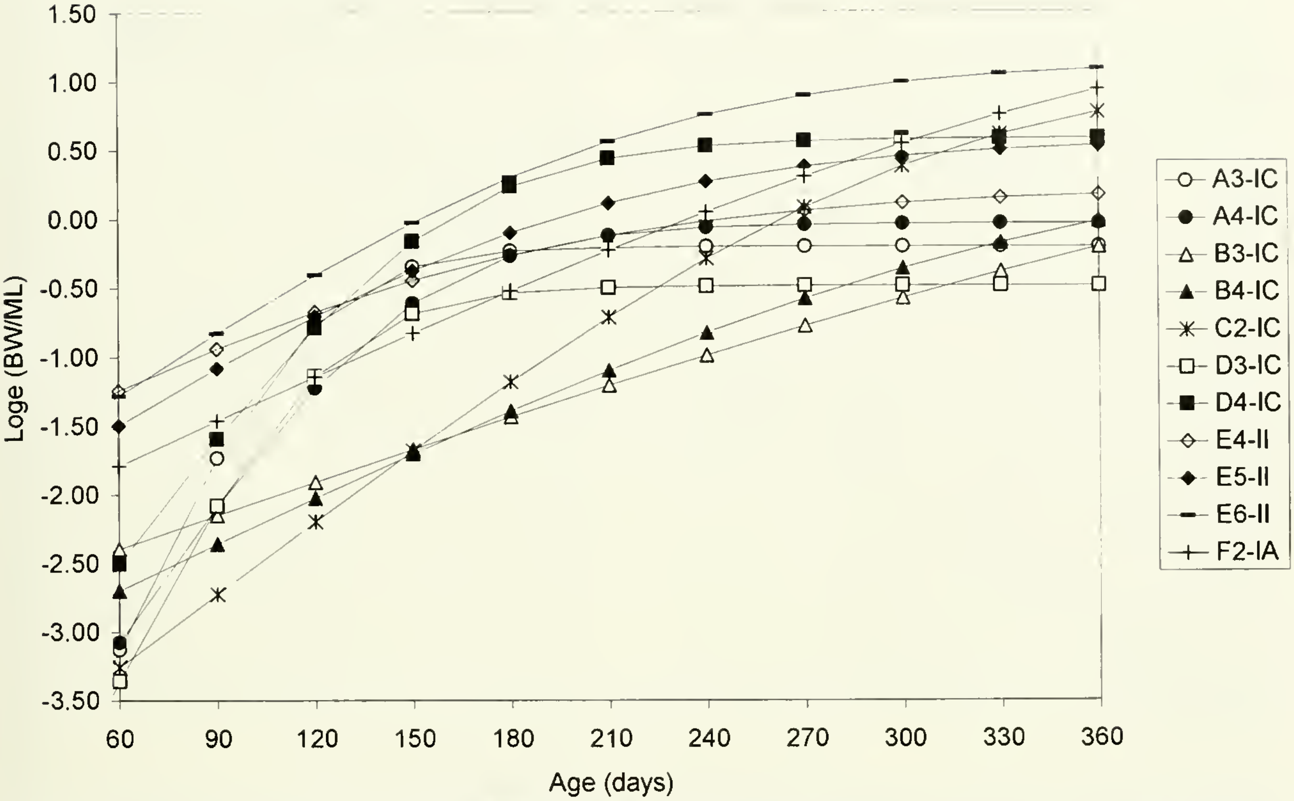

Figure 4. Log$_e$ of body weight (BW) at mantle length (ML) ratio (based on predicted values, symbols) vs. age and computed specified logistic models (lines) for *Illex* males (see Table 1 for case specifications).

Application of Model ii resulted in rapid convergence and satisfactory agreement between predicted and empirical values (Table 4). Both the slopes (B) and asymptote (A) increased with month of hatching in each sex. Differences in these parameter values between sexes were slight for all hatching groups.

Case B, C, D, and F: Illex spp.

For these cases, for which no raw data were available, both models performed quite well (Table 4), but Model i did not achieve complete linearity in D cases. There were some strong differences in model parameters between the sexes but none that were consistent among groups and between Models i and ii. All cases for all three species are compared using Model ii for females (Fig. 3) and males (Fig. 4). Two patterns emerged: relationships with a slight curvature (Cases B1–B4; C1–C2; F1–F2) and relationships with a pronounced curvature and asymptotic trend (all D cases).

Clear differences in model slopes between sexes were evident in *I. coindetii* off Sierra Leone (D1, D3) and in *I. argentinus* (F1, F2), but in the former the slope was higher for females than males, whereas the opposite was true in the latter.

A comparison among and within species indicates that B cases (*I. coindetii* from the Catalonian Sea; Figs. 3 and 4) are unique. They are consistently different from the other curves, suggesting relatively slow and near linear growth, regardless which model is considered.

The Inflection Point and Maturity

The relationship between age-at-the-inflection point (i.e., C parameter; Table 4) and the mean age of mature animals of a specific group (as directly computed or roughly estimated from the literature) was examined (Fig. 5). Despite the rough approximation, a positive and significant linear trend between the two parameters was evident, suggesting that C values reflect to a certain extent ages at maturity. The estimated slope (1.7), however, is higher than the value expected in case of direct proportionality (close to 1). The inflection parameter tended to be relatively lower than (or equal to) the age at maturity for groups where almost all the life stages were represented in the samples (i.e., A1–A4 and D1–D4). It tended to be relatively higher in cases in which mature specimens were underrepresented in the samples, i.e., mean age at maturity was probably underestimated (i.e., C1–C2 and F1).

DISCUSSION

The most appropriate model for describing growth in cephalopods is currently a subject of strong debate. One argument is that squid are fundamentally different from fish and so any of the several available empirical growth models may be appropriate and applied (Jackson 1994). The alternative argument is that most principles of fish population biology do apply to squid; therefore the most appropriate growth function to use is the von Bertalanffy Model (Pauly 1985, Longhurst & Pauly 1987, Pauly 1998).

There is no need of entering into this matter here because an index of growth performance was modeled, not growth in absolute size itself. Therefore we were justified in embracing, the view of Ricker (1979), that "the only criteria for choosing a growth curve that have proven valid are goodness of fit and convenience." It is, however, of considerable interest to compare trends in growth performance obtained here with trends in growth from studies of absolute size-at-age.

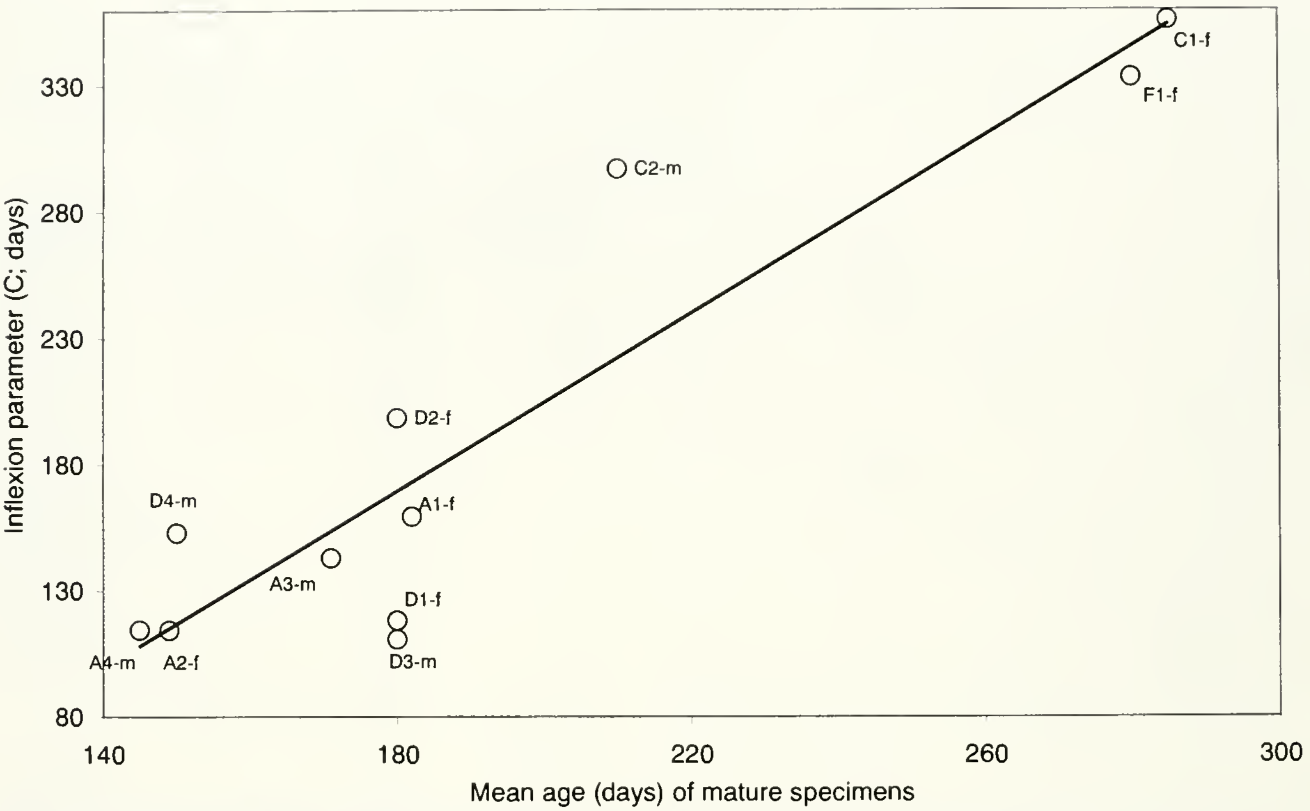

Figure 5. Relationship between age at inflexion point (C parameter of the specific logistic model) and mean age of mature *Illex* females (see Table 1 for case specifications). The fitted straight line is significant ($r^2 = 0.835$; df = 9).

Trends in Growth Performance

A single curve has seldom been suitable to describe the whole life cycle when modeling size-at-age (Ricker 1979, Jackson 1994); therefore, a single model is more often a compromise that deals with different growth phases, each of which could be better described independently.

In the case of *Illex* spp, at least three phases of growth can be identified: an early (larval) exponential phase, a "juvenile" (power or log linear) phase and a "mature and post mature" phase. Because of this, the exponential and the power models are often defined as "early growth curves" (Peters 1983).

Linear modeling of length-at-age data fits satisfactorily some restricted portions of the life cycle (Rodhouse & Hatfield 1990, Gonzalez et al. 1996, Dawe & Beck 1997), but clearly does not apply to the entire cycle (Dawe & Beck 1997, Gonzalez et al. 1998).

A logistic model was already used quite satisfactorily to represent growth in length and weight of A1–A4 squids (Arkhipkin et al. 2000).

However, several different models can fit the same set of data (Arkhipkin et al. 1998) and in some situations both linear and curvilinear models could perform quite well, as was recently reported for length-at-age of *I. argentinus* (Uozumi & Shiba 1993).

In our study of growth performance, the logistic model was quite suitable for cases in which most of the ontogenetic development was represented in the samples (i.e., individual and predicted data for cases A and values based on predicted sizes for cases D). Nevertheless, some imprecision in the estimate of the A (asymptotic) parameter was evident, likely as a consequence of the poor representation in the samples of spent males and females, i.e., a poor representation of the last portion of the life cycle.

Besides the problem related to sampling the whole life cycle, poor model fits obtained with raw data may be caused by several different biases that are related to the different aspects of the methodology applied, starting with the partitioning of specimens into groups or "microcohorts" based on periods of hatching (e.g., month). Statolith increment counts in fact, can be affected by systematic and measurement errors due to preparation techniques and reader's interpretation (Jackson 1994, Dawe & Beck 1997, Arkhipkin et al. 1998, Gonzalez et al. 1998, Gonzalez et al. 2000). Thus, the hatching month to which any individual is assigned may be largely a function of ageing error (Gonzalez et al. 2000).

The use of mean values, despite statistical problems in fitting models, reduces the incidence of these errors thus reflecting in a better model fit.

Comparisons of absolute growth can also be biased by differences in the sampling gear used. Although little is known about the catching capacity of gear such as trawls, traps and jigs, it is most likely that their selectivity by size do differ, so that none of them individually would provide a truly representative sample. Our approach facilitates comparisons when such sampling biases are present, since different gears are likely to be much more highly selective for absolute size than for physical condition.

Evaluation of Models

One of the immediate questions to answer, i.e., "Is there any advantage to modeling WaL above modeling ML and BW separately?" requires comparisons to be answered. Such comparisons were possible only for individual *I. coindetii* (A1–A4 cases) and *I.*

illecebrosus (E1–E6) data sets, based on the logistic models reported in Arkhipkin et al. (2000) and the simple linear and log-log models presented in Dawe and Beck (1997).

The r^2 for A cases ranged between 0.87–0.91, 0.77–0.89, and 0.95–0.97 for ML-at-age, BW-at-age, and $\log_e$WaL-at-age, respectively. Considering the E cases, the r^2 values ranged between 0.37–0.84, 0.37–0.90, and 0.35–0.90 for ML-at-age, $\log_e$BW-at-$\log_e$age, and $\log_e$WaL-at-age, respectively. Results indicate that similar (E1–E6) or even better (A1–A4) model fits were obtained by using WaL instead of ML and BW separately, with the advantage of using only one model to take into consideration two size indices. A possible explanation for that is that while length will increase with age under any conditions, weight may increase or decrease, but does not account for concurrent increases in length. However, weight-at-length does account for concurrent length increase, and so it is a better descriptor of growth performance.

Another very interesting point is the comparison of results obtained by applying the same models to the same data sets and using alternatively raw data from individuals and values computed from predicted lengths and weights. While both Models i and ii (i.e., the log-log and the specific logistic) do fit consistently well for both *I. coindetii* and *I. illecebrosus* datasets when using data based on predicted sizes, when raw individual data were used, Model ii fitted well *I. coindetii* datasets (Cases A), but did not fit *I. illecebrosus* datasets. Such differences in Model ii fits are likely the consequence of the "quality" of the available datasets. Raw individual age data in fact, are almost neither "balanced" (i.e., the same number of aged specimens for each age level) nor "optimal" (i.e., number of counts proportional to the variance of the estimates) because statolith processing is very time consuming and age classes are numerous. In cases of such high variability, few points could have a great influence on the estimates and the model may not fit properly. If the samples are larger, however, or if repeated blind counts are available (see, for example, Arkhipkin et al. 1998), then a statistical "weight" can be assigned to each point and a weighed regression performed to improve the fitting quality (Neter et al. 1985).

Comparisons Within and Among Species

WaL modeling showed some common patterns among species and groups, with the exception of the *I. coindetii* population of the Catalonian Sea. Regardless of the model applied to those exceptional cases, the parameters generated were quite different from those of all the other cases. To a certain extent, such differences may be related to the indirect method used in the present work to compute body weight-at-age, but it is also likely that age was originally overestimated for that group, as a consequence of the ageing method used (Arkhipkin personal communication; Dawe & Beck 1997, Gonzalez et al. 2000).

Results obtained for the other groups showed several common features of growth performance within the genus *Illex*, which are consistent with results of other studies (e.g., Dawe & Beck 1997, Haimovici et al. 1998, Arkhipkin et al. 2000). These features include superior growth performance of *I. coindetii* and *I. illecebrosus* specimens hatched in warm conditions relative to those hatched in colder conditions. Also consistent with previous studies, a superior growth performance in populations inhabiting warm waters (Strait of Sicily in the Central Mediterranean Sea, West Sahara, and Sierra Leone in the Eastern Atlantic) relative to that of con-specific or con-generic populations living in colder waters resulted. Last but not least, the previous conclusion that the Galician *I. coindetii* population appears to be more similar to the South Patagonian stock of *I. argentinus* than to any other *Illex* populations (Gonzalez et al. 1996) was confirmed.

One of the most interesting results of our study is the direct relationship found between the inflexion parameter C (from application of the specific logistic model) and the age-at-maturity. Size-at-maturity in *Illex* squid has rarely been objectively defined (e.g., as the size at which 50% of the specimens were classified as mature; cf. Jereb & Ragonese 1995). Usually, only ranges or mean size values of mature animals have been reported, although the onset of sexual maturation is considered to be a critical point in cephalopod life cycles (Mangold et al. 1993).

The C parameter may represent a useful maturity objective index for future studies of changes or trends in sexual maturation. For example, Pauly (1998) argued that principles of fish dynamics are also applicable to cephalopods. If this were true, then temperature would be directly related to growth rate and inversely related to maximum size- and age-at-maturity. Consequently, when comparing among populations, a shift of the inflection parameter to younger ages would be expected from colder to warmer habitats, related to an improvement in growth performance. This is consistent with results obtained in the present work.

Obviously further comparative studies are required especially within populations. Independent estimates of size- and age-at-maturity would be very useful in evaluating if a true relationship exists between the C parameter from the specific logistic model and the age at the onset of maturity.

COMPARISON OF NUTRIENT COMPOSITION OF GONADS AND COELOMIC FLUID OF GREEN SEA URCHIN *STRONGYLOCENTROTUS DROEBACHIENSIS*

CHANDRIKA LIYANA-PATHIRANA,[1] FEREIDOON SHAHIDI,[1,2]* AND ALAN WHITTICK[1]
[1]*Department of Biology,* [2]*Department of Biochemistry, Memorial University of Newfoundland, St. John's, Newfoundland, A1B 3X9, Canada*

ABSTRACT The compositional characteristics of sea urchin gonads and coelomic fluid from *Strongylocentrotus droebachiensis* harvested in the coasts of Newfoundland and thereafter reared in an aquaculture facility and fed on a *Laminaria* diet for a 3-week period, were assessed. Evaluations were performed on the basis of proximate composition, lipid class distribution, fatty acid composition, total and free amino acid composition, and contents of nucleic acids and carotenoids. Noticeable changes existed between proximate composition of sea urchin gonads and coelomic fluid. Moisture content was 74.7 ± 0.04 and 96.5 ± 0.03% in gonads and coelomic fluid, respectively. Gonads contained very high levels of lipids, proteins, and carbohydrates; whereas, these were present at very low levels in the coelomic fluid. Major nonpolar lipid classes were triacylglycerols (TAG), free fatty acids (FFA), and sterols (ST) while dominant polar lipid classes were phosphatidylcholine (PC), phosphatidylethanolamine (PE), sphingomyelin/ lysophosphatidylcholine (SM/LPC), and phosphatidylserine / phosphatidylinositol (PS/PI) in both the gonads and the coelomic fluid. Major saturated fatty acids (SFA) were 14:0 and 16:0; whereas, 20:1n-15 was the main monounsaturated fatty acid (MUFA) present. Furthermore, 20:5n-3 (eicosapentaenoic acid, EPA) was the dominant polyunsaturated fatty acid (PUFA) in the gonads and the coelomic fluid. The total amino acid (TAA) and free amino acid (FAA) profiles were dominated by glycine. The total FAA content was much higher in the gonads than in the coelomic fluid. In addition, the total carotenoid content of sea urchin gonads was approximately 6.4 times greater than that of coelomic fluid. Hence, most of the carotenoids were concentrated in the gonadal tissue. Echininone and fucoxanthin were the dominant carotenoids in the gonads and the coelomic fluid, respectively. The content of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) was much higher in the gonad than in the coelomic fluid, thus indicating greater biomass and protein synthetic activity in the former tissue. The present study demonstrates that sea urchin gonads have much in common with sea urchin coelomic fluid on a qualitative basis. However, there were marked quantitative differences between the two tissues.

KEY WORDS: amino acid composition, carotenoids, fatty acid composition, lipid class distribution, nucleic acids, *Strongylocentrotus droebachiensis*

INTRODUCTION

Sea urchins belong to the marine invertebrate phylum Echinodermata or spiny-skinned animals. These relatively small echinoderms have spherical bodies enclosed in a hard shell or "test" completely covered with numerous sharp spines. Sea urchins are omnivorous animals that live on the ocean floor, feeding on small crustaceans, fish offal, but mainly seaweed (Smith 1980). Thus, the eating quality of sea urchin gonads is dictated, to a certain degree, by the quality of kelp consumed. *Laminaria* kelps are the preferred source of feed for sea urchins. Kramer and Nordin (1979) reported that the green sea urchin *Strongylocentrotus droebachiensis* produces high-quality gonads when the availability of fresh kelp is adequate. The edible green sea urchin *S. droebachiensis* is abundantly distributed in the North Atlantic, Arctic, and North Pacific Oceans, but this species is currently exploited to a much lesser extent in the Northwest Atlantic and in the Northeast Pacific, and Northeast Atlantic (Walker & Lesser 1998). Furthermore, *S. droebachiensis* is a target species for the development of commercial echiniculture (Hagen 1996).

The edible portions of the sea urchin body are its reproductive organs; ovaries, and testes. Gonad yield from sea urchin may vary with the time and the site of harvest and generally ranges from 8–20% of the total body mass. When sea urchins are processed for gonads, the initial step is to break the shell and open it so that the five gonad sacs are exposed. The cracked shells are then allowed to drain for several minutes to dispose of coelomic fluid. Thus, during extraction of sea urchin gonads, large amounts of coelomic fluid are obtained. So far, there are no effective means of using sea urchin coelomic fluid in a useful manner. Furthermore, no information is available on the nutrient composition of sea urchin coelomic fluid. In fact, knowledge of nutrient composition may be useful to determine whether sea urchin coelomic fluid could serve as a potential source of a flavoring in fabricated seafood.

The objective of this study was to assess the nutrient composition of sea urchin coelomic fluid as compared with that of the gonads. Thus, proximate composition, lipid class distribution, fatty acid composition, amino acid composition, and contents of carotenoids and nucleic acids of gonads and coelomic fluid were determined. This may lead to potential commercial utilization of the processing byproducts from sea urchins, which would otherwise be discarded.

MATERIALS AND METHODS

Materials

One hundred twenty-five sea urchins were procured from the Sea Urchin Research Facility (SURF) at Bonavista Bay, Newfoundland and subsequently transported in aquarium coolers to our laboratory at Memorial University of Newfoundland. Urchins were captured from the wild (June 2000) and raised in raceways feeding on a *Laminaria* diet. Urchins were harvested for analysis after three weeks of feeding on a purely algal diet. Live urchins were stored at 4°C before the extraction of tissues. The gonads and coelomic fluid of sea urchins were separated after breaking the shell, using a specially devised sea urchin cracking tool. After extraction, sea urchin gonads were homogenized for 2 min using a cooled Waring blender (Dynamics Corporation, New Hartford, CT), and coelomic fluid was used for analysis as it is. In this study, sea urchin male and female gonads were pooled together for analysis. The tissues (both gonads and coelomic fluid) were flushed with liquid nitrogen and stored at −20°C until used for further analyses. All chemicals used were obtained from either Fisher Scientific (Fair Lawn, NJ) or Sigma Chemical Co. (St. Louis, MO). The solvents were of ACS-, pesticide-, or HPLC-grade.

Determination of Proximate Composition

Moisture and ash contents of sea urchin tissues were determined according to the standard AOAC (1990) procedures. Crude protein content was obtained by Kjeldhal method (AOAC 1990), and total lipids were extracted and quantified by the Bligh and Dyer (1959) procedure. Carbohydrate content of each sample was determined by difference.

Analysis of Lipid Classes by Iatroscan

Instrumentation

The crude lipids obtained from Bligh and Dyer (1959) extraction were chromatographed on silica gel-coated Chromarods - S III and then analyzed using an Iatroscan MK-5 (Iatroscan Laboratories Inc., Tokyo) analyzer equipped with a flame ionization detector (FID) connected to a computer loaded with TSCAN software (Scientific Products and Equipment, Concord, ON) for data handling. A hydrogen flow rate of 160 mL per min and an airflow rate of 2,000 mL per min were used in operating the FID. The scanning speed of rods was 30 sec per rod.

Preparation of Chromarods

The Chromarods were soaked in concentrated nitric acid overnight followed by thorough washing with distilled water and acetone. The Chromarods were then impregnated by dipping in a 3% (w/v) boric acid solution for five minutes to improve separation. Finally, the cleaned Chromarods were scanned twice to burn any remaining impurities.

Standards and Calibration

A stock solution of each of the nonpolar lipids; namely, free fatty acid (FFA; oleic acid), cholesterol ester (CE), cholesterol (CHOL), monoacylglycerol (MAG; monoolein), diacylglycerol (DAG; diolein), and triacylglycerol (TAG; triolein), and the polar lipids; namely, phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), phosphatidylserine (PS), lysophosphatidylcholine (LPC), lysophosphatidylethanolamine (LPE), cardiolipin (CL), and sphingomyelin (SM) was prepared by dissolving each in a chloroform/methanol (2:1, v/v) solution and stored at −20°C. A range of dilutions of the stock solution, from 0.1 to 10 μg per μL, was prepared for use as working standards. Each compound was developed individually and run on the Iatroscan-FID to determine its purity and Rf value. For each compound peak, area was plotted against a series of known concentrations to obtain the calibration curve.

Iatroscan (TLC-FID) Analysis of Sea Urchin Lipids

The total lipids extracted were dissolved in chloroform/methanol (2:1, v/v) to obtain a concentration of 1 μg lipid per mL. A 1 μL aliquot of sample was spotted on silica gel-coated Chromarods - S III and conditioned in a humidity chamber containing saturated $CaCl_2$ for 20 min. The Chromarods were then developed in two solvent systems. The solvent system hexane/diethyl ether/acetic acid (80:20:2, v/v/v) was used for separation of nonpolar lipids (Christie 1982). Following their development, Chromarods were dried at 110°C for three minutes and scanned completely to reveal nonpolar lipids. For polar lipids, following the same procedure and drying, the Chromarods were scanned partially to a point just beyond the MAG peak to burn the nonpolar lipids. These partially scanned Chromarods were developed in a second solvent system of chloroform/methanol/water (80:35:2, v/v/v) for the separation of polar lipid classes (Christie 1982) followed by drying at 110°C for three minutes. Finally, the Chromarods were scanned completely to reveal polar lipids; the identity of each peak was determined by comparison with a chromatogram of standards acquired concurrently with the samples. The determination of weight percentages of individual lipid classes was achieved using the standard curves obtained for each authentic standard.

Analysis of Fatty Acid Composition of Lipids

Fatty acid composition of lipids was determined using gas chromatography (GC) as described by Wanasundara and Shahidi (1997). Fatty acid methyl esters (FAMEs) of total lipids of sea urchin gonads and coelomic fluid were prepared by transmethylating approximately 10 to 20 mg of each lipid sample in 2 mL of freshly prepared transmethylating reagent [6% (v/v) sulfuric acid in 99.9 mol% HPLC-grade methanol containing 15 mg of t-butylhydroquinone (TBHQ)] at 65°C for 15 h in a 6 mL Teflon-lined screw-capped conical vials. After incubation, the mixture was cooled, and 1 mL of distilled water was added to it. This was followed by extracting the FAMEs three times with 1.5 mL pesticide-grade hexane. A few crystals of TBHQ were added to each sample before extraction with hexane. The hexane layers were removed and combined in a clean test tube followed by washing twice with 1.5 mL of distilled water by vortexing. The aqueous layer was discarded after the first wash, while the hexane layer was removed and placed in a GC vial following the second wash. Hexane was evaporated under a stream of nitrogen in a fume hood. The dried FAMEs were then dissolved in 1 mL of carbon disulfide and used for GC analysis. FAMEs were separated using a gas chromatograph (Hewlett-Packard 5890 Series II, Hewlett-Packard, Mississuaga, ON) equipped with a fused silica capillary column (SUPELCOWAX-10, 0.25-mm diameter, 30-m length, 0.25-μm film thickness; Supelco Canada Ltd., Oakville, ON). The sample was injected into the GC analyzer using a Hewlett-Packard 7673 autoinjector (Hewlett-Packard, Toronto, ON). The temperature of the oven was programmed at 220°C for 10.25 min followed by ramping to 240°C at 20°C per min, where it was held for nine minutes. Helium at a flow rate of 2 mL per min was used as the carrier gas. The FAMEs were identified by comparing their retention times with those of authentic standard mixtures (GLC - 461, Nu-Check-Prep) and literature values (Takagi et al. 1980, Takagi et al. 1986). The relative content of fatty acids in the sample was determined using the peak areas of fatty acids.

Carotenoid Pigments

Extraction and Determination of Total and Individual Carotenoids

Carotenoids from each tissue were extracted three times with a total of 50 mL of acetone for two minutes. The homogenized samples were centrifuged (IEC Centra MP4 Centrifuge, International Equipment Co., Needham Heights, MA) at 4000 × g for five minutes. The supernatant was subsequently filtered through a

Whatman No. 1 filter paper. Carotenoid pigments in acetone were then transferred to 40 mL of n-hexane in a 250-mL separatory funnel. One hundred milliliters of a 0.5% sodium chloride solution were added to the mixture to maximize the transfer of carotenoids. The hexane layer was then transferred into a 50-mL volumetric flask and made up to volume. The absorption spectrum was then recorded (400–600 nm) using a Spectronic spectrophotometer (Spectronic Genesis, Toronto, ON). The total and individual carotenoid contents were determined by the method of McBeth (1972). The total content of carotenoids present per 100 g of tissue was calculated using the following equation.

$$\text{mg Carotenoid per 100 g tissue} = (A \times V \times 10^3)/\varepsilon \times W)$$

where, A = absorbance at λ_{max}; V = total volume of the sample (mL); ε = molar extinction coefficient, and W = weight of the tissue (g). Because the crude extracts usually contained a variety of carotenoids an average coefficient of 2,500 was used in the calculations.

The total pigment extracted was separated into individual carotenoids by means of thin-layer chromatography (TLC). The crude carotenoids were separated by preparative TLC on silica gel G (20 × 20 cm, 250 μm, Aldrich Chemical Co., Inc., Milwaukee, WI) using acetone/n-hexane (3:7, v/v) as the developing solvent.

Characterization of Fractions

Cochromatography on TLC provided the ultimate test for identification when authentic samples were available for comparison with unknown pigments. The unknown fraction and the authentic sample were spotted on either side in an equally proportionated mixture of the two pigments on silica gel G plates (20 × 20 cm, 250 μm, Aldrich Chemical Co., Inc., Milwaukee, WI); unknown fractions were considered to be identical to the authentic sample if the two did not separate upon subsequent development of the plate. When authentic samples were unavailable, the type of carotenoid in each fraction was tentatively identified according to its absorption maximum in n-hexane, ethanol, and chloroform (Goodwin 1955, Krinsky & Goldsmith 1960, Fox & Hopkins 1966, Britton 1995).

Determination of Total Amino Acids

The amino acid composition of sea urchin gonads and coelomic fluid was determined according to the procedure described by Blackburn (1968). Samples were lyophilized and then hydrolyzed for 24 h at 110°C with 6M HCl. Hydrochloric acid in the hydrolyzate was removed under vacuum, and the dried sample was reconstituted with a lithium citrate buffer (0.2 M, pH 2.2) for analysis. The amino acids in the hydrolyzate were separated, identified and quantified using a Beckman 121 MB amino acid analyzer (Beckman Instruments Inc., Palo Alto, CA). Sulfur-containing amino acids were determined by oxidizing the samples with performic acid before their hydrolysis in a 6M HCl solution (Blackburn 1968). Cysteine and methionine were measured as cysteic acid and methionine sulphone, respectively. To determine tryptophan, samples were hydrolyzed in 3M mercaptoethanesulfonic acid at 110°C for 22 h under nitrogen and then neutralized with lithium hydroxide and adjusted to pH 2.2 (Penke et al. 1974).

Determination of Free Amino Acids

Samples (10 g) were extracted with 20 mL of a 6% (v/v) perchloric acid (PCA) solution by homogenization using a Polytron homogenizer (Brinkmann Instruments, Rexdale, ON) at 10,000 rpm for two minutes in an ice bath. The homogenized samples were then incubated in an ice bath for 30 min. This was followed by centrifugation (IEC Centra MP4 Centrifuge, International Equipment Co., Needham Heights, MA) at 2,000 × g for 15 min. The residue was re-extracted with another 20 mL of 6% PCA. The supernatants were combined and filtered through a Whatman No. 4 filter paper. The pH of the filtrate was adjusted to 7.0 using a 33% KOH (w/v) solution. Precipitates of potassium perchlorate were removed by centrifugation at 2000 × g for 10 min. The supernatant was then acidified to pH 2.2 using a 10 M HCl solution, and the volume of the extract was brought to 50 mL with distilled water. Three milliliters of lithium citrate buffer (pH 2.2, 0.3M) were added to 1 mL of the extract, and the resultant solution was analyzed using a Beckman 121 MB amino acid analyzer (Beckman Instruments, Inc., Palo Alto, CA) for individual amino acids.

Determination of Nucleic Acids

The DNA and RNA contstituents of gonads and coelomic fluid of sea urchins were extracted according to the method of Schmidt and Thannhauser (1945) as modified by Munro and Fleck (1969). Five grams of each sample were homogenized in 80 mL ice-cold deionized water using a Polytron homogenizer (Brinkman Instruments, Rexdale, ON) at 10,000 rpm. Five milliliters of the homogenate were allowed to stand for ten minutes in ice and then centrifuged (IEC Centra MP4 Centrifuge, International Equipment Co., Needham Heights, MA) at 2000 × g for ten minutes. The residue was subsequently washed with 2.5 mL of ice-cold 0.2 M PCA and centrifuged at 2,000 × g for ten minutes followed by digestion of the residue in 4 mL of a 0.3 M KOH for one hour at 37°C in a water bath. The resultant solution was cooled in ice and mixed with 2.5 mL of 1.2 M PCA and allowed to stand for ten minutes, which finally resulted in the coagulation of proteins. The mixture was centrifuged at 2,000 × g for ten minutes, and the supernatant was recovered (Extract No.1). The precipitate was then washed twice with 2.5 mL of a 0.2 M PCA solution and centrifuged at 2,000 × g for five minutes. The supernatant was combined with extract No. 1 and 10 mL of a 0.6 M PCA were added to the mixture. This was used for RNA determination after diluting it up to 100 mL with distilled water. The residue was dissolved in 17 mL of a 0.3 M KOH solution at 37°C and diluted to the 50 mL mark in a volumetric flask with distilled water. The content of DNA in the samples was estimated by determining the deoxyribose content in the extract using the indole procedure of Ceriotti (1952), while RNA was determined by recording the absorbance of the nucleotide extracts at 260 nm using a Hewlett-Packard diode array spectrophotometer (Hewlett-Packard, Model 8452A, Hewlett-Packard [Canada] Ltd., Mississauga, ON). Protein interference at this wavelength was eliminated by employing a correction factor of 0.001 absorbance unit for each 1 μg per mL protein concentration in the extracts. The protein concentration of the extracts was measured using the Folin–phenol procedure of Lowry et al. (1951). Bovine serum albumin (BSA) was used as a standard. Calf thymus DNA (containing 82% single stranded DNA) and calf liver RNA (96% purity) were used as the standards for DNA and RNA determinations, respectively.

Statistical Analysis

Each experiment was replicated three times and mean values ± standard deviations reported for each sample. For statistical analyses, mean values of the experimental data were subjected to one way analysis of variance (ANOVA) using GraphPAD Instat Version 1.0. Significance was determined at 5% probability level.

RESULTS

Proximate Composition

Proximate composition of sea urchin gonads and coelomic fluid is shown in Table 1. The moisture and ash contents of sea urchin coelomic fluid were much higher than those of the gonads. On the other hand, the levels of protein, lipid, and carbohydrate in the coelomic fluid were much lower than those in the gonads on a fresh weight basis.

Lipid Class Distribution

The nonpolar and polar lipid classes of gonads and coelomic fluid of sea urchin *S. droebachiensis* are shown in Table 2. Major nonpolar lipid classes were TAG, FFA, and ST; whereas, main polar lipids classes were PC, PE, SM/LPC, and PS/PI in both gonads and coelomic fluid. Triacylglycerols constituted the main energy reserve in both tissues, contributing more than 65% to the total nonpolar lipids. On the other hand, PC was the dominant polar lipid, accounting for more than 60% in both gonads and coelomic fluid. The polar lipid classes SM and LPC as well as PS and PI did not show a clear chromatographic separation from each other during Iatroscan analysis.

Fatty Acid Composition

Fatty acid composition of sea urchin gonads and coelomic fluid is presented in Table 3. Qualitatively, the fatty acid compositions were the same in both tissues, while there were significant ($P < 0.05$) quantitative variations. In both tissues, 14:0 and 16:0 were the main saturated fatty acids. In addition, 18:0 and 20:0 were present in considerably high levels. The fatty acid 20:1n-15 was the dominant MUFA in both gonadal and coelomic fluid lipids. Furthermore, 16:1n-7, 16:1n-9, 18:1n-7, 20:1n-7, 20:1n-9, and 22:1n-11 were detected in noticeable amounts. Among PUFA, 20:5n-3 contributed the highest proportion to the total fatty acid content in both gonadal and coelomic fluid lipids.

Carotenoid Pigments

The total carotenoid content, on a dry weight basis, of sea urchin gonads and coelomic fluid was 23.2 ± 0.04 and 3.7 ± 0.1 mg per g tissue, respectively. Crude pigments from gonads and coelomic fluid were separated by TLC into eight and seven fractions, respectively. Crude pigments of both tissues, upon TLC separation, exhibited two major bands. In gonads, fractions I (Rf = 0.96) and II (Rf = 0.88) ran close to the solvent front, but they were adequately separated. For coelomic fluid, fraction I (Rf = 0.94) ran almost close to the solvent front; whereas, fraction IV (Rf = 0.42) ran well behind. The carotenoid fraction I of both gonads and coelomic fluid of sea urchin *S. droebachiensis* was confirmed to be β-carotene using an authentic β-carotene sample as established by cochromatography on silica gel TLC plates. Similarly, gonadal fractions III, IV, VI, and VII contained astaxanthin ester (Rf = 0.57), zeaxanthin (Rf = 0.51), canthaxanthin (Rf = 0.22), and free astaxanthin (Rf = 0.1), respectively. Furthermore, fraction II of gonadal crude pigments corresponded to echininone by means of absorption maxima in hexane, chloroform, and ethanol (Goodwin 1955, Krinsky & Goldsmith 1960, Fox & Hopkins 1966, Britton 1995). Thus, the observed λ_{max} values of echininone were 484/460, 466, and 475 nm in hexane, ethanol, and chloroform, respectively. In coelomic fluid, the pigment in fraction IV corresponded with fucoxanthin based on absorption maxima of 424/447/474, 423/446/472, and 454/488 nm in hexane, ethanol, and chloroform, respectively. Other minor carotenoids in the coelomic fluid were astaxanthin etser (Rf = 0.58), canthaxanthin (Rf = 0.23), and free astaxanthin (Rf = 0.1), which corresponded to fractions III, V, and VI, respectively. The other minor carotenoids were not analyzed because of their insufficient concentration to obtain absorption maxima and also lack of authentic samples.

TABLE 1.

Proximate composition of sea urchin gonads and coelomic fluid after feeding urchins on a *Laminaria* diet for three weeks.

Constituent	Gonads	Coelomic Fluid
Moisture	74.7 (0.04)	96.5 (0.03)
Ash	2.2 (0.2)	3.0 (0.02)
Protein	7.4 (0.2)	0.1 (0.02)
Lipid	4.7 (0.1)	0.1 (0.03)
Carbohydrate[a]	10.6 (0.2)	0.4 (0.1)

Results are mean values of three replicates (standard deviation). Values in each row with the same superscript are not different ($P > 0.05$) from one another.

[a] Determined by difference.

TABLE 2.

Quantification of non-polar and polar lipids (weight %) of sea urchin gonads and coelomic fluid after feeding the urchins on *Laminoria* diet for three weeks.

Lipid Classes	Gonad	Coelomic Fluid
Non polar lipids		
TAG	66.7 (0.8)	56.5 (0.7)
FFA	22.7 (1.1)	37.4 (1.0)

SM/LPC	8.4 (0.7)	2.6 (0.2)
PS/PI	8.5 (0.6)	1.1 (0.5)

Results are mean values of three replicates (standard deviation). Values in each row with the same superscript are not different ($P > 0.05$) from one another. Abbreviations: TAG, triacylglycerol; FFA, free fatty acid; ST, sterol; MAG, monoacylglycerol; DAG, diacylglycerol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; SM, sphingomyelin; LPC, lysiphosphatidylcholine; PS, phosphatidylserine and PI, phosphatidylinositol; and tr, trace.

Amino Acid Composition

The total and free amino acid compositions of sea urchin gonads and coelomic fluid are shown in Tables 4 and 5, respectively. Results so obtained did not show any clear variation on a qualitative basis for tissues examined. Thus, the spectrum of amino acids, both total and free, present was nearly the same for both gonads and coelomic fluid. Total amino acid profile indicated the

Tyrosine	36.3 (0.8)^{a}	38.6 (0.4)^{b}
Valine	78.3 (0.4)^{a}	75.1 (1.0)^{b}
Total (mg/g protein)	989.4 (2.2)	985.4 (1.3)

Results are mean values of three replicates (standard deviation). Values in each row with the same superscript are not different ($P > 0.05$) from one another.

dominance of glycine in both tissues analyzed. However, on a dry weight basis, the content of glycine in sea urchin coelomic fluid was significantly ($P < 0.05$) higher than that of gonads. Almost all the essential amino acids were present in both gonads and coelomic fluid of *S. droebachiensis*. With respect to FAA content of sea urchin tissues, the total FAA content was much higher in sea urchin gonads than that in the coelomic fluid. However, in both tissues glycine was the dominant FAA contributing 57.1 and 56.3% to the total amount in the gonads and coelomic fluid, respectively.

Content of Nucleic Acids

The content of nucleic acids in sea urchin gonads and coelomic fluid, on a dry weight basis, was different. The content of DNA of sea urchin gonads and coelomic fluid was 3.93 ± 0.1 and 1.02 ± 0.07 μg per g tissue, respectively; whereas, corresponding values for the content of RNA were 2.63 ± 0.06 and 0.49 ± 0.03 μg per g tissue, respectively. Thus, the content of DNA was higher than that of RNA in both tissues analyzed. Furthermore, the ratio of RNA/DNA was 0.7 ± 0.1 and 0.5 ± 0.03 for sea urchin gonads and coelomic fluid, respectively.

DISCUSSION

Reproductive State of Sea Urchins

For feeding experiments, sea urchins were obtained from the wild in the month of June, representing the spring season. In general, gonad development in sea urchins may include five different stages of resting, growing, premature, mature, and spawning (de Jong-Westman et al. 1996). In resting, gonad size is at a minimum, which usually occurs after spawning. *S. droebachiensis* has an annual reproductive cycle with major spawning period in the late winter or early spring (Keats et al. 1984). Therefore, at this stage, urchins were presumably in the state of resting; hence, they have undergone a large drop in gonad size following spawning.

In general, gonadal yield is strongly affected by the seasonal reproductive cycle of sea urchins. During spawning, a high proportion of the gonad mass is released as gametes (Thompson 1984). Once spawning occurred, this may exert a significant effect on the biochemical composition of gonads. Because urchins were fed on a *Laminaria* diet after harvesting and consequently subject to intense feeding, this may have a significant effect on the nutrient composition of sea urchin tissues. Generally, both food quality and quantity affect sea urchin growth (Lawrence & Lane 1982), thus excessive feeding resulting in the accumulation of nutrients in the tissues.

Proximate Composition

The major nutrients of sea urchin *S. droebachiensis* gonads were polysaccharides, proteins, and lipids, similar to that reported

TABLE 5.

Free amino acid content (μ/g dry weight) of sea urchin gonads and coelomic fluid after feeding urchins on *Laminaria* diet for three weeks.

Amino Acid	Gonads		Coelomic Fluid	
	μg/g	%	μg/g	%

Valine	273 (16)^{a}	1.3	272 (9)^{b}	2.3
Total (mg/g)	21 (1.0)^{a}		12.0 (0.8)	

Results are mean values of three replicates (standard deviation). Values in each row with the same superscript are not different ($P > 0.05$) from one another.

by Fernandez et al. (1995). However, coelomic fluid contained 96.5 ± 0.03% moisture; thus, its contents of lipid, protein, and polysaccharide were extremely low. On the other hand, the ash content of sea urchin coelomic fluid was much higher than that of the gonads. In general, sea urchin gonads are known to contain high levels of protein. They also have considerably high lipid levels; whereas, carbohydrate levels are low (McClintock & Pearse 1987). However, in our study, the carbohydrate content was high and accounted for approximately 10% of the total amount, on a fresh weight basis. Furthermore, in coelomic fluid, although the relative proportion of carbohydrate was only 0.4 ± 0.1%, this was four times more than that of its protein and lipid contents. From this study, it is apparent that content of lipid, protein and carbohydrate in the coelomic fluid was much less than that of the gonads. The urchins in this work were given a diet purely comprised of *Laminaria* kelp to resemble the urchin's preferred natural diet. In general, the diet plays a very important role in the compositional characteristics of these animals (Nishikiori 1989, Fernandez et al. 1995, Agatsuma 1998) and almost all studies have only determined compositional characteristics of the gonads. Thus, Agatsuma (1998) showed that a diet of fishmeal increased moisture levels, and Nishikiori (1989) observed that moisture content in the gonads of *S. nudus* was below 70% when the urchins were fed *Laminaria japonica* to satiation. None of these studies reported compositional characteristics of sea urchins' coelomic fluid. In our study, when urchins were fed on a *Laminaria* diet, gonads contained 74.7 ± 0.04% moisture, which was significantly ($P < 0.05$) lower than that of the coelomic fluid.

Lipid Class Composition

The lipid composition of marine invertebrates is influenced by several factors, including pattern of feeding, gametogenesis, and possibly environmental conditions (Jezierska et al. 1982). Wax esters have been reported to constitute energy reserves in various marine invertebrates (Sargent 1976), but this was not the case for sea urchin *S. droebachiensis*. TAG formed the main energy reserve in these animals, and their gonads and coelomic fluid were qualitatively composed of similar lipid classes. The same nonpolar lipid class distribution has been observed in *S. droebachiensis* gonads and coelomic fluid collected form Nova Scotia (Takagi et al. 1980). The nonpolar lipids of gonads and coelomic fluid consisted mainly of TAG, FFA, and ST. Triacylglycerols are usually considered to serve as storage lipids in eukaryotic cells (Sul et al. 2000). Thus, sea urchin lipids contained much larger amounts of storage lipids, principally TAG, which constituted more than 60% of the total nonpolar lipids of gonads and coelomic fluid.

Although, qualitative composition of nonpolar lipids of gonads and coelomic fluid of *S. droebachiensis* was similar, relative content of individual classes differed. Hence, both sea urchin gonads and coelomic fluid were composed of the same major lipid classes, both nonpolar and polar, but their relative contents were markedly different. Thus, relative content of TAG in sea urchin gonads was much higher than that of coelomic fluid; whereas, that of FFA in gonads was much less than that of coelomic fluid. It was apparent in the preliminary experiments that both gonads and coelomic fluid contained high levels of FFA. Therefore, it was thought that partial hydrolysis of TAG may lead to an underestimation of TAG content. However, the impact of this on a nutritional value of the fatty acids involved is inconsequential. To verify the above fact, fatty acid content was determined in a set of freshly harvested sea urchins. The gonads were extracted as quickly as possible at 0°C immediately after homogenization. It was assumed that hydrolysis of lipids because of the activity of endogenous enzymes is minimized under these conditions. The FFA content was 15.5 ± 1.7% of the total nonpolar lipids upon Iatroscan analysis. Hence, the high levels of FFA observed for stored sea urchin tissues following homogenization could be attributed to the hydrolysis of TAG during storage of samples at −20°C.

In general, the energy supplied to the animal by the breakdown of lipid reserves comes primarily from oxidation of fatty acids. Farkas (1979) has shown that the production of FFA can be induced by stress. Thus, the environmental temperature and diet can be specified as factors exerting a major impact on the content and metabolism of fatty acids in animals (Farkas et al. 1978).

There were noticeable differences in the relative content of sterols in sea urchin tissues. In general, cholesterol level may depend on dietary level and stage of sexual development (Love 1970). In fact, diet and nutritional status are known to be the main factors that influence cholesterol levels (Dave et al. 1975). On the other hand, during gametogenesis, a redistribution of cholesterol takes place that may lead to high levels of cholesterol in the gonads (Idler & Tsuyuki 1985). Therefore, all relevant factors must be considered to explain the content of cholesterol in different tissues.

In the present study, the relative content of ST in the gonads was significantly ($P < 0.05$) higher than that in the coelomic fluid.

Vaskovsky and Kostetsky (1969) have performed TLC on polar lipids of sea urchin *S. nudus* and *S. intermedius*. The polar lipid fraction was separated into five components of which PC, PE, and SM constituted the major polar lipid classes present. Furthermore, lipid extracts of different organs of the same animal had a similar qualitative polar lipid composition (Vaskovsky & Kostetsky 1969). In this study, both gonads and coelomic fluid showed qualitative similarities in their polar lipid fractions. Thus, PC, PE, SM/LPC, and PS/PI constituted the polar lipids of *S. droebachiensis* gonads and coelomic fluid, and PC was dominant in both tissues, with a contribution of more than 65% to the total content of polar lipids. Similarly, Floreto et al. (1996) demonstrated that sea urchin *Tripneustes gratila* fed on a seaweed diet had PC and PE as the major lipid constituents, and PC contributed a greater proportion than PE.

Fatty Acid Composition

The fatty acids of total lipids of sea urchin gonads and coelomic fluid were typically similar to those of other marine species with a dominance of 16:0 and 20:5n-3 (Wanasundara 1996). Although, 22:6n-3 is a typical fatty acid in marine lipids, it contributed only 1.4 ± 0.1 and 0.6 ± 0.1% to the total fatty acids in the lipids of sea urchin gonads and coelomic fluid, respectively. Holland (1978) reported that the predominance of 20:5n-3 and 22:6n-3 in typical marine fatty acids is a result of low- temperature adaptation. This helps in the maintenance of cell membrane fluidity in organisms living in the cold environments.

Considerable data are available on the fatty acid composition of sea urchins (Takagi et al. 1980, Kaneniwa and Takagi 1986). The fatty acid 16:0 was the major SFA in the sea urchin *S. droebachiensis* harvested from Herring Cove, Nova Scotia (Takagi et al. 1980). Fujino et al. (1970) analyzed fatty acid composition of sea urchins *Anthocidaris crassispina*, *S. pulcherrimus*, *S. franciscanus*, *S. intermedius*, and *Echinus esculentus*. In all these samples, 16:0 was the prominent SFA followed by 14:0. The fatty acid 18:0 was found to occur in considerable amounts. Similarly, in the present study, the predominant SFA were 16:0 and 14:0 in the lipids of both gonads and coelomic fluid of *S. droebachiensis*.

Among MUFA 20:1n-15 was present up to 11% in the total fatty acids of urchins (Takagi et al. 1980). Ackman and Hooper (1973) reported that such marine animals as periwinkle (*Littorine littorea*), moon snail (*Lunata triseriata*), and sand shrimp (*Crangon septemspinosus*) contain 20:1n-15, but at much lower levels of up to 0.2% of the total fatty acids. However, this has not been commonly reported as being typical of marine lipids. In our study, 20:1n-15 was also the major MUFA in both tissues analyzed. On the other hand, seaweeds, the natural diet of sea urchins, have not been reported to contain 20:1n-15 (Ackman & McLachlan 1977); hence, the formation of 20:1n-15 in sea urchin tissues may be biosynthetic in origin, because this was not dependent on the diet.

The occurrence of such unusual 5-olefinic fatty acids as 18:1n-13, 20:1n-15, 20:2Δ5,11, 20:2Δ5,13, 20:3Δ5,11,14, and 20:3Δ5,11,14,17 has been noticeable in lipids of sea urchins accounting for as much as 6–21% of the fatty acids of total lipids (Takagi et al. 1980, Kaneniwa & Takagi 1986). In this study, the amount of 5-olefinic acids found in the lipids of both gonads and coelomic fluid was in the range of 7–10%. The presence of 5-olefinic fatty acids has been reported in 12 species of Echinoidea collected in Japan (Takagi et al.1986); thus, they serve a common and characteristic feature of sea urchin lipids.

The amount of eicosapentaenoic acid (20:5n-3) was quite high in sea urchin lipids (Takagi et al. 1980). Pohl and Zurheide (1979) reported that urchins that consumed *Laminaria* had a high content of 16:4n-3, 18:4n-3, 20:4n-6, and 20:5n-3. Similarly, sea urchin *S. droebachiensis* in our study consumed *Laminaria* for only a three week period, and their gonadal and coelomic fluid lipids contained quite high levels of these fatty acids. Thus, the fatty acid profiles of sea urchin tissues somewhat reflect that of their diets as was also observed by Floreto et al. (1996). However, certain fatty acids, such as 16:4n-3, 20:4n-6, 20:5n-3, and 20:1n-11, which constitute the major fatty acids of sea urchin tissues, were not detected in their diets; therefore, suggesting that sea urchins are capable of synthesizing them from lower fatty acid precursors. Similarly, in the present study 16:4n-3, 20:1n-11, 20:4n-6, and 20:5n-3, among others, may have been formed by chain elongation of precursors. In general, the sea urchin fatty acids; namely, 16:4n-3, 20:4n-6, and 20:5n-3, may possibly confer some structural function and, hence, are purposely synthesized by the animal (Floreto et al. 1996).

Carotenoid Pigments

In the sea urchin *S. droebachiensis*, carotenoids were mainly concentrated in the gonadal tissue. Hence, the total content of carotenoids in the gonads was about 6.3 times more than that of the coelomic fluid. However, the content of carotenoids in different tissues may vary with the reproductive stage of urchins. Hence, during gametogenesis most of the carotenoids in other tissues may be transferred into gonads, consequently increasing their carotenoid content (Griffiths & Perrott 1976).

Echininone and fucoxanthin were characterized as the major carotenoids present in the gonads and the coelomic fluid, respectively. In addition, β-carotene was identified in both tissues. Echininone was found to be the main pigment with a lesser amount of β-carotene in the gonads of *S. purpuratus* (Griffiths 1966), *S. droebachiensis* (Griffiths & Perrott 1976) and *Tripneustes gratila* (Shina et al. 1978). Tsushima et al. (1995) found that β-echininone and β-carotene were the major carotenoids in the gonads of 19 out of 20 sea urchin species examined. Meanwhile, the major carotenoids of brown algae, the natural preferred diet of sea urchins, consist of β-carotene, violaxanthin, and fucoxanthin (Matsuno & Hirao 1989). Furthermore, there is bioconversion of β-carotene to β-echininone via β-isocryptoxanthin in sea urchins; which takes place mainly in the gut wall, and the resultant β-echininone is incorporated into the gonads (Tsushima et al. 1993). Kawakami et al. (1998) showed that fucoxanthin, the major carotenoid in brown algae, did not accumulate in the gonads. In fact, in the present study on *S. droebachiensis*, fucoxanthin did not occur in the gonads. On the contrary, coelomic fluid had fucoxanthin as its major carotenoid.

Amino Acid Composition

Although marine invertebrates characteristically contain a high intracellular concentration of FAA, the composition of the FAA pool may vary among species (Gilles 1979). In the present study, glycine was the dominant amino acid in both TAA and FAA profiles in both sea urchin gonads and coelomic fluid. Komata et al. (1962) reported that glycine was dominant in the gonads of sea urchin *S. pulcherrimus*, and its content ranged from 35–41% of total FAA. Lee and Haard (1982) reported that glycine constituted 18–60% of the FAA in the gonads of sea urchin *S. droebachiensis*. The gonads and coelomic fluid of sea urchin *S. droebachiensis* in this study contained 11.9–14.6% glycine in the TAA profile, respectively. However, glycine was not the dominant amino acid in the gonads of the sea urchin *Paracentrotus lividus*, although it contributed a considerable amount to the TAA pool (Cruz-Garcia et al. 2000). Other than glycine, alanine, arginine, glutamic acid, lysine, and methionine are considered important for taste, even though some of them were present in small quantities (Lee & Haard 1982). These amino acids were present in considerable amounts in both gonads and coelomic fluid of sea urchins in this study.

It has been found that different combinations of taste-active components (substances that influence the taste of any food) as well as their relative amounts are of paramount importance in producing the characteristic flavor of each seafood (Fuke 1994). In general, glutamine and glycine, which were present in higher amounts in the gonads than coelomic fluid, are known to be taste-active in sea urchins and other seafoods, regardless of their quantity. Sea urchin gonads seemed to be sweeter when little or no glutamine was present, and alanine was found in considerably high levels. Alanine is a taste-active component in sea urchin tissues, contributing noticeably to both TAA and FAA contents. Furthermore, valine and methionine are known to be taste-active only in sea urchins; whereas, arginine was also taste-active in sea urchins because of its high content (Fuke 1994). Both methionine and arginine were present at a higher proportion in the coelomic fluid than in the gonads. Similarly, the contents of aspartic acid, histidine, and especially proline were much higher in the coelomic fluid than those in the gonads. Thus, amino acids play a major role in the taste of sea urchin gonads. In our study, various amino acids contributed differently to both the TAA and FAA of sea urchin gonads and coelomic fluid.

Contents of Nucleic Acids

In general, quantitative analysis of nucleic acid provides a relatively simple means of estimating recent growth rate of sea urchins. The processes of cellular growth and division require the synthesis of nucleic acids and proteins. The fact that RNA is a precursor to protein synthesis led to its use as an indicator of growth rate (Church & Robertson 1966). The primary function of RNA involves protein synthesis; whereas, DNA is the primary carrier of genetic information. Because the majority of cellular DNA is chromosomal, the quantity of DNA per cell is quasiconstant in somatic tissues; the tissue DNA concentration reflects cell numbers (Sulkin et al. 1975; Bulow 1987). Therefore, DNA content has usually been used as an index of cell numbers or biomass (Regnault & Luquet 1974). In this study, the DNA content in the gonads was approximately four times higher than that in the coelomic fluid. Although the gonad is a tissue with a higher biomass as compared with coelomic fluid, the latter contains mostly coelomic fluid with a lower biomass. On the other hand, the RNA/DNA ratio has been used as an estimate of growth for a variety of invertebrates (Sulkin et al. 1975). Thus, the RNA/DNA ratio is an index of protein synthetic activity per cell and reflects the protein synthesizing capacity for estimating recent *in situ* protein increase (Bulow 1987, Hovenkamp & Witte 1991). In fact, correlation between RNA concentration or RNA/DNA ratio and growth rate has been observed for a wide variety of organisms (Sutcliffe 1970). Furthermore, the gonadal RNA content was about 5.4 times higher than that in the coelomic fluid, thus demonstrating higher protein synthetic activity in the gonads. In general, gonad is the site of gametogenesis, which involves much protein synthesis. Furthermore, the RNA/DNA ratio was much lower in coelomic fluid than that in gonads, indicating greater protein synthetic activity per cell in the gonads. This is an indication that gonad is a tissue with greater *in situ* protein growth as compared with coelomic fluid.

CONCLUSIONS

The present study demonstrated that sea urchin gonadal and coelomic fluid tissues had many common compositional characteristics. Most of the parameters analyzed did not show qualitative differences; whereas, there were quantitative differences. In fact, gonads of sea urchins are a site of nutrient storage in addition to being the reproductive organs. The accumulation of nutrient reserves contributes to the growth and development of the commercially important sea urchin gonads. Although sea urchin coelomic fluid has not yet been exploited commercially, evaluation of its composition may lead to its potential use as a flavoring source.

ACKNOWLEDGMENTS

The author (C. L.-P.) gratefully acknowledges the assistance of the Canadian International Development Agency (CIDA) through a Marine Science Scholarship. Thanks are also extended to Mr. Keith Collins at the Sea Urchin Research Facility (SURF) at Bonavista Bay, Newfoundland for providing sea urchin samples for the study.

THE DEVELOPMENT OF A POSITIVE NON-INFECTIOUS CONTROL FOR THE DETECTION OF *PERKINSUS* USING THE RAY TEST

B. R. MOORE, S. N. KLEEMAN, AND R. J. G. LESTER*
Department of Microbiology and Parasitology, The University of Queensland, Brisbane, Australia 4072

ABSTRACT To establish a noncontagious control for the Ray thioglycollate test for the detection of *Perkinsus* in mollusks we evaluated nonviable stages of *P. olseni* for enlargement of hypnospores and blue/black iodine stain. Trophozoites made nonviable with formalin, irradiation or colchicine failed to swell in thioglycollate. They remained small and did not differentially stain in iodine. Trophozoites that had already developed into hypnospores in thioglycollate were rendered inactive by freezing, ethanol or formalin immersion. They retained their iodinophilic properties and thus could provide a partial control for the Ray Test.

KEY WORDS: *Perkinsus*, abalone, fluid thioglycollate medium

INTRODUCTION

Members of the genus *Perkinsus* are protozoan parasites found exclusively in mollusks. *Perkinsus* parasites have long been recognized as a cause of mortality in commercially important mollusks (Ray & Chandler 1955). *Perkinsus marinus* has been demonstrated to have profound effects on the oyster *Crassostrea virginica*, leading to reduced growth, reduced fecundity, and increased mortality (Menzel & Hopkins 1955, Mackin 1962). In Australia, *P. olseni* infections result in deep abscesses and soft yellow pustules in commercially important abalone, *Haliotis rubra* and *H. laevigata*. This is of great concern to the endemic abalone industry as infected individuals are unacceptable for processing (Lester & Davis 1981). Transmission appears to occur through zoospores that develop via hypnospores (Goggin et al. 1989). Hypnospores can be found within the abscesses (Goggin & Lester 1995) and may also be produced by culturing trophozoites in fluid thioglycollate medium (FTM) (Ray 1952). Other species of *Perkinsus* produce hypnospores though the role of zoospores in transmission between mollusks is not clear (Perkins 1996).

Diagnosis of *Perkinsus* infections is commonly accomplished by the FTM assay (Ray 1952). Trophozoites in infected tissue develop into usually much larger hypnospores that stain blue-black with Lugol's iodine (Ray 1952). The reaction with iodine relies on the development of hypnospores; trophozoites remain brown (Ray 1952, Stein & Mackin 1957). Prior to the development of this technique, diagnosis relied on fresh tissue smears or histologic sections. These methods are labor intensive, use expensive materials, rely on a high degree of expertise, and lack sensitivity to detect low levels of infection (Ray 1954).

Infected hosts frequently show no overt sign of disease, and as such, infected tissue can easily reach processing plants undetected (Goggin et al. 1990). Here they may be examined for the presence of *Perkinsus* with the FTM assay, however, due to inexperience in recognizing the parasite or through errors in the formulation of the culture media, investigators may fail to detect infections.

The development of positive reference material to assist *Perkinsus* diagnosis in fisheries laboratories would be an invaluable tool to help minimize misidentifications and false negatives. The material needs to be noncontagious to prevent cross-infection into local mollusk populations during shipping or in disposal after use, while maintaining the key attributes of the FTM assay: enlargement of hypnospores in FTM and uptake of the iodine stain (Ray 1952).

Fisher and Oliver (1996) stated that dead trophozoites of *P. marinus* fail to enlarge in FTM. We sought to make *P. olseni* material nonviable to see if swelling would still occur. We also sought to determine whether hypnospores, following enlargement in FTM, could be rendered inactive while retaining their iodinophilic properties.

MATERIALS AND METHODS

Trophozoite Inactivation

Pieces of infected mantle tissue from three blood cockles, *Anadara trapezia*, infected with *P. olseni* (Murrell et al. 2002) were exposed to either dilute formalin, irradiation, and colchicine to attenuate the viability of hypnospores while retaining the characteristics of the Ray Test. Several tests were run on tissues from one animal to enable the results from different dose levels to be compared. Tissue from animal 1 was immersed in one of four dilute formalin solutions [1:4 × 10^3, 1:4 × 10^4; 1:4 × 10^5; 1:4 × 10^6 formalin:seawater (approximately 34‰)]. For a period of 30 minutes tissue from animal 2 was treated with gamma irradiation. The self-contained gamma radiation source of ^{60}Co had a dose rate of 670 Gy h^{-1}. Duplicate wet tissue samples were placed in glass petri dishes and irradiated to a maximum absorbed dose rate of 600 Gy in increments of 200 Gy. Variations in absorbed dose were minimized by placing thin tissue samples within a uniform portion of the radiated field. Two tissue samples from animal 3 were placed in FTM to which was added colchicine, at one of two concentrations: 10^{-4} M and 10^{-6} M for six hours, after which they were rinsed in seawater.

After treatment all tissues were placed in FTM, supplemented with 200 mg chloromycetin and 200 units of mycostatin to reduce fungal and bacterial contamination (Ray 1966), and incubated at 25°C for five days. A second pair of samples from animal 3 was left in the colchicine-supplemented FTM for the full period of incubation (5 days).

Following incubation, a portion of infected tissue was examined and hypnospore abundance counted, using a compound microscope at ×40 magnification in five fields of view. To facilitate easy enumeration, part of the tissue sample was stained with iodine prior to counting. Hypnospores were teased out of the unstained tissue and transferred to a glass petri dish containing seawater. The seawater in the dish was replaced twice daily. Hypnospores that adhered to the dish were allowed to develop; a process that typi-

cally took 1–5 days. Parasites were inspected under a dissecting microscope and were deemed viable only if cell division occurred within five days. To assess whether treated cells retained their iodinophilic properties irrespective of viability, individual hypnospores were isolated from the treated tissue and transferred to a separate petri dish, where they were stained with 3–4 drops of Lugol's iodine. Iodinophilia was based qualitatively on the uptake of stain by the hypnospore and was assessed approximately three minutes after application (Quick 1972). Control tissues from all three mollusks were placed directly into FTM and incubated for the equivalent period of time to confirm that they were infected with *Perkinsus*.

Hypnospore Inactivation

To obtain hypnospores, pieces of mantle, foot, digestive gland, and gill from *A. trapezia*, from Wynnum, Queensland and from *H. rubra* and *H. laevigata* collected from South Australia, were incubated in 20 ml FTM at room temperature (approximately 24°C) for 4–6 days. The medium was supplemented with 200 mg chloromycetin and 200 units of mycostatin (Ray 1966). The incubated tissues containing resulting hypnospores were then subjected to various treatments: freezing at −20°C; immersion in 10% formalin; and immersion in 70% ethanol. The effectiveness of each treatment on hypnospore viability and iodinophilia was assessed after 24, 48, and 72 h. The viability of hypnospores prior to treatment was confirmed by viability testing of a random subset of enlarged cells.

RESULTS

Trophozoite Inactivation

In all treatments, trophozoites that developed into hypnospores in FTM were capable of further development and were evidently

viable (Table 1). Treatment had little effect on the parasitic stages that had enlarged. No hypnospores were evident in tissues exposed to formalin concentrations of 1:4 × 10^3, 1:4 × 10^4; 1:4 × 10^5. Tissues exposed to 1:4 × 10^6 formalin:seawater provided similar hypnospore numbers to those of the control (Table 1). Trophozoites exposed to gamma irradiation showed a progressive decline in hypnospore numbers with increasing radiation exposure (200 Gy, 400 Gy, and 600 Gy) (Table 1). Colchicine treatment had little effect on hypnospore enlargement and viability, irrespective of treatment concentration. The majority of hypnospores retained from incubation appeared viable, with motile zoospores evident after five days examination (Table 1).

Hypnospore inactivation

All treatments killed hypnospores within 24 h of treatment. Nevertheless, all the dead hypnospores exhibited clear iodinophilia, staining a deep blue on application of Lugol's iodine (Table 2).

DISCUSSION

The negative correlation between treatment intensity (or duration) and hypnospore abundance, particularly for the irradiated tissue, followed by the successful development of recovered hypnospores indicate that nonviable trophozoite stages fail to enlarge in FTM. This is in agreement with Fisher and Oliver (1996), who stated that enlargement of *P. marinus* trophozoites in FTM only occurs if the parasite is viable. Formalin treatment at concentrations ≥1:4 × 10^5 formalin:seawater appeared to prevent hypnospore enlargement, with no hypnospores recovered from these concentrations. The extremely weak formalin (1:4 × 10^6 formalin:seawater) appeared to have little effect on trophozoite viability, with treated tissues exhibiting a similar enlarged hypnospore abundance to that of the control. Similarly, colchicine concentrations of 10^{-4} M or 10^{-6} M had little effect on parasite viability. Colchicine has been demonstrated to be a potent microtubule inhibitor at such concentrations (Wiest et al. 1993), thus preventing cell division. The fact that parasites treated with colchicine remained viable and underwent division once out of the treatment is consistent with microscopic observations that no cell division occurs during trophozoite differentiation to hypnospores and cell enlargement. Swelling of *Perkinsus* cells in FTM had been suggested to occur as a result of the direct uptake of the media (Ray 1952), although the mechanisms of this process are not yet described.

As nonviable trophozoites failed to enlarge in FTM, and thus failed to become iodinophilic, we tested whether hypnospore stages could be killed and still retain their iodinophilic properties. All treatments tested killed hypnospores. The sensitivity of hypnospores to low temperature is in accordance with Chu and Greene (1989), who observed that hypnospores of *P. marinus* exhibited 100% mortality at 0°C for 24 h. Goggin et al. (1990) observed motile zoospores from cultured tissues previously chilled at 4°C, 0°C and frozen at −20°C, showing that trophozoites are more tolerant to low temperatures than hypnospores.

In all cases, nonviable hypnospores were iodinophilic. Thus, such tissue could be transported risk-free to processing plants to serve as a positive reference for sample comparison. Although this is not a control for FTM development, it still supplies users with a positive control that is safe, noncontagious, and simple to use.

ACKNOWLEDGMENTS

Mr. Tavis Anderson, Department of Microbiology and Parasitology, University of Queensland, assisted with experimentation and viability testing, and Dr. David Hunter, Department of Chemistry, University of Queensland, guided the irradiation experiments. Financial support from the Fisheries Research and Development Corporation (2000/151) is gratefully acknowledged.

EVALUATION OF SUBSTITUTE DIETS FOR LIVE ALGAE IN THE CAPTIVE MAINTENANCE OF ADULT AND SUBADULT UNIONIDAE

S. J. NICHOLS[1]* AND D. GARLING[2]

[1]*USGS-GLSC, 1451 Green Road, Ann Arbor, Michigan 48105;* [2]*Department of Fisheries and Wildlife, 217 Natural Resources, Michigan State University, East Lansing, Michigan 48824*

ABSTRACT Ten nonlive algal diets were evaluated as potential broodstock diets for adult and subadult unionids. These diets varied significantly in their ability to support growth, reproduction and survival. Growth, increase in glycogen stores, and limited glochidial formation were seen in most unionid species on two of the diets. However, long-term survival (>3 y) remained problematic, and the cause of mortality in these animals could not be determined. While two of the diets tested are potentially useful for supplemental feeding of adult unionids to increase glycogen levels during quarantine, or during short-term captive maintenance in the laboratory, none can be recommended without reservation for long-term maintenance because of the lack of survival after three years during this study.

KEY WORDS: unionidae diets

INTRODUCTION

Nearly 70% of the freshwater mussels (Unionacea) in North America are currently facing extinction (Williams et al. 1993). Conservation efforts have focused on relocation of endangered populations, and aquaculture of recently transformed larvae. Captive maintenance of endangered animals is a common technique used to enhance and preserve species-at-risk, however unionids have proved difficult to maintain in captivity or to relocate into new habitats (Cope & Waller 1995). Most aquaculture efforts have concentrated on developing live algal diets that will support the growth and survival of larvae (≤1 year of age). A tri-algal diet has recently been produced that appears to support survival of a few species for about one year after larval transformation (see Gatenby et al. 1994, Gatenby et al. 1996, Gatenby et al. 1997). Adult unionids have rarely been kept alive for more than three years even in hatchery ponds or raceways. One problem in maintaining adult unionids is the lack of information regarding actual nutritional requirements. Recent studies have indicated that while live algae may be supplying certain key nutrients, detritus and bacteria are an important part of unionid diets (Nichols & Garling 2000).

Marine aquaculturists have experienced similar difficulties in long-term feeding of adult oysters and clams, and usually rely on natural food supplies found in offshore grow-out areas. Hatchery production of live algae is often used to rear seed marine bivalves to planting size (1–2 mm), but is rarely used as a sole food source for adult animals due to the difficulties and costs associated with maintaining sufficient year-round supplies and lack of knowledge of long-term nutritional needs (Knauer & Southgate 1999, Heasman et al. 2000). In recent years, attempts have been made to replace live algae with artificial diets to reduce the need for expensive algal production (Coutteau & Sorgeloos 1993). These artificial feeds have been successful, but this success varies with both feed type and farm operator. The objective of our study is to determine if similar types of non-live algal feeds could be developed to support adult unionid survival, growth, and reproduction under captive conditions.

MATERIALS AND METHODS

We tested commercial and laboratory-prepared (experimental) feeds from 1994 to 1998 on eight unionid species *Amblema plicata* (Say, 1817), *Cyclonais tuberculata* (Rafinesque, 1820), *Lampsilis fasciola* (Rafinesque, 1820), *Lampsilis ventricosa* (Say, 1817), *Lampsilis siliquoidea* (Barnes, 1823), *Leptodea fragilis* (Rafinesque, 1820), *Pyganodon grandis* (Say, 1829), and *Quadrula quadrula* (Rafinesque, 1820). The size and age of the animals varied and both adult and subadult animals were tested. Adult animals in our experiments were at least five years of age according to external annuli. Subadults animals were less than three years but younger than one year based on external annuli. Shell morphometrics for all animals were measured upon arrival in the laboratory and individual tracking numbers etched onto one of the shell valves.

Unionids were held at the Great Lakes Science Center in a flow-through system of 8-L rectangular aquaria, containing 10 cm of coarse gravel, with a water replacement rate of 4L/h. Baseline water quality parameters were: $CaCO_3$ of ~100 mg/L (EDTA titrimetric method, APHA 1989); dissolved oxygen 8.0 ppm (Winkler method, APHA 1989); dissolved ammonia of <0.5 ppm (phenate method, APHA 1989); and a pH of 7.8 (Fisher Scientific Accumet pH meter model #AB15). Water quality parameters were measured weekly and during any die-off of unionids. Water temperature averaged 15°C, and the light regimen was on a 12 light/12 dark cycle.

Diet Formulations

We tested 10 diet formulas in this study (Table 1). Five were commercially available (treatments #1–5), and 5 were experimental mixtures (treatments #6–10). The diets were chosen on availability and/or prior successful use in culturing marine bivalves or zebra mussels *Dreissena polymorpha* (Pallas, 1771).

The five commercial diets were: treatment (TR) #1-dried *Chlorella* sp. (Earthrise Co., California); TR#2-marine algal paste *Thalassiosira pseudonana* (Hust.) (Hasle and Heimdal) (from Coastal Oyster Inc.); TR#3-Hatchfry Encapsulon (30 μ size particles, Argent Co. Washington); TR#4-fish flake food (tropical, various retailers), and TR#5-a manipulated yeast diet (Artemia Reference Center, Ghent Belgium).

The five experimental diets were a combination of bacterial/ciliate cultures grown in the laboratory, commercially available invertebrate enrichment feeds, and animal feed supplements incorporated for protein, dextrose, and other nutrients. The first experimental diet (TR #6) was a microencapsulated feed with food particles embedded in a gel matrix prepared according to Langdon's

work on marine bivalves (Langdon & Levine 1983, Langdon & Bolton 1984; Buchal & Langdon 1995). Diet Tr#7, was based on the analysis of the gross biochemical composition of freshwater bivalves (Secor et al. 1993). This formula, (called egg chow) was a mixture of 60% dried powdered chicken egg (ICN Biomedicals Inc.), 30% powdered dextrin (ICN Biomedicals Inc.), 9% liquid safflower oil, and 1% vitamin supplement (Rep-Cal Herptivite, Los Gatos, California) mixed and finely ground prior to feeding.

The other three experimental diets were formulated from bacterial/ciliate slurry based on Stuart's (1982) work on the marine bivalve *Aulacomya ater* (Molina, 1782). These were prepared by soaking finely ground vegetation in water for three days to encourage the growth of bacteria and ciliates and the breakdown of cellulose. Stuart used kelp as a base; we used freshwater marsh grass (*Phalaris* spp.). This basic bacterial slurry formula is TR#8 (bacterial/slurry #A). Treatment #9 (bacterial slurry #B) was a mixture of 50% TR#9 and 50% dried *Chlorella* spp. Treatment #10 (bacterial slurry #C) was a mixture of 30% TR#8, 30% dried *Chlorella*, 10% Rich Advanced (a liquid mixture of lipids and algal growth enhancers from Sanders Corp. Ogden, Utah) and 10% Sanders Black Gold (a flake similar in composition to Rich Advanced).

The ration level of all diets was maintained at 5–8 mg diet dry weight/L of aquarium water for at least 15 h out of the day. This ration was based on the average total organic particulate matter values found in the Huron River near a large free-living unionid bed as described in Nichols and Garling (2000).

Measuring Success of Diet Formulations

Growth and survival were the critical criteria for assessing diet success for subadult unionids; reproduction (glochidia formation) and survival were the criteria used for adult unionids. Changes in maximum shell length were also recorded, but not further statistically tested. There was a wide variation in age of adult animals used and even a nutritionally ideal diet, older animals could not be expected to show the same potential for shell growth as younger adults. In tests using adult unionids, 10 randomly selected individuals from each of the following six species for six species—A. plicata (size range measured across longest anterior/posterior shell plane 45–110 mm), *L. siliquoidea* (56–119 mm), *L. ventricosa* (71–98 mm), *L. fragilis* (61–167 mm), *Pyganodon grandis* (78–149 mm), and *Quadrula quadrula* (48–61 mm)—were assigned to all ten diet treatments. Fewer *C. tuberculata* (51–77 mm) and *L. fasciola* (36–45 mm) were available (15 individuals each) thus, only 5 adults from these two species were randomly assigned to three diets (TR#7, TR#9 & TR#10).

The number of subadult unionids available varied by species; *A. plicata* (n = 75), *C. tuberculata* (n = 15), *L. fasciola* (n = 2), *L. ventricosa* (n = 10), *L. siliquoidea* (n = 2), *L. fragilis* (n = 100), *P. grandis* (n = 100), and *Q. quadrula* (n = 50). Within each species, ages and sizes of animals were similar to minimize variability. Due to the unequal sample size, the number of individuals and number of diets tested were limited. Two diets (TR#7 & TR#10) were tested for a period of 280 days. The distribution of mussels in these treatments was as follows: in TR#7 *A. plicata* (n = 27), *C. tuberculata* (n = 7), *L. fasciola* (n = 1), *L. ventricosa* (n = 5), *L. siliquoidea* (n = 1), *L. fragilis* (n = 50), *P. grandis* (n = 50), and *Q. quadrula* (n = 18); in TR#8 and TR#9, *A. plicata* (n = 5) and *Q. quadrula* (n = 3). The remaining subadults were fed TR#10.

Adult unionids were measured monthly (maximum shell length to the nearest mm) and survival checked daily. Reproductive efforts were monitored by the development of glochidia in the marsupium, mantle lure behavior, and glochidial release in the test aquaria. Marsupia were examined by gently prying open the animal and visually examining the gills for obvious swelling on a monthly basis. Each individual subadult unionid was measured every two weeks (maximum shell length to the nearest mm) and survival checked daily. Autopsies were performed on any animals that died and tissues dissected and examined for flukes, fungus, or bacteria, or gross structural changes in appearance.

Changes in glycogen content were measured in an additional group of animals from January to December 1998. Only one species, *P. grandis*, was readily available and used for the test. Twenty adult *P. grandis* were placed on TR#7 and TR#10 (10 animals each diet) to determine the glycogen status of all soft tissues as a measure of fitness. Glycogen content based on wet soft tissue weights was obtained using the homogenized tissue and the phenol-sulfuric acid method used by Haag et al. (1993) to assess clam fitness and reported as mg/g wet tissue. This was a whole body analysis, using 3 randomly selected animals from each of the two diets at the beginning of the (January 2) and at the end (December 28) of the 1997 test year. All ten animals were from the same age class based on external age lines (10 y old) and had a shell length of 135–140 mm.

Two of the nonproprietary diets were analyzed for biochemical content. The diets, TR#7 and TR#10 were prepared in the laboratory and then whole samples frozen to −40 C. Analyses were performed on an HPLC using standard techniques as cited in Association of Official Analytical Chemists (AOAC 1995). Protein (total), lipids (cholesterols, phytosterols, and total lipids), and carbohydrates (total) and fiber content were measured.

The statistical relationship between differences in growth rates, survival rates and glycogen concentrations of adult and subadult unionids on the various diets was tested. Differences in growth rates between subadults of within each species over time, on different diets, were analyzed using a linear regression of the monthly measurements of all individuals. Since the test group within each species was identical in number and similar in length and age, no data transformations were performed. Analysis of covariance (ANCOVA) in a sequential analysis of the slopes was used to determine growth differences between species in the same diet treatment. Growth statistics were based on changes in length, not in length at T = 0. Percent survival data was analyzed using a χ^2 test. Treatments without survivors were not included in any of the analyses. Results were considered significantly different at the $P < 0.05$ level.

RESULTS

Adults

Of the ten diets tested on adult unionids, none can be recommended without reservation. At least two, however, do show potential for use in long-term captive maintenance. Initially, all of the ten diet formulations were cleared from the water column, and directly ingested (based on fecal production) by all species of unionids. However, two of the diets caused apparent stress in the animals and failed to support growth or survival for more than 30 days; six diets supported growth and survival for at least one year; three diets supported glochidia formation, and; one supported growth, reproduction, and survival but the animals died after the third year (Table 2). All diet formulations caused problems with water quality and some mortality was more directly related to rapid changes in water quality than to diet.

Diet TR#2 caused all adult animals tested to extrude extensive mucous strands outside of the shell that proved detrimental to water quality. Within 24 h after feeding long strands of mucus were drifting through the water column, the water was cloudy, and ammonia levels spiked from <1 to 8 ppm. Twenty-five percent of the unionids on this feed died within the first month, probably due to water quality problems; thus this diet was eliminated from the experiment after 30 days.

A second commercial diet, TR#3, was dropped from the tests after eight months although this commercial rotifer-replacement feed was initially very successful. All adult unionid species fed well on it, and growth was seen in the first three months on the diet in some species. Five of the ten adult *Q. quadrula* grew an average of 2 mm in the first three months, with one individual adding 4 mm of shell in that time period. Two of the ten adult *L. siliquoidea* grew 2 mm each and seven of the ten *Leptodea fragilis* grew an average of 3 mm each in the first three months. No growth was seen in any animal after this period or in other species during the test. After the fifth month of testing, when we began using feed from a different batch, the unionids refused to eat the new feed. The feed was not ingested (no fecal matter produced). We reordered the feed to see if the problem was batch related, but the mussels did not feed on the next batch either. Since the unionids continued to refuse this diet, it was eliminated from the experiment after an additional sixty days.

Of the three remaining commercial diets, TR#4 and TR#5 could not support survival of any adult unionid species for >13 mo (Table 3 and Table 4). None of the unionids showed any shell growth while on these diets. Percent survival and growth did occur on the last commercial feed TR#1. Individuals of all species survived at least 15 mo and two species, *P. grandis* and *L. fragilis*, showed shell deposition during the first four months, but not afterwards. Four out of 10 adult *P. grandis* and 3 out of 10 adult *L. fragilis* grew 1–2 mm over the first four months on these dried green algae, but shell growth then ceased. Mortality rates of 100% occurred within 13 mo.

Four of the five experimental diets (TR #7–10) were successful in supporting initial limited growth and survival, but long-term survival (>3.5 y) was still problematic (Table 2 and Table 4). The exception was the encapsulated feed, TR#6. This encapsulated feed was ingested by the unionids, but within 12 h of feeding all the animals were gaping and non-responsive to touch on soft body parts. We dropped this feed from the diet tests after 30 days and 60% mortality in all species.

The best diet for supporting survival, growth and reproduction of adults of most species, at least up to year 3, was the high-protein egg chow (TR#7). The exception was *L. fasciola*, all of who died regardless of diet treatment. At the beginning of year 3, the survival rates of the adult unionids feeding on TR#7 were: *A plicata* 81%, *C. tuberculata* 80%, *L. ventricosa* 72%, *L. siliquoidea* 65%, *Leptodea fragilis* 64%, *P. grandis* 71%, and *Q. quadrula* 69%.

* Indicates diet not fed to that species

Twenty-one percent of the *P. grandis* and 15% of the *L. fragilis* females formed glochidia during year 2, on this diet. However, during the third year adult unionids began to die, and by the beginning of year four all had perished. The body weight and glycogen levels (discussed below) of these animals were high, indicating that starvation was not a factor. At times soft tissue growth was so rapid that the mussels could not completely close their shells. Autopsies showed no signs of parasitism or other disease factor, but all of these animals had greatly enlarged kidneys. The proximate analysis indicates that TR#7 is a high protein (~65%)/low carbohydrate (22%)/high lipid (13%) feed that is naturally high in cholesterol (78% of total lipid), but contains no phytosterols.

The series of bacterial/ciliate slurries, TR#s 8–10, differed in their ability to support adult unionid growth and survival. Treatment #8 proved an acceptable feed for species such as *A. plicata* and *Q. quadrula*, but killed all of the *P. grandis* within a day or two of the initial feeding and 99% of the *Lampsilis* species within a few weeks. Most of the other species died within the 13-month period. On the other hand, *Amblema plicata* and *Q. quadrula* adults survived and grew well on this diet during the two years of testing. The greatest increase in shell growth was seen in *A. plicata*. The average increase was 6 mm; maximum was 11 mm and minimum 3 mm over the 48-mo period. The amount of growth in *Q. quadrula* was about half that seen in the *A. plicata* adults. No reproductive effort was seen in any species (Table 4).

TR#9 did not improve survival and growth when compared with TR#8. Neither adult *P. grandis* nor *L. fragilis* could tolerate this feed, but once again, 82% of the *A. plicata* and 77% of the *Q. quadrula* survived for 2 y. *Amblema plicata* grew more than *Q. quadrula*, averaging 9 mm, with a maximum of 17 mm, and a minimum 4 mm over the 48-mo period. The amount of growth in *Q. quadrula* averaged 9 mm, with a maximum of 12, and a minimum of 2. No reproductive effort was seen in any species (Table 4).

Treatment #10, which combined the basic bacterial/ciliate slurry, dried algae, with various micronutrients and lipids proved acceptable to adults of all species. *Pyganodon grandis* and *L. fragilis* did well on this diet, as did all the other unionid species tested. Survival of the adults of all species was 100% after one year, with the exception of *L. fasciola*, which we were not successful at handling regardless of what they were fed or handled. Note that this diet was only tested for a one-year period and long-term data is not available. TR#10 is a low protein (~8%), low lipid (5%), high carbohydrate (87%) feed. Cholesterol comprises 75% of total lipid, algal sterols at 20% and miscellaneous lipids at 5%.

Pyganodon grandis fed TR#7 and TR #10 showed a consistent increase in glycogen levels from January 1998 to December 1998. The glycogen levels of animals on TR#10 rose from an average of 7.2 ± 1.9 mg/g in January 1998, to an average of 9.7 ± 2.4 mg/g by December 1998 but this increase was not significantly different (t-test, $n = 10$, $P = 0.059$). During the same period, animals on the TR#7 showed a statistically significant increase ($P < 0.05$) in glycogen from an average of 7.6 ± 1.1 mg/g to 11.2 ± 0.5 mg/g (t-test, $n = 10$, $P = 0.036$). Glycogen concentrations of *P. grandis* that had been feeding on TR#7 for at least 36 mo (36–45 mo) were significantly higher than *P. grandis* that had been on TR#7 for only 12 mo, averaging 14.1 ± 2.6 mg/g as compared with the 11.2 ± 0.5 mg/g (t-test, $n = 20$, $P = 0.042$). Initial glycogen concentrations are not available for the animals kept on TR#7 for the 36–mo period.

Subadults

The growth rates of subadult unionids fed on TR#7 and onTR#10 differed more by species than by diet. *Pyganadon grandis* and *L. fragilis* grew significantly faster on TR#7 and on the TR#10 than did the other species over a 350-day period, with *P. grandis* showing an average increase in shell length of 8.7 mm and *L. fragilis*, 8.1 mm. There was no significant difference in growth rates between these species on either diet. The thick-shelled species (*A. plicata*, *C. tuberculata*, and *Q. quadrula*) grew significantly less, averaging 6 mm. *Lampsilis siliquoidea* and *L. ventricosa* grew even less, averaging only 3 mm during the test period. Survival during the test period was 100% for all species except *L. fasciola*. Mortality rates for *L. fasciola* were 100%. The growth equations, r^2, and P values are presented in Figure 1. Significant differences in growth rates are as follows, with species sharing a line not significantly different (Arcsine transformed data, ANCOVA, $P \leq 0.05$): A = *A. plicata*, C = *C. tuberculata*, L = *L. fragilis*, P = *P. grandis*, Q = *Q. quadrula*, E = TR#7, B = TR#10.

Water Quality

Water quality was difficult to maintain in the test chambers, particularly when feeding the bacterial slurries. There were 22 episodes of water quality problems during the four years of tests. During these events, dissolved oxygen levels would plummet to <1 ppm and ammonia levels rise to >3 ppm often in less than 12 h. Mortality was seen in adult mussels of all ten species being fed TR#2 and TR#6 during these events (25% and 60% respectively within 24 h). None of the other test animals died during these events, but gaping and lack of response to touch on soft tissue body parts were noted. No other diet treatments lead to mortality events affecting all ten species of unionids within 12 h of feeding. Rapid mortality seen in TR#8 and 9 were limited to two species (*P. grandis* and *L. fragilis*), not all ten.

DISCUSSION

One problem in evaluating these diets is that none of the unionids survived for longer than 3.5 y, although a couple of feeds supported growth and short-term survival (≤3.5 y). Our data indicate that unionids are capable of feeding on a wide variety of materials, and can survive and grow for months on non-live algae diets. Long-term survival as would be needed for broodstock maintenance remains problematic. Other than survival, the criteria we selected for measuring diet success, such as growth, reproduction

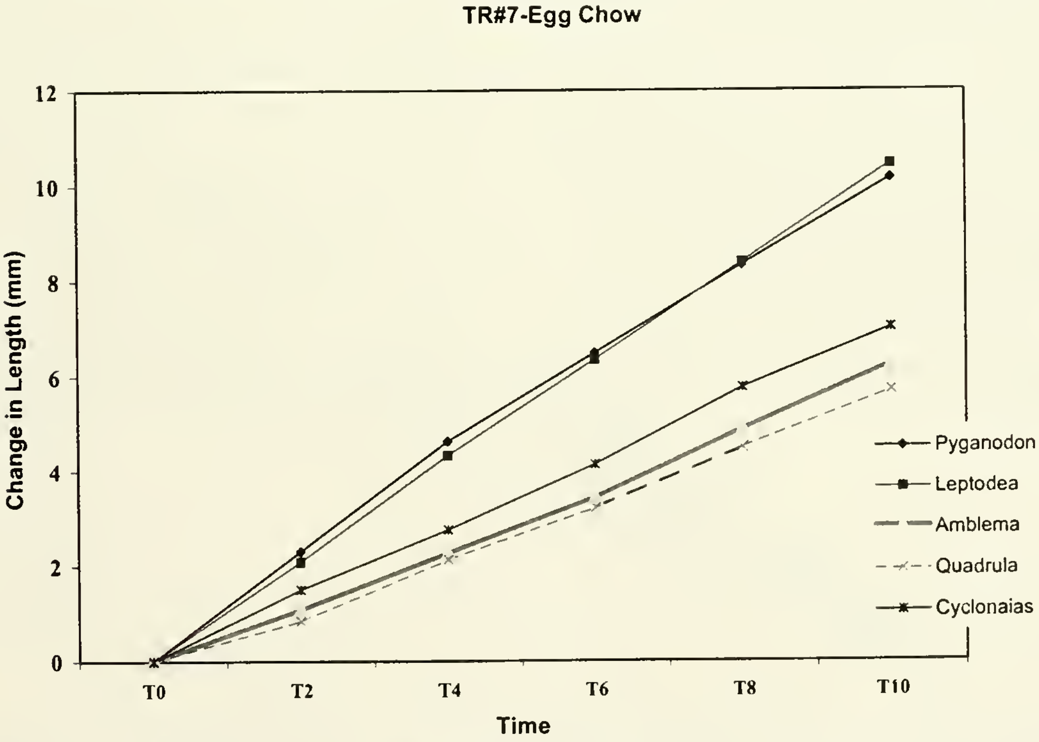

Figure 1. Comparison of growth equations of various unionid subadults fed the diet TR#7 for 350 days. ***Ambelma plicata*** **$y = 3.33677\mathrm{Ln}(x) - 0.7147$ $R^2 = 0.9095$;** ***Cyclonais tuberculata*** **$y = 3.8123\mathrm{Ln}(x) - 0.6746$ $R^2 = 0.935$;** ***Leptodea fragilis*** **$y = 5.7222\mathrm{Ln}(x) - 1.0147$ $R^2 = 0.941$;** ***Pygandon grandis*** **$y = 5.5916\mathrm{Ln}(x) - 0.8214$ $R^2 = 0.9602$;** ***Quadrula quadrula*** **$y = 3.1152\mathrm{Ln}(x) - 0.6959$ $R^2 = 0.9112$.**

and glycogen concentration were not capable of predicting the gradual die-off of all test animals after 36 mo. Additional criteria relating to physiologic mechanisms and underlying digestive capabilities are needed so that changes in diet and environmental conditions can be implemented before mortality occurs.

The two diets that were most effective in our tests, TR#7 and TR#10, differed substantially in protein, lipid, carbohydrate, and phytosterol composition, but did not differ in their ability to support subadult unionid growth or adult survival. TR#10 is a low protein (~8%), low lipid (5%), high carbohydrate (87%) feed with added algal sterols. In contrast, TR#7 is a high protein (~65%), low carbohydrate (22%), higher lipid (13%) feed that is naturally high in cholesterol, but contains no phytosterols. Our hypothesis is that TR#10 is the closest in nutritive content and physical structure to the food resources used by wild unionids in shallow temperate rivers (see Nichols & Garling 2000). This diet proved acceptable to all species tested in our study, supported significantly higher growth rates in subadults and kept 100% of the test animals alive for the entire year of the study. However, while promising results were obtained, the problem in whole-heartedly recommending this diet is that it was tested for only one year. It is possible that this diet, like TR#7 cannot support long-term (>3 y) survival.

Up until year three of our study, we thought TR#7 was a successful diet formula. It was easy to make in the laboratory, was readily ingested by all species, and supported growth, survival, glycogen storage, and limited reproduction, at least until year three. The question remains unanswered as to why long-term survival was not supported. One problem might relate to protein levels. This TR#7 is a high protein feed (~65% protein), and high protein may not be a dietary requirement of the age class of mussels used in this study. Subadults grew as well on the low protein (8%) levels found in TR#10 as they did on the high protein TR#7 (Fig. 1 and Fig. 2). Our work on a unionid community in a small temperate river indicate that they preferentially use a lower protein food (the <28 μ fine particulate organic matter,~6.7% protein) as their main food source (Nichols & Garling 2000).

Feeding a high-protein feed such as the TR#7 as a sole diet at the amount used in this study may have overfed the animals. Glycogen levels in animals fed on egg chow were far higher than those recorded by Naimo et al. (1998), Naimo and Monroe (1999), and Patterson et al. (1999) for newly caught unionids. However, food quantity may not have been the only problem. Feeding excessive dietary protein to vertebrates that normally use low protein feeds will support rapid growth and reproduction initially, but can cause high mortality due to excess nitrogen excretion causing kidney failure after a few years and alter mineral metabolism. This supposition is not a direct cause-and-effect relationship in unionids. While all the dying unionids on this feed did show greatly enlarged kidneys, unionid kidneys do not excrete excess nitrogen, as do vertebrate kidneys; the gills perform that function. However, the primary function of unionid kidneys is to control ionic balance, including mineral balance, of bodily fluids. Theoretically, excess protein can affect ionic balance due to alteration of blood pH through excess amine production and stress the metabolic balance of the unionid; we could not determine cause and effect from our study. We cannot recommend the long-term use of high protein feeds for unionids. However, short-term or supplemental feeding at a lower ration than used in this study might be acceptable to prevent glycogen loss during quarantine as reported by Patterson et al. (1999).

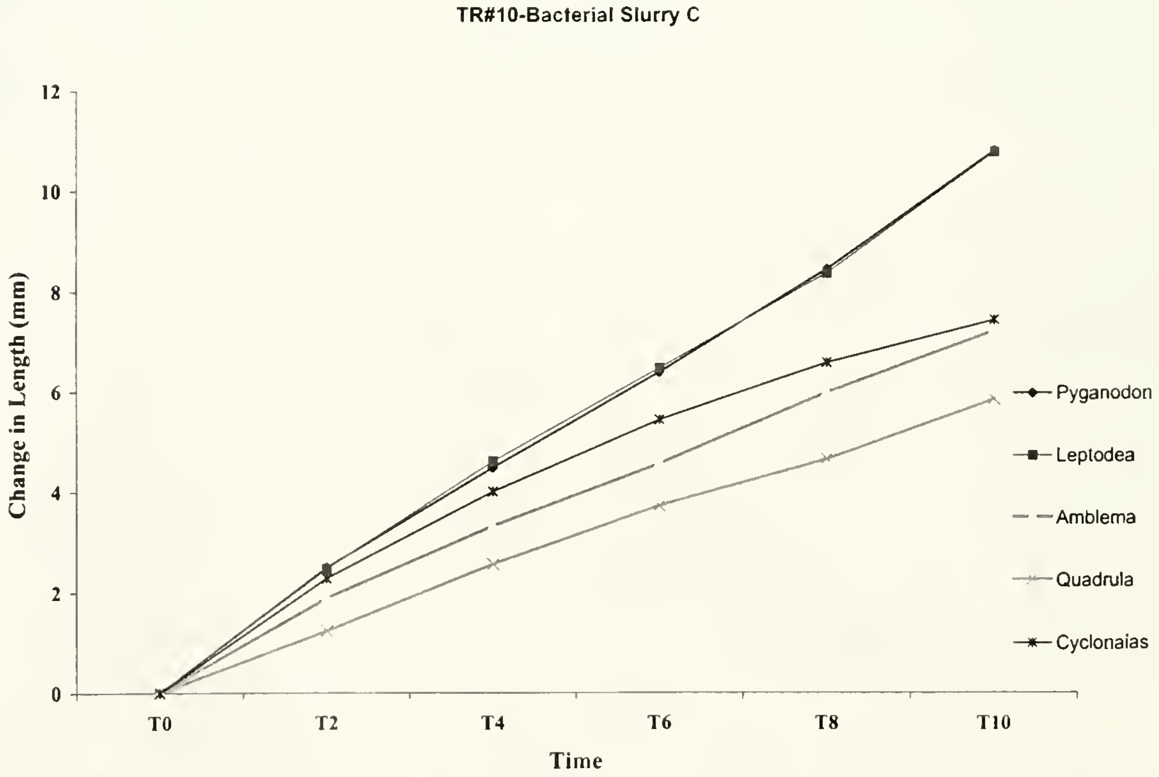

Figure 2. **Comparison of growth equations of various unionid subadults fed diet TR#10 over 350 days.** ***Ambelma plicata*** **$y = 3.9346Ln(x) - 0.4899$ $R^2 = 0.9649$;** ***Cyclonais tuberculata*** **$y = 4.1877Ln(x) - 0.3063$ $R^2 = 0.9909$;** ***Leptodea fragilis*** **$y = 5.5873Ln(x) - 0.7751$ $R^2 = 0.9608$;** ***Pygandon grandis*** **$y = 5.7785Ln(x) - 0.903$ $R^2 = 0.9426$;** ***Quadrula quadrula*** **$y = 3.1988Ln(x) - 0.5076$ $R^2 = 0.9533$.**

There is certainly the possibility that unionid mortality after three years in captivity relates more to environment than nutrition. Even aquaculture efforts that feed their unionids live algae report incidents of poor water quality that at times does not lead to immediate mortality (Gatenby et al. 1994, Gatenby et al. 1996). However, such events may produce sublethal stress that over a period of time and after a number of incidents may eventually kill the adult unionids. One of the greatest problems in using the types of feeds we tested is that of maintaining water quality, especially with bacterial/ciliate slurries (Tr#s 8–10).

There are a number of other environmental factors that may produce sublethal stress, including altered flow, light, and temperature regimes. Such environmental factors need further study before we can establish captive management protocols for the various unionid species, as there will be variability in environmental tolerances. Survival was to some degree species-specific. *L. fasciola* could not be kept alive under any type of environmental condition, even though we were able to keep other *Lampsilis* species alive for several years.

Unionids can survive, grow, and even reproduce for about 3–3.5 y on non-live algal diets, but long-term survival remains problematic. Health monitoring criteria using glycogen concentrations, shell growth rates, reproduction, and survival did not provide enough warning to prevent mortality. Additional criteria to judge success or failure of captive management protocols, other than death, need to be developed. These types of non-live algal diets may function for supplemental feeding, but at this time, maintaining adult unionid populations in captivity will require access to natural foods and water supplies from water systems that support native unionid fauna to increase the likelihood of long-term survival.

BROOD STOCK SOURCES FOR HATCHERY-BASED STOCK ENHANCEMENT OF OYSTER REEFS: ESSENTIAL QUESTIONS AND RECOMMENDATIONS.

S. K. **Allen, Jr.**, Aquaculture Genetics and Breeding Technology Center, Virginia Institute of Marine Science, College of William And Mary, Gloucester Point, VA 23062.

Oyster populations are subdivided into genetically distinct units with major divisions occurring over large geographic scale because of larval dispersal. Populations resist local adaptation because of population mixing through migration. However, over the course of the last 50 years, populations of Chesapeake Bay oysters may have lost alleles for disease resistance from the combination of disease mortality followed by heavy harvesting of survivors. Artificial breeding can increase the frequency of disease-resistant alleles, and several varieties of disease-resistant oysters are available as brood stock today. Some of these strains have been used to populate reefs and are likely to survive, grow, and breed on the reefs. Reproduction of the disease-resistant strains will produce disease-resistant spat over surrounding areas. There may also be natural stocks of oysters that resist disease, such as those from the Gulf of Mexico, where Dermo historically occurs. However, using "artificial" or genetically distinct oysters from the hatchery for reef restoration could also entail some risk to natural genetic diversity. For example, artificially selected populations have (by definition) reduced genetic variation over wild stocks. Interbreeding of the two may alter wild populations. At present, the risk (or benefit) of using alternative stocks is unknown. The results and recommendations from a workshop on genetic considerations for hatchery-based reef restoration will be presented.

ECOLOGICAL FUNCTION OF OYSTERS IN SOUTHEASTERN NORTH CAROLINA.

T. D. Alphin and **M. H. Posey**, Center For Marine Science, UNC-Wilmington, 1 Marvin Moss Lane, Wilmington, NC 28409.

Oysters serve a variety of functions within the estuarine systems of Southeastern North Carolina. A number of juvenile fish and decapods use oyster habitat for refuge/forage during some portion of their lives. Here, we present results from several studies evaluating the use of oyster habitat by juvenile fish and decapods compared with alternate habitats. An abundance of fish and decapods were examined in isolated and mixed oyster habitats using Breder traps in small tidal creek estuarine systems whereas net sampling was used to compare faunal abundances in oyster reefs along larger spatial scales in the presence and absence of sea grass beds. In both cases, abundance in oyster reefs were compared with vegetated or unvegetated marsh edge habitats. On the larger scale, use of oyster reefs was also compared with abundance patterns within seagrass beds. The mixed results of these studies indicate that the importance of oyster reefs as a refuge/forage habitat varies seasonally within a given system as well as among small estuarine systems based on the presence of alternate habitats. We also present preliminary information on more indirect effects of oysters as modifiers of water quality using transplant/removal studies.

SIMPLIFICATION OF SHELLFISH RESTORATION METHODS.

D. Bishop, Fukui North America, P.O. Box 119, 523 Island View Drive, Golden Lake, Ontario, Canada.

As the shellfish aquaculture industry continues to grow, methods of husbandry to reduce labor, increase yield, and produce higher quality products are in a constant evolution. Based on the simple fact that smart people learn from their mistakes and really smart people learn from other's mistakes, there is a lot that can be learned from the aquaculture industry to transfer to restoration projects. Although all the answers for husbandry are not in place, many dynamics and protocols positively affect restoration projects by moving them forward at a faster pace. Attitudes towards labor efficiency using different equipment ideas and management techniques will be discussed. This will give attendees references that, used as-is or with slight modification, could benefit their efforts significantly. An interactive audiovisual presentation with examples of methods from around the world used today will enhance the presentation.

EXPANDING AND SUSTAINING SHELLFISHERIES OF CASCO BAY.

M. Bowen,[1] **K. Groves,**[2] **C. Heinig,**[3] and **A. Frick,**[4] [1]Normandeau Associates, Normandeau Associates Inc., 251 Main Street, Yarmouth, ME 04096; [2]Casco Bay Estuary Project, University of Southern Maine, Law School Building, Portland, ME 04104; [3]Mer Assessment Corporation, 14 Industrial Parkway, Brunswick, ME 04011; and [4]Albert Frick Associates, Inc., 95a County Road, Gorham ME 04038.

One of the missions of the Casco Bay Estuary Project is to ensure communities around Casco Bay in Maine have a healthily shellfish harvest that sustains commercial and recreational shellfishing for generations to come. A "clam team" of stakeholders, including the US Environmental Protection Agency, the Friends of Casco Bay, Maine Department of Marine Resources, individual cities and towns, and the Maine Department of Environmental Protection was formed to find the most productive shellfish areas currently closed to harvest, determine sources of contamination, and find ways to remediate. A field review of the 57 clam flats—800 acres—of soft-shell clam habitat that are currently closed to harvest targeted 22 of these, totaling 370 acres of highly productive clam flats. Review of water quality data pinpointed sources of contamination. Many of the flats are closed simply because of the presence of an overboard discharge system that treats household waste. The project is currently supporting an intensive effort to design and construct replacement systems, a collaborative effort between the towns, state, and individual homeowners. Additional water sampling efforts are in progress to determine other nonpoint sources of contamination, including farm runoff, leaking septic systems, and wildlife. A third element of the project is investigating the sustainability aspect, investigating the effectiveness of regulatory options, including licensing, harvest limits and techniques, and conservation closures.

DNA FINGERPRINTING OF NONPOINT SOURCE *ESCHERICHIA COLI* CONTAMINATION IN A CHESAPEAKE BAY WATERSHED. **M. F. Frana,[1] E. A. Venso,[2] K. Brohawn,[3] W. Beatty,[3] M. Ellwanger,[3] R. McKay,[3] B. Evans,[3]** and **M. Phipps-Dickerson,[4]**

[1]Department of Biological Sciences, Salisbury State University, 1101 Camden Avenue, Salisbury, MD 21801; [2]Environmental Health Science, Salisbury State University, 1101 Camden Avenue, Salisbury, MD 21801; [3]Maryland Department of the Environment, Technical & Regulatory Services Administration, 2500 Broening Highway, Baltimore, MD 21224; and [4]Wicomico County Environmental Health Department, Seth H. Hurdle Health Center, 108 East Main Street, Salisbury, MD 21801.

Fecal coliform contamination has closed shellfish harvesting areas and public beaches and threatened recreational areas in the Chesapeake Bay watershed. Bacteriological water quality testing currently performed in these watersheds does not identify the sources of contamination. Therefore, no pollution control or mitigation efforts have been undertaken, despite the large economic impact for this area of the Midatlantic. Possible sources include runoff from crop fields, wildlife, discharge from boats, and runoff from >1,300 animal production farms on the Eastern Shore of the Chesapeake Bay. Although municipal waste water plant effluent and on-site waste water treatment (septic) systems could contribute, shoreline surveys conducted by the Shellfish Sanitation Program of the Maryland Department of the Environment indicate that nonpoint sources are responsible for the elevated levels of coliform bacteria in this watershed. It is understood that these sources would contribute not only bacteria but also excess nutrients and possibly other water contaminants that can negatively impact public health as well as the sensitive plant and animal species that dwell in the watershed. The methodologies used to determine the specific sources of *Escherichia coli* contamination are described, including choice of sample locations and environmental variables, sampling techniques, DNA analysis of strain-specific *E. coli*, and interpretation of the data. Preliminary data are presented, including selected DNA fingerprints and relationships among and between total coliforms and *E. coli* MPNs and six environmental and water chemistry variables. Ultimately, Geographic Information Systems mapping will be used for spatial analysis as a key to the understanding needed for pollution control and mitigation.

A NATIONAL STRATEGY FOR COASTAL HABITAT RESTORATION. **D. W. Brown,**

National Marine Fisheries Service, 1315 East West Hwy, Ssmc#3, Room 15221, Silver Spring, MD 20910-3282.

Shellfish habitats make up a significant portion of the important aquatic habitats in our coastal waters that provide the living space for marine and estuarine fish and shellfish. Unfortunately, in many areas along our coastline, many habitats, including shellfish habitats, are being destroyed and the natural systems they support are failing. The National Oceanic and Atmospheric Administration recently joined with Restore America's Estuaries and the Pew Charitable Trusts to launch a major partnership initiative to restore important habitats in our coastal estuaries. A major element of this initiative is to develop a national strategy for coastal habitat restoration, including important shellfish habitats. The purpose of the strategy is to identify specific habitat problems in each coastal region and to determine the most viable restoration approaches to address degraded areas for these regions. The National Strategy will (1) actively promote the increased protection of existing habitats; (2) establish specific regional and national restoration goals and objectives; (3) provide a framework for setting restoration priorities; (4) identify and integrate the science and new technologies needed for effective restoration; and (5) energize cooperative partnerships among private and public stakeholders. This presentation will review ongoing and planned actions by the NGO community, federal agencies, and the private sector to develop a national strategy for coastal habitat restoration, including shellfish habitats, by the fall of 2001.

BEYOND THE PROJECT: VALUES OF COMMUNITY-BASED HABITAT RESTORATION. **R. J. Bruckner[1]** and **R. L. Takacs,[2]**

[1]NOAA Restoration Center, 1315 East West Highway, Silver Spring, MD 20910 and [2]NOAA Chesapeake Bay Office, 410 Severn Avenue, Annapolis, MD 21403.

The NOAA Community-based Restoration Program (CRP) began in 1996 to inspire local efforts to conduct meaningful, on-the-ground restoration of marine, estuarine, and riparian habitat. The CRP is a systematic effort to catalyze partnerships at the national and local level to contribute funding, technical assistance, land, volunteer support, or other in-kind services to help citizens implement restoration projects that promote stewardship and a conservation ethic for living marine resources. The CRP links funding and technical expertise to citizen-driven restoration projects and emphasizes collaborative strategies built around improving NOAA trust resources and the quality of the communities they sustain. Oyster restoration projects, although not all explicitly off-limits to harvesting, have emphasized the habitat benefits of reef restoration, from three-dimensional habitat conducive to spat settlement, to the benthic organisms that make up the ecological diversity of oyster reefs themselves, to the fish and openwater communities that aggregate around hard-bottom reef habitat. In addition to implementing projects, this innovative funding/partnership source has provided the mechanism to "field test" new restoration strategies, such as reef design and construction, unique management approaches like sanctuaries, reserves, and satellite bars, and often has served as the springboard for larger-scale, river-wide restoration efforts. The availability of technical expertise and matching funds and the positive results achieved by community-based shellfish restoration efforts have catalyzed other federal, state, and local entities to participate, effectively broadening the partnering and stewardship opportunities, increasing the areas available for shellfish restoration, and leveraging the amount of funds available for habitat restoration efforts.

OYSTER BROODSTOCK ENHANCEMENT IN VIRGINIA AND APPLICATION OF A NEW MONITORING TECHNIQUE.

R. D. Brumbaugh,[1] **W. J. Goldsborough,**[1] **L. A. Sorabella,**[1] and **J. A. Wesson,**[2] [1]Chesapeake Bay Foundation, 142 W. York Street, Suite 318, Norfolk, VA 23510 and [2]Virginia Marine Resources Commission, P.O. Box 756, 2600 Washington Ave., Newport News, VA 23607.

The transplanting of both wild and hatchery-produced oysters onto oyster sanctuary reefs is increasingly frequent as a component of oyster restoration efforts in the Chesapeake Bay. Since 1996, oysters have been added to more than a dozen state or privately managed sanctuary reefs in Virginia in an effort to enhance localized oyster spawning success. Wild oysters, purchased with both state and private funds, have accounted for approximately 70% of the total number of oysters added to reefs. Increasingly, however, the oysters added to reefs are hatchery produced, grown by citizens and students volunteering through programs such as the Chesapeake Bay Foundation's Oyster Corps. To date, more than 800,000 oysters grown by volunteers have been added to Virginia's system of reefs. Although definitive data are scarce, there appears to be good empirical evidence that these stocking efforts have enhanced spat settlement rates on and around sanctuary reefs. Dive surveys and patent-tong data show substantial increases in localized spat settlement in tributaries where oysters have been added to reefs in recent years. To better understand spat settlement dynamics around the reefs, spat cages, small cages filled with a known volume of shell, are now being used to monitor oyster settlement around selected reefs. A strong correlation exists between spat cage data and diver-surveys on nearby reefs ($r = 0.95$, $P < 0.01$), suggesting that spat cages may be a low-cost means of both involving the public in restoration and of evaluating results of broodstock enhancement and reef restoration projects.

NUTRIENT CYCLING IN INTERTIDAL CREEKS ALONG THE SOUTHEAST US: ARE OYSTERS IN CONTROL?

D. Bushek,[1] **R. F. Dame,**[2] **D. M. Allen,**[1] **A. J. Lewitus,**[1] **E. T. Koepfler,**[2] and **D. Edwards,**[1] [1]Baruch Marine Field Laboratory, Baruch Institute for Marine Biology and Coastal Research, University of South Carolina, Georgetown, SC 29442 and [2]Department of Marine Science, Coastal Carolina University, Conway, SC 29528.

Ecologically, oyster reefs provide habitat, filter water, and facilitate nutrient cycling. We experimentally removed oyster reefs to examine their role in the structure and function of intertidal creek ecosystems. Surprisingly, the removal of oyster reefs did not significantly alter nutrient concentrations, nekton usage, or phytoplankton production. Our calculations show that oysters do not produce enough ammonium to satisfy phytoplankton productivity, but nekton, water column remineralization, and sediments more than account for the deficit. These observations were interpreted as an indication of functional redundancy in the system. Flagellates, which are preferred over diatoms as food by the oysters, dominated the phytoplankton during summer when ammonium concentrations were high. Diatoms dominated during the colder months. Shifts in phytoplankton dominance corresponded to the seasonal arrival and departure of nekton in the creeks. Because nekton comprised more than double the biomass of oysters during summer, fishes and macrocrustaceans may play a greater role in nutrient remineralization than has been previously considered. At the meso-scale ecosystem level, the loss of nutrient remineralization activities attributable to the removal of oyster reefs was compensated by other components within the system, but phytoplankton communities changed, apparently in response to changes in grazing. Oysters clearly play important roles, but defining the importance of shellfish restoration in the management of coastal ecosystems requires an understanding of the ecosystem science, a consideration of scale, and the realization that tidal creek systems exhibit complex responses.

DISEASE RESISTANCE IN A SELECTIVELY BRED *CRASSOSTREA VIRGINICA* STRAIN.

G. W. Calvo, L. M. Ragone Calvo, and **E. M. Burreson,** Virginia Institute of Marine Science (VIMS), College of William and Mary, Gloucester Point, VA 23062.

During 1997 to 1999, DEBY oysters, a VIMS stock that was selectively bred for four generations at a disease endemic site in the lower York River, Virginia, were evaluated for survival, growth, and disease susceptibility in comparison with progeny from wild Mobjack Bay (MB) and Tangier Sound (TS) brood stocks. MB and TS stocks are relevant to rehabilitation of Chesapeake Bay oysters because the former have been routinely used for aquaculture and the latter have been recently used for reef restoration because of their putative disease resistance. Oysters ($n = 1500$ of each group, mean shell height = 15–17 mm) were deployed in floating mesh cages at a low salinity (<15 ppt) site and a moderate salinity (15–25 ppt) site in the lower Chesapeake Bay, and at a high salinity (>25 ppt) site on the Atlantic Coast of Virginia. Twenty-eight months after deployment, cumulative mortality in MB and TS was 84–100%. In contrast, cumulative mortality in DEBY at low, moderate, and high salinity sites was, respectively, 21, 51, and 36%. By November 1999, mean shell height in MB and TS at low-, moderate-, and high-salinity sites was, respectively, 77, 88–90, and 57–59 mm. In comparison, mean shell height in DEBY was 92, 101, and 72 mm. Although similar low levels of MSX were observed in all groups, *P. marinus* infections in MB and TS were more intense than in DEBY throughout the study. This promising oyster strain has potential to facilitate commercial aquaculture and reef restoration efforts in Chesapeake Bay.

SUMMER MORTALITY OF THE PACIFIC OYSTER, *CRASSOSTREA GIGAS:* INFLUENCES OF CULTURE METHODS, SITE CONDITIONS, AND STOCK SELECTION.

D. Cheney,[1] R. Elston,[1] B. MacDonald,[1] K. Kinnan,[1] A. Suhrbier,[1] G. Cherr,[2] C. Friedman,[2] F. Griffin,[2] A. Hamdoun,[2] J. Mitchell,[2] L. Righetti,[2] and **L. Burnett,[3]** [1]Pacific Shellfish Institute, 120 State Ave NE #142, Olympia, WA 98501; [2]University Of California, Davis, Bodega Marine Laboratory, P.O. Box 247, Bodega Bay, CA 94923; and [3]Grice Marine Laboratory, 205 Fort Johnson, Charleston, SC 29412.

During the late summer to early fall period, Pacific oysters cultured on the west coast of the United States and elsewhere may experience high levels of mortality. In the 1960s to 1980s, this condition was subject to intensive investigation focusing on broad areas of disease pathology, genetics, physiology, and the environment. Results of these studies were largely inconclusive or pointed to a poorly defined etiology. Recent studies in Puget Sound, Washington and Tomales Bay, California, center on the influence of multiple stressors and their affects on oyster survival, physiology, and pathology. The goal of this research is to identify possible modifications in culture practices, brood stock selection, or growout location to increase survival of Pacific oysters. Field observations indicate oysters are subject to extreme variations in a number of parameters during intertidal cycles. An increased rate of oyster mortality and modified physiological response appear to be strongly correlated with both elevated temperatures and extended periods of depressed DO. The DO reductions are sometimes coupled with heavy macroalgae blooms and high phytoplankton densities. This and other works indicate oyster summer mortality rates are also strongly influenced by ploidy and broodstock origin/stock selection. These observations have renewed interest in testing stocks selected for reduced rates of summer mortality and which retain desirable characteristics of good growth and meat yield. This research was supported by grant numbers NA86RGOOl5 and NA96RG0488 from the National Sea Grant College Oyster Disease Research Program and matching contributions from West Coast shellfish farmers.

PHYSIOLOGICAL CONDITION AND DEFENSE–RELATED ACTIVITIES AMONG EASTERN OYSTER POPULATIONS.

F.-L. E. Chu,[1] V. G. Encomio,[1] S. Stickler,[1] S. Allen,[1] and **J. La Peyre,[2]** [1]Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062 and [2]Louisiana State University, Baton Rouge, LA 70803-6002.

The goal of our study is to identify oyster stocks that are resistant/tolerant to the disease caused by the parasite, *Perkinsus marinus* (Dermo). We are comparing the physiological condition and defense factors of putative "Dermo resistant" and "nonresistant" oysters (*Crasssostrea virginica*) deployed in the fall of 1999 at two sites in the Chesapeake Bay (Port Kinsale, Yeocomico River; Regent Point, Rappahannock River), where Dermo disease is known to occur, but not MSX (disease caused by *Haplosporidium nelsoni*). These oysters are F1 progenies from presumably genetically distinct oyster populations (three Gulf of Mexico and three Chesapeake Bay populations, and one hatchery strain) and represent geographical disparity. Oysters have been sampled monthly since May 2000. Initial analysis showed that all the stocks have grown significantly since deployment and the Rappahannock River Stock has the fastest growth. Tissue dry weights of this stock increased significantly over time at both sites. Contents of glycogen, protein, and lipid increased with growth. All stocks sampled from May to July had low *P. marinus* infection and prevalence. Mortality was low in all stocks and lower in the Gulf of Mexico than Chesapeake Bay populations. No significant differences were noted in levels of plasma protein and lysozyme among stocks. Currently we are analyzing oysters sampled in August and September. Correlation between growth, physiological, biochemical, and defense condition and *P. marinus* infection among oyster stocks will be discussed. This research was funded by the NOAA-Virginia Sea Grant-Oyster Disease Research Program.

A UNIFIED INFORMATION SYSTEM FOR SHELLFISH RESTORATION.

P. Comar, L. Kracker, P. Bauersfeld, and **M. Meaburn,** Center For Coastal Environmental Health and Biomolecular Research, National Ocean Service, NOAA, 219 Fort Johnson Road, Charleston, SC 29412.

The Shellfish Information Management System (SIMS) is an intergovernmental data system designed to provide a current central source of information on shellfish safety, resource, and habitat useful to multiple users at local, state, regional, and national levels. SIMS is being developed as a GIS-enabled, web-accessible relational database of shellfish harvest water survey, classification, and resource information. Most of the data in SIMS is provided by state agencies, and SIMS will allow more extensive access to and integrative analysis of that information. In 1999, the National Ocean Service, Center for Coastal Environmental Health and Biomolecular Research in Charleston, South Carolina, began partnering with a growing number of coastal states in the design and applications for SIMS. This spatially enabled, Oracle database is designed with extensive query functionality, visualization, and analytical capabilities for a wide range of shellfish safety, water quality, resource, and restoration concerns. Shellfish restoration is a new component being developed for incorporation into SIMS so that trends in restoration can be quantified and visualized. Water quality, benthic and habitat suitability, shellfish resource, presence of disease agents, social and economic factors, and other influences impact shellfish restoration decisions and actions. Discussion will include the rationale and means for collecting and integrating such restoration data layers into SIMS.

EFFECTS OF PEARL NET STOCKING DENSITY ON SURVIVAL, GROWTH, AND GONADAL MATURATION OF BAY SCALLOPS.

M. Davidson,[1] **L. Holst,**[1] **H. Bokuniewicz,**[2] **C. Smith,**[3] and **K. Tetrault,**[3] [1]Nysdec, 205 North Belle Mead Road, East Setauket, NY 11733, [2]Marine Science Research Center, Suny Stony Brook, NY 11790; and [3]Dornell Cooperative Extension Marine Program, 3059 Sound Avenue, Riverhead, NY 11901.

The stocking densities under which bay scallops are reared can have long-term effects on survival. growth, and spawning success that may not be evident while the scallops are in culture. To investigate the influence of stocking density on scallop production, hatchery reared bay scallops were stocked in pearl nets at three different densities during the summer. In the fall, bay scallop survival and shell heights were recorded. The animals were transferred to lantern nets and stocked at two different densities, grouped by their initial densities in the pearl nets, and over wintered. Bay scallops raised at high densities exhibited lower survival and slower growth than those raised at lower densities. Regardless of density in the lantern nets, growth and survival still showed the negative effects of initial crowding in the pearl nets. Two-way analyses of variance revealed significant differences among the pearl net and lantern net treatments in scallop survival and growth. Gonadal indices show that all the bay scallops, regardless of treatment, spawned at the same time. At the time of spawning there were no significant effects of density on gonadal index. Bay scallop restoration efforts should ensure that scallops are reared under conditions that maximize survival and growth.

PROBIOTIC APPROACH TO ENHANCE HEALTH OF HATCHERY PRODUCED SHELLFISH SEED.

R. A. Elston,[1] **R. M. Estes,**[2] **A. Gee,**[3] **R. P. Herwig,**[4] **K. Kinnan,**[5] and **S. Rensel,**[6] [1]Aquatechnics/Pacific Shellfish Institute, P.O. Box 687, Carlsborg, WA 98324; [2]School of Fisheries, University of Washington, 3707 Brooklyn Ave. N.E., Seattle, WA 98105-6715; [3]Department of Biology, Pacific Lutheran University, Tacoma, WA 98447-0003; [4]School of Fisheries, University of Washington, 3707 Brooklyn Ave. N.E., Seattle, WA 98105-6715; [5]Aquatechnics/Pacific Shellfish Institute, P.O. Box 687. Carlsborg, WA 98324; and [6]Department of Biology, Pacific Lutheran University, Tacoma, WA 98447-0003.

Bacterial diseases of intensively cultured larval and juvenile shellfish cause significant losses in hatcheries and nurseries. In addition, chronic bacterial infections are a significant cause of bivalve seed losses postplanting. From commercial hatchery case histories, a number of virulent juvenile oyster bacterial pathogens have been isolated, characterized, and pathogenicity confirmed by challenge procedures. Prevention and control strategies for bacterial pathogens in hatcheries and nurseries must include routine sanitation of system surfaces, water filtration, brood stock sanitation, and maintenance of low dissolved organic levels. Antibiotics have been used in experimental settings but are not routinely used on production scale systems because of cost as well as risk of producing resistant strains. A program to select and test probiotic strains of bacteria, as an alternative to antibiotic use, is underway. and results to date will be presented. Bacterial pathogens were first screened by comparing whole cell fatty acid profiles. Based on this evaluation, most pathogens were consistent or close to the *Vibrio* genus, but probiotic candidates represented a variety of bacterial genera. Selected representative isolates were further characterized using biochemical criteria and 16s rDNA sequencing. Candidate probiotic bacteria are first tested in agar plate inhibition tests. Strains showing inhibition to isolated pathogens are tested for haemolytic activity and pathogenicity to shellfish seed. Candidates passing these tests are then tested for inhibition of mortality and morbidity response in laboratory pathogen challenges. This research was supported in part by Saltonstall-Kennedy program (National Marine Fisheries Service, U.S. Department of Commerce) grant to Pacific Shellfish Institute, Olympia, Washington.

MANAGEMENT BY SIZE LIMIT OF THE WHELK *BUCCINUM UNDATUM* FISHERY IN THE SOUTH WEST IRISH SEA.

E. Fahy, Marine Fisheries Services Division, Marine Institute, Abbotstown, Castleknock, Dublin 15, Ireland.

Whelk landings in the south west Irish Sea increased from 56 t in 1990 to 6,575 t in 1996 after which they stabilized between 3,600 and 4,600 t annually. At its peak, the fishery supported approximately 80 vessels but this number has halved since this time. In 1994, a size limit of 50 mm was introduced for conservation purposes. Age-based assessments of the landings were conducted in 1994, 1996. 1997, and 1999, for which purpose the fishery, ranging from 52°10′ to 53°30′, is divided into four sectors. Landings to the four sectors display biological characteristics that indicate the occurrence of a number of stocklets rather than a single stock unit. Compliance with the size limit has been poor. From 20 to 33% of total landings (by number) in any of the assessed years have been less than the legal limit. Trends in cpue have been monitored since 1990. Some fishermen in the center sectors improved their yield between 1994 and 1998. Whelk have responded to a reduction in fishing effort since 1996, immediately after which averaged mortality coefficients (Z) were highest (0.79); they declined to 0.61 in 1999. The survival of the whelk fishery in the south west Irish Sea is attributed to the instability of the market which is dominated by a single customer, South Korea. A more effective size limit for this fishery would be 68 mm (83 mm in the northern sector), and this is considered unrealistic. suggesting that alternative management measures will have to be introduced.

MANAGING THE FUTURE OF SOUTH CAROLINA'S OYSTERS: AN EXPERIMENTAL APPROACH EVALUATING CURRENT HARVESTING PRACTICES AND BOAT WAKE IMPACTS. L. D. Coen and **A. Fischer,** Marine Resources Research Institute, SCDNR, Charleston, SC 29412.

Oyster reefs provide an important intertidal habitat to the Southeastern United States. However, harvesting and recreational boating invariably impact these critical habitats and their associated functions. In 1998, we began to experimentally evaluate the direct impacts of four harvesting practices (complete harvest, cull-in-place, clamming, and rake down) on intertidal oyster resources. Initially, 26 sites were sampled by quadrat to establish baseline assessments. Initial mean oyster size (SH) across sites ranged from 23–33 mm, with initial densities ranging from 1,700–7,500 oysters/m^2. Then, the above harvesting practices were simulated at replicated sites, each paired with an adjacent control site. Water quality (temperature, DO, salinity, chl *a*) was measured during the study period. Trays of shell were deployed at each site to evaluate oyster recruitment and growth. After approximately 1 year, more than 133,000 oysters recruited to the 130 deployed trays. This recruitment, a surrogate for larval supply/habitat quality, and the baseline assessments are analyzed and discussed. In 1999, we conducted experiments to understand how boat wakes compromise shell (cultch) deployments for oyster restoration and marsh erosion control. For this, we deployed stabilized (mesh) and unstabilized shell treatments, monitoring cultch retention after controlled boat wakes. In the first pilot experiment, unstabilized treatments lost 33.6% (7.7 cm) more shell than stabilized treatments after exposure to 32-controlled boat passes. In a second experiment, 22.4% (5.17 cm) more was lost after only 24 passes. Both harvesting practices and recreational boating wakes can potentially impact the growth, recruitment, and recovery of intertidal oyster resources. Additionally, oyster reefs that fringe marshes can serve as moderators of both marsh and bank erosion. Further studies with remote sensing technologies should be employed to monitor the oyster-marsh interaction.

GENOMIC APPROACHES TO MARKER DEVELOPMENT AND MAPPING N THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*. P. M. Gaffney,[1] K. S. Reece,[2] and **J. C. Pierce,[3]** [1]College of Marine Studies, Lewes, DE 19958; [2]Virginia Institute of Marine Science, Rt. 1208, Gloucester Point, VA 23062; and [3]University of the Sciences in Philadelphia, 600 S. 43d St., Philadelphia, PA 19104.

In response to the dramatic decline in the Atlantic oyster fishery, efforts are underway to expand hatchery production of the Eastern oyster, for both commercial farming and for replenishment of disease-challenged natural populations. In particular, there is a strong demand for genetically improved oyster strains resistant to two common protozoan parasites, Dermo and MSX. The genetic improvement process will be enhanced by the development of molecular markers and a genetic linkage map. To facilitate future marker development in *C. virginica,* we obtained 0.7 MB of random genomic sequence data from a small-insert (1 kb) pGEM library. A modest number of significant BLASTX hits may prove valuable for designing type I markers for comparative mapping with the Pacific oyster. In addition, we the searched the sequence database for repetitive sequences. Several satellite DNA sequences were identified and compared with putative satellite sequences obtained by traditional cloning methods. Our database yielded useful information on the distribution of microsatellite loci. Dinucleotide microsatellites were dominated by the AG motif (66%). Trinucleotide microsatellites included all possible motifs in apparently equal frequencies. Tetranucleotide microsatellites were more common than trinucleotides and, unlike the other microsatellite classes, were frequently associated with repetitive sequences, with a strong tendency for certain tetranucleotide motifs to be associated with particular repetitive sequences. This information will be useful for tetranucleotide microsatellite marker design, as well as interpretation of linkage mapping data. The repetitive sequence database will be used as an adjunct for designing new primers, to reduce the frequency of non-target amplification.

COMMUNITY-BASED OYSTER RESTORATION: CASE STUDIES FROM CHESAPEAKE BAY. W. J. Goldsborough,[1] R. D. Brumbaugh,[1] D. W. Meritt,[2] and **J. A. Wesson,[3]** [1]Chesapeake Bay Foundation, 162 Prince George Street, Annapolis, MD 21401; [2]University of Maryland, Center For Environmental Science, P.O. Box 775, Cambridge, MD 21613; and [3]Virginia Marine Resources Commission, P.O. Box 756, 2600 Washington Avenue, Newport News, VA 23607.

Public support for oyster restoration in the Chesapeake Bay region has increased in recent years, largely because of expanded opportunities for direct citizen involvement in restoration work The commercial value of oyster restoration is the most easily appreciated aspect of restoration, whereas associated benefits such as improved fish habitat and water quality are only recently being more widely recognized. As opportunities for public participation have expanded, the support for restoration has increasingly been based on these associated ecosystem benefits, particularly in developed areas where water quality may preclude commercial or recreational harvest of bivalves. One of the principal ways that the public now participates in oyster restoration is by growing hatchery-produced oysters using small-scale aquaculture techniques (i.e., "oyster gardening") for eventual transplanting onto broodstock sanctuary reefs. Analyses of four local examples of citizen involvement in oyster gardening/restoration in the Chesapeake reveal a general pattern of roles and responsibilities for successful community-based restoration. Local leadership, sources for shell and seed, education, technical guidance, amenable government rules and regulations, media exposure, and funding emerge as key factors. In the Chesapeake, a partnership approach based on cooperation between various combinations of citizens, schools, local businesses, local service organizations, watershed associations, academic institutions, state and federal agencies, conservation organizations, and private foundations has successfully addressed these needs. It is becoming increasingly clear that the groundswell of public support for restoration resulting from community-based approaches is a key factor in generating increased public funding for restoration.

MOLECULAR IMMUNE RESPONSES OF THE EASTERN OYSTER TO THE PARASITE *PERKINSUS MARINUS*.

M. Gomez-Chiarri and **P. Muñoz**, Department of Fisheries, Animal and Veterinary Science, University of Rhode Island, 127 Woodward Hall, Kingston, RI 02881.

Microbial pathogens and parasites like *Perkinsus marinus* and *Haplosporidium nelsoni* place a large economic burden on oyster fisheries and aquaculture. Although there has been a steady increase in our knowledge on the pathology and epizootiology of the diseases caused by these parasites, relatively little is known about the molecular mechanisms involved in the response of oysters to infection. The goal of this project funded by the ODRP is to monitor systematically the induced expression of genes involved in the response of *Crassostrea virginica* to infection by the parasite *Perkinsus marinus*. An mRNA differential display technique coupled with stringent verification assays (reverse Northern blot) will be used to isolate oyster and parasite sequences expressed in a differential manner after challenge of oysters with cultured *P. marinus*. Genes will be cloned and sequenced using standard molecular techniques. The temporal and tissue patterns of expression of the candidate genes in oysters will be studied using Northern blot. Preliminary results from the challenge experiments will be presented at this meeting.

FACTORS AFFECTING THE STRESS RESPONSE IN OYSTERS ON THE WEST COAST: IMPLICATIONS FOR SUMMER MORTALITY.

G. C. Cherr,[1] **C. S. Friedman,**[1] **F. J. Griffin,**[1] **A. Hamdoun,**[1] **J. Mitchell,**[1] **L. Righetti,**[1] **D. P. Cheney,**[2] **R. A. Elston,**[2] and **B. McDonald,**[2] University of California, Davis, Bodega Marine Laboratory, P.O. Box 247, Bodega Bay, CA 94923 and [2]Pacific Shellfish Institute, 120 State Ave. N.E. #142, Olympia, WA 98501.

Summer mortality of *Crassostrea gigas* on the West Coast of the United States is an unpredictable phenomenon of unknown etiology but one that is hypothesized to be caused by multiple stressors. Previous research has identified a dinoflagellate *(Gymnodinium sanguineum)*, temperature, and low dissolved oxygen as possible contributors. We have attempted to delineate the independent effects of two of these suspected factors, phytoplankton and temperature, while conducting parallel field studies in California and Washington to determine the effects of seed stock lineage and seed planting times. Laboratory challenges confirmed that G. *sanguineum* can produce stress/mortality in the absence of other insults. Phytoplankton bloom events have coincided with field mortality; however, the species present were a *Pseudonitzchia*-like species and *Prorocentrum spp.*, not *G. sanguineum*. Previous research on temperature effects showed that the ability of *C. gigas* to tolerate otherwise lethal temperatures occurred after sublethal thermal shock and induction of the heat shock protein 70 (HSP70) family. This is termed the heat shock response (HSR). We have examined the abilities of *C. gigas* from three different habitats (Toten Inlet, WA; Mud Bay, WA; Tomales Bay, CA) to mount a HSR and compared this ability with environmental and summer mortality data. Our current findings suggest that chronic sublethal environmental stressors such as heat and immersion can induce HSP70 expression and acquisition of thermal tolerance in *C. gigas*. However, these chronically stressed animals exhibit a compromised HSR; they do not tolerate post-heat shock temperatures as high as nonchronically stressed counterparts. This research was funded by National Sea Grant College Program Office: Oyster Disease Research Program.

COMMUNITY-BASED OYSTER HABITAT RESTORATION AND ENHANCEMENT IN SOUTH CAROLINA.

N. H. Hadley and **L. D. Coen**, Marine Resources Research Institute, SCDNR, P.O. Box 12559, Charleston, SC 29422.

Oyster reefs provide important habitat for finfish, crabs, and shrimp; improve water quality; and, when located adjacent to *Spartina* marsh, form a natural bulwark to reduce erosion. Oyster habitats nationwide are threatened by adverse effects of coastal development. The majority of oysters in South Carolina occur intertidally, where they may be exposed for as much as 6 h because of the ~2 meter tidal range. This makes them especially vulnerable to physical disturbances such as boat wakes. Substrates in South Carolina are typically soft mud and oyster shell provides one of the few hard surfaces for larval oyster attachment. Oysters readily recruit to shell placed in areas which otherwise may have no recruitment because of lack of suitable substrate. At sites with appropriate characteristics functional oyster reefs may be established in 3 to 5 years, with some attributes beginning earlier. This program will use community volunteers to establish multiple small-scale oyster habitats by planting oyster shell and covering it with stabilizing mesh. We will also develop a volunteer-based monitoring program to evaluate restoration success. Community partners with existing volunteer contacts have been enlisted to assist in this program. An oyster shell-recycling program is being established to generate shell for future restoration projects. Schoolchildren will be involved through collaboration with the Charleston Math and Science Hub to develop classroom and field activities directly related to oyster habitats. Materials (pamphlets, a website, CD) will be developed to educate the public about oyster habitats and shell recycling.

ESSENTIAL OR JUST OPPORTUNISTIC FISH HABITAT? UTILIZATION OF RESTORED COMPLEX SHELLFISH HABITAT BY FISH SPECIES.

J. M. Harding and **R. Mann,** School of Marine Science, Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062.

Shellfish restoration typically creates complex habitat in regions where such habitat is limited or absent. Observations to date suggest that increasing habitat complexity supports more diverse representation in other trophic levels. Such observations have been used to argue for shellfish restoration sites in the wider context of essential fish habitat. We present temporal and spatial data on fish utilization of a cline of habitats from a complex, "restored" site, through a two-dimensional but spatially complex site, to a monotonous sand bottom, and pose the question as to whether fish utilization of this cline suggests "essential" or simply opportunistic utilization of the varying resource.

EFFECTS OF CLIMATE VARIABILITY ON THE PREVALENCE AND INTENSITY OF DERMO AND MSX DISEASES IN EASTERN OYSTER POPULATIONS.

E. E. Hofmann,[1] J. M. Klinck,[1] E. N. Powell,[2] S. E. Ford,[2] S. Jordan,[3] and **E. Burreson,[4]** [1]CCPO, Old Dominion University, Norfolk, VA 23529; [2]Haskin Shellfish Research Laboratory, Rutgers University, Port Norris, NJ 08349; [3]Sarbanes Cooperative Oxford Laboratory, 904 South Morris Street, Oxford, MD 21654; and [4]Virginia Institute of Marine Science, P.O. Box 1346, College Of William and Mary, Gloucester Point, VA 23062.

With previous funding from the National Sea Grant Oyster Disease Research Program, we developed numerical models that simulate the annual cycles of intensity and prevalence of the diseases, Dermo, caused by *Perkinsus marinus,* and MSX, caused by *Haplospordium nelsoni,* in Eastern oyster *(Crassostrea virginica)* populations in Delaware Bay and the upper Chesapeake Bay. The host-parasite models consist of models for the growth of the parasites, as well as a model for the growth and development of the oyster. The external forcing for the models is from time series of temperature, salinity, food supply, and total suspended solids. Our recent project has focused on combining the two disease models with the oyster growth model. Simulations with the combined two disease-oyster model provide insight into the effect of variability in environmental conditions in initiating and controlling epizootics of Dermo and MSX in Chesapeake and Delaware Bays. The combined model also provides a mechanism for investigating possible interactions between Dermo and MSX diseases that modulate the level of intensity and overall prevalence of the two diseases in oyster populations. Initial results suggest that there is only limited interaction between the two diseases in the host and that environmental conditions are the primary determinant of which disease is dominant at a given location, as long as the oysters are susceptible to both disease agents and that the dose of infective particles does not vary.

FIELD TRIAL OF A BAY SCALLOP *(ARGOPECTEN IRRADIANS)* SPAWNER SANCTUARY.

C. Smith,[1] S. Dumais,[1] L. K. Holst,[2] and **M. Davidson,[2]** [1]Cornell Cooperative Extension of Suffolk County, Marine Program, 3059 Sound Avenue, Riverhead, NY 11901 and [2]New York State Department of Environmental Conservation, Division of Fish, Wildlife, and Marine Resources, 205 North Belle Meade Road, East Setauket, NY 11733.

The populations of Bay scallop in New York waters have experienced critical decline over the past two decades, caused in large part by the occurrence of Brown Tide algal blooms and its concomitant effects on habitat and shellfish health. Management efforts in the past have focused heavily on hatchery-produced stock, which has been free planted into the estuary. Frequently, follow-up investigations show no juvenile scallops at the release sites, and the ultimate fate of the seed stock is unknown, except through extrapolation of harvest data. New York State Department of Environmental Conservation, working with Cornell Cooperative Extension's Marine Program, set out to evaluate "spawner sanctuaries" as a management method to ensure that reproducing scallops are present in the system in densities sufficient to increase the population. Mature scallops ($n = 15{,}000$) that had been over wintered in a creek adjacent to Cornell's hatchery were stocked into lantern nets at a density of 100 animals per tier and deployed into Cutchogue Harbor in Peconic Bay, New York. A larval drift model and diver transects were used to calculate relative contribution of the sanctuaries to the 1999 year class set in Cutchogue Harbor. Results were further normalized to reflect differences in gonad weight between wild stock and hatchery-reared scallops.

RESTORING CRITICAL HABITATS IN THE NIGER DELTA FOR SHELLFISH PRODUCTION.

A. C. Ibe[1] and **P. O. Abohweyere,[2]** [1]The Regional Coordination Centre Gef's Large Marine Ecosystem Project for the Gulf of Guinea and [2]United Nations Industrial Development Organization, Nigerian Institute for Oceanography and Marine Research, P.M.B. 12729, Victoria Island, Lagos, Nigeria.

The Niger Delta is a fan-shaped piece of land located between 504'.00 and 7040'.00 longitude and stretching from the Benin River in the west to the Bonny River in the east, covering an area of about 16,340 km^2. This low lying region, riddled with intricate water channels through which the river Niger empties into the sea, consists of three broad ecological zones: freshwater, mangrove, and the coastal sandridges. The mangrove ecosystems are prime areas for production, constituting spawning and nursery grounds for near shore, demersal and pelagic fish species including shellfishes. Shellfish of economic importance found in the Niger Delta include the oyster *Crassostrea gasar* that settles as spat on mangrove aerial roots at intertidal levels, the periwinkles *Tympanotonous fuscatus* and *Pachymelia quadriserata,* and Penaeid shrimps that generate over US $195,977.26 from 10,664 MT annually in foreign exchange. Anthropogenic activities in the form of deforestation, sand mining and nourishment, channelization, dredging, oil and gas exploitation, and rapid urbanization are presently reducing the aerial extent of the mangroves as well as degrading the mangrove environment. This has an impairing effect on the shellfish production potential of critical habitats of the Niger Delta. This work thus advocates rational use of the mangrove ecosystem and reforestation of the mangrove swamp where possible such that one of the goals of the shellfish restoration effort of "restoration or enhancement of populations of commercially exploited shellfish depressed by over-harvesting and or reduced environmental quality" could be achieved in the Niger Delta.

STAKEHOLDER AND CONSENSUS—HOW DO WE MAKE THESE ELEMENTS WORK FOR EFFECTIVE ACTION? **M. Janowicz,** New Brunswick Department of Environment and Local Government, 364 Argyle Street, Fredericton, New Brunswick, E3B 1T9 Canada.

One model for effective stakeholder involvement requires implementation of a consensus decision-making process. This allows each stakeholder to understand the context within which each participant is working and requires the development of respect among the participants. This is an age-old concept but in reality, few in 21st century North America can easily accept and work within it. This article will examine why stakeholder involvement is a necessary means to formulate approaches to shellfish restoration or any other local economic development and planning program. It will explore the foundations of consensus decision-making including examination of concepts of democracy, discussion on Native North American decision-making processes and other decision-making models. And, finally, it will identify some methodology for achieving an effective stakeholder, consensus decision-making process with the emphasis on developing a common ground of understanding.

OYSTER BIOMASS AND ABUNDANCE IN NORTHERN CHESAPEAKE BAY: TRENDS IN RELATIONSHIP TO HARVEST, RECRUITMENT, PARASITIC DISEASES, AND ENVIRONMENTAL VARIATION. **S. J. Jordan, K. N. Greenhawk, C. B. McCollough,** and **M. L. Homer,** Maryland Department of Natural Resources, Sarbanes Cooperative Oxford Laboratory, 9045 S. Morris St., Oxford, MD 21654.

The Chesapeake Bay Program has committed to a 10-fold increase in the Bay's oyster population. Oysters are patchily distributed over about 1,500 km^2 of the Bay floor. Therefore, it is impractical to assess their absolute numbers by direct means. Traditionally, landings data, with their inherent inaccuracies and biases, have been the only means of estimating trends in the population. Maryland's monitoring program records relative numbers and size distributions of oysters annually at 43 fixed sites. By applying a length:weight equation to size-frequency data from this fishery-independent survey, we computed an index of relative biomass that varied from year to year in response to the relative abundance and size distribution of the oyster populations. The index reflects interannual variations in recruitment and growth, as well as mortality caused by the oyster parasites *Haplosporidium nelsoni* and *Perkinsus marinus*. An index of market oyster (>72 mm shell height) biomass had a strong predictive relationship with annual harvests, but an index of sub-market oysters (<72 mm) was not a good predictor of harvests in subsequent years, probably because of high and variable rates of natural mortality due to parasitic diseases. Relative biomass is a sound indicator for measuring progress towards the oyster restoration goal, and has promising applications in fisheries-related stock assessment.

PUBLIC AND PRIVATE OYSTER RESTORATION IN MARYLAND'S CHESAPEAKE BAY. **C. J. Judy** and **E. Campbell,** Maryland Department of Natural Resources, Shellfish Division, 580 Taylor Avenue, Annapolis, MD 21401.

Oyster restoration is a shared venture between government and the private sector. Maryland oyster projects through the 1990s have been a collaboration between state, federal, and private groups. Projects have focused on the creation of oyster sanctuaries to protect broodstock and enhance benthic community diversity, restoration of habitat; and planting of seed oysters, primarily from hatcheries. In round numbers, the acreages for a cooperative project range from a few to over 10 and the number of oysters planted in a year range from about 10 million to over 50 million total. A wide range of participants constitutes the private sector: environmental groups, non-profit oyster restoration groups, community groups, private citizens, watermen and school groups. The number of projects by such groups has risen dramatically since the early 1990s and encompasses types of projects not normally conducted by State agencies alone. Other projects are more uniquely governmental. The long standing Maryland Department of Natural Resource's seed and shell programs plant about 400 acres of seed and 800 acres of shell per year. The number of oysters planted as seed range between 120 million to over 800 million per year. These projects mostly produce market oysters, but environmental and broodstock benefits accrue from such mass plantings. The Federally funded Reef Program conducted by the State restores oyster populations in sanctuaries using shell and seed resources. Together, public and private entities are working toward improving oyster habitat and oyster populations to improve the industry and the ecological role of oysters.

MUSSEL CULTURE AND COCKLE FISHERIES IN THE NETHERLANDS: FINDING A BALANCE BETWEEN ECONOMY AND ECOLOGY. **P. Kamermans** and **A. C. Smaal,** Netherlands Institute For Fisheries Research, Centre for Shellfish Research, P.O. Box 77, 4400 Ab Yerseke, The Netherlands.

In the Netherlands, mussel seed is fished in a coastal sea in the North of the country (Wadden Sea) and cultured in an estuary the

South (Oosterschelde). Dredging for cockles takes place in the Wadden Sea, and two estuaries in the South (Oosterschelde and Western Scheldt). The Wadden Sea and the Oosterschelde are nature reserves where human activities are possible only when they do not cause negative effects. In 1993, a policy was formulated to ensure preservation of bird populations and restoration of mussel banks and seagrass meadows. As a result of this policy, fishing for mussel seed and cockles is not allowed in areas with a high potential for the development of mussel banks and seagrass fields. The location of these areas is based on GIS models. All vessels are equipped with a black box to control the closed areas. There is some debate about the closure because fishermen have the impression that fishing improves the sediment for settling of mussel larvae. Consumption-sized cockles and mussels are also the preferred prey of oystercatchers and eider ducks. Therefore, the policy makes use of a quotum system in the cockle fisheries. Each year, basin-wide surveys take place to determine the total amount of cockles present. In years when cockle stocks are low an amount is reserved for the birds. Both fishermen and environmentalist question the calculated amounts needed by the birds. An overview of the viewpoints of the interest groups and the role of policy makers and scientists is given.

AN ECONOMIC ANALYSIS OF PUBLIC GROUND OYSTER REEF RESTORATION IN CENTRAL LOUISIANA DAMAGED BY HURRICANE ANDREW.

R. J. Dugas,[1] W. R. Keithly,[2] M. Bourgeois,[3] P. Meier,[3] D. Lavergne,[4] and A. Diagne,[4] [1]Louisiana Department of Wildlife and Fisheries, Marine Fisheries Division, 1600 Canal Street, New Orleans, LA 70112; [2]Louisiana State University, Coastal Fisheries Institute, Wetland Resources Building, Baton Rouge, LA 70803-7503; [3]Louisiana Department of Wildlife and Fisheries, Marine Fisheries Division, 1600 Canal Street, New Orleans, LA 70112; and [4]Louisiana Department of Wildlife and Fisheries, Socioeconomic Division, P.O. Box 98000, Baton Rouge, LA 70898-9000.

In August 1992, Hurricane Andrew heavily damaged Louisiana coastal environments, particularly oyster, *Crassostrea virginica,* reef communities. The transport and transfer of tremendous amounts of sediment and vegetative matter resulted in massive oyster mortalities and extensive reef damage. The Louisiana Department of Wildlife and Fisheries received $5.1 million of federal funds for restoration of oyster habitats on both Louisiana public and private oyster grounds. Of these funds, $3.2 million were used in Terrebonne Parish, the area most severely impacted. Restoration efforts were comprised of sweeping buried reefs and depositing cultch material for oyster reef construction. Some 1,780 acres of waterbottoms were swept by commercial oyster harvesters with bag-less oyster dredges. Mined oyster shells/clam, *Rangia,* shell mixture were deposited (at a rate of approximately 132 cubic yards per acre) on 306 acres of waterbottoms in 1994 (42,576 cubic yards) and 553 acres in 1995 (70,902 cubic yards). Economic benefits associated with a restoration effort of this nature accrue to both oyster consumers and oyster producers. To consumers, the benefits reflect a reduction in price paid for the harvested product, which in turn translates to an increase in willingness to pay relative to what was paid (i.e., consumer surplus). To producers, the benefits reflect an increase in returns to the scarce resource, oyster population, used in the production process (i.e., producer surplus). This study provides an estimate of benefits derived from the restoration efforts and compares these benefits to costs. Overall, the results indicate a favorable benefit to cost ratio.

THE REROUTING OF STORMWATER DISCHARGES FOR WETLANDS ENHANCEMENT, LEVEE PROTECTION, AND OYSTER HABITAT PROTECTION AND RESTORATION.

K. E. Landrum,[1] K. M. St. Pé,[1] B. Ache,[2] and F. Kopfler,[3] [1]Barataria-Terrebonne National Estuary Program, P.O. Box 2663, Nicholls State University, Thibodaux, LA 70310; [2]Battelle, 191 East Broad Street, Suite 315, Athens, GA 30601; and [3]Epa/Gulf Of Mexico Program, Stennis Space Center, Building 1103, Room 202, MS 39529-6000.

The Barataria-Terrebonne estuary is losing over 22 square miles of emergent wetlands each year because of erosion, saltwater intrusion, and natural and anthropogenically-induced subsidence. An extensive levee system has successfully halted overbank flooding of the Mississippi River, eliminating sustaining inputs of sediments and freshwater to the Barataria-Terrebonne estuary. This situation represents not only the imminent loss of a nationally significant wetland resource but also threatens a unique culture, local infrastructure, and the region's significant contribution to the national economy. Runoff from rural and agricultural areas is collected in a borrow canal inside the back levee and then pumped into adjacent wetland areas by a series of stormwater pump stations. Over 250 pump stations currently discharge stormwater, draining approximately 500,000 acres, in the Barataria-Terrebonne estuary. These pump discharges are generally directed into large, human-made canals to ensure that stormwater is quickly evacuated from the leveed area and they often flow directly to high-salinity bays through some of Louisiana's prime oyster growing waters. Redirecting discharges so that they are retained in adjacent wetlands may maintain lower local salinities, provide a sediment source to subsiding wetland areas, and support plant growth, directly benefiting the degrading wetland systems, especially those directly seaward of levees that protect property from storm surges and flooding. Retention of storm water may also produce corollary water quality benefits, such as nutrient uptake and pathogen die-off prior to encountering oyster-growing areas. The Barataria-Terrebonne National Estuary Program is leading an effort to monitor changes at pump station sites in the estuary to demonstrate the benefits of this unique process.

THE SHELLFISH CHALLENGE INITIATIVE: A COOPERATIVE SUCCESS STORY IN THE BARATARIA-TERREBONNE NATIONAL ESTUARY. **K. E. Landrum,** Barataria-Terrebonne National Estuary Program, P.O. Box 2663, Nicholls State University, Thibodaux, LA 70310.

The Shellfish Challenge Initiative is an interagency and interstate effort undertaken to establish progress on the Environmental Protection Agency's Gulf of Mexico Program Shellfish Challenge. With an overall goal of increasing Gulf shellfish beds available for safe harvest by ten percent, more than 200 experts in shellfish management, habitat restoration, and pollution control helped develop 32 shellfish restoration strategies targeting 24 watersheds in the Gulf of Mexico. A watershed implementation initiative was developed within the Barataria-Terrebonne National Estuary resulting in the identification of 61 oyster restoration opportunities, including geographically targeted projects to reduce inputs of fecal coliform bacteria, enhance shellfish habitat, revise shellfish management procedures, and collect and analyze additional needed information to better assess project feasibility. The 61 candidate restoration projects were ranked by members of the Barataria-Terrebonne National Estuary Program Management Conference, and detailed implementation plans were developed for the four selected priority projects. The priority projects included the following: the installation and improved use of marina pumpouts and dump stations; connecting poorly operating individual wastewater treatment systems to community level treatment systems; rerouting stormwater runoff to suitable wetlands; and revising the shellfish relay system. Implementation of the four projects is underway with active educational and interactive workshop components designed for state and local officials and the general public. Funding allocations by local and state government attest to their involvement and acceptance of the implementation process and their agreement to promote active stewardship of an economically important resource and conservation principal.

OYSTER POPULATION RESTORATION IN CARAQUET, N.B.; PHASE I, POPULATION ASSESSMENT. **T. Landry, M. Ouellette,** and **P. Cormier,** Department of Fisheries and Oceans, GFC, P.O. Box 5030, Moncton N.B., E1A 4Y1 and Department of Agriculture, Fisheries and Aquaculture, 22 Boul. Saint-Pierre, Caraquet, N.B. E1W 1B6, Canada.

A decrease in the productivity of oysters in Caraquet Bay, N.B. is generating some interest in restoration projects. The first phase of this initiative is to conduct a quantitative assessment of the distribution, abundance and population structure of the natural beds in this bay, which represents the most northern location with a sustainable oyster *(Crassostrea virginica)* population. The results from 1999 assessment is the fifth of a series of similar exercises conducted in 1974, 1979,1987, and 1991 but the first to use a geostatistical approach to data analysis. A comparison between the two assessment methods reveals that the geostatistical approach is more accurate and of greater use for the next phase of this project, which will look at identifying and characterizing the suitable oyster habitat of this bay for restoration efforts. The comparison among the five assessments over the past three decades is showing that the status of this population is approaching a critical state in terms of recruitment and habitat quality and quantity. The restoration of this oyster population is of great socio-economical and ecological importance to this area.

COMMUNITY-BASED INITIATIVES FOR IMPROVING WATER QUALITY IN SOUTHWESTERN NEW BRUNSWICK, CANADA—AN UPDATE ON SUCCESS. **K. L. LeBlanc,** Eastern Charlotte Waterway Inc., 17 Main Street, St. George, New Brunswick, E5c 3h9, Canada.

The Southwestern New Brunswick Clam Resource Committee (CRC) was formed in 1997 to better understand the importance of the soft-shell clam *(Mya arenaria)* fishery and to prevent further loss of shellfish growing areas due to monitoring cutbacks in Southwestern New Brunswick (NB). Soft-shell clams are the main molluscan shellfish harvested in the region. The committee has over 20 stakeholders that include nonprofit groups, industry and government and is chaired by Eastern Charlotte Waterways Inc. (ECW, a nonprofit group). The mandate of the committee is to preserve the clam fishery in Southwestern NB because of its long-term socio-economic importance to the region. In 1998, the CRC developed the Cooperative Bacterial Monitoring Program (CBMP), which allows industry and community-based contributions for the maintenance and improvement of the classification of growing areas. Under this community-based initiative coastal water samples are collected over a 1,500-km length of shoreline over a two-year period. Presently, 67% of the growing areas are available for the harvest of clams in Southwestern NB during all or selected times of the year, an increase of 32% over 3 years. However, it is important to note that clean-up efforts in growing areas coupled with the CBMP are responsible for the improvements of water quality that have permitted an increase in soft-shell clam harvest. The CRC coordinates clean-up efforts through the Fundy Flats Remediations plan, a program managed under ECW.

APPLICATION OF COMMERCIAL-SCALE OYSTER AQUACULTURE TO REEF RESTORATION. **A. T. Leggett, R. Brumbaugh, W. Goldsborough,** and **A. McDonald,** Chesapeake Bay Foundation, 142 W. York Skeet, Suite 318, Norfolk, VA 23510.

Oyster reef restoration projects in the Chesapeake Bay increasingly involve the addition of broodstock to enhance localized oyster spawning activity. Since 1996, more than 4 million adult oysters have been transplanted onto sanctuary reefs in Maryland and Virginia waters. Volunteers and school students have grown and transplanted a significant number of hatchery-produced oysters, in collaboration with state management agencies. In an effort to increase the numbers of hatchery-produced oysters being transplanted onto sanctuary reefs, the Chesapeake Bay Foundation has initiated a commercial-scale grow out operation in the lower York River with a annual production goal of 1 million adult oysters. Oysters produced by this program will approximately double the number of oysters available for transplanting onto sanctuary reefs in the lower Chesapeake Bay each year. A new cage system was developed in accordance with existing regulations in Virginia governing shellfish aquaculture, and was used to maximize the number of oysters produced over a relatively small acreage of leased oyster grounds. Data on growth and mortality as well as water quality parameters are collected as a routine part of the operation. Early monitoring results showed a 78% increase in size (measured volumetrically) of 4–8 mm seed, and a 63% increase in 8–12 mm seed one week after deployment in mid-July. The oysters produced by the operation will not only be used to enhance broodstock populations on sanctuary reefs, but will also be used as "natural capital" to enticing further public and private investment in oyster restoration.

DOLLARS AND SENSE OF OYSTER RESTORATION: AN EXAMINATION OF NITROGEN REMOVAL BY A RESTORED OYSTER REEF.

M. Luckenbach,[1] **F. O'Beirn,**[1] **P. Ross,**[1] **J. Nestlerode,**[2] and **L. Sorabella,**[2] [1]Virginia Institute of Marine Science, College of William and Mary, Wachapreague, VA 23480 and [2]Virginia Institute of Marine Science, College of William And Mary, Gloucester Point, VA 23062.

Arguments for the conservation and restoration of oyster reefs, often at the expense of fisheries exploitation, include water quality benefits derived from feeding activities of the oysters and reef-associated fauna. Yet, there has been limited basis for directly evaluating the water quality improvements associated with conservation or restoration of oyster reefs and for comparing those benefits to the economic value derived from oyster fishery production. Using data from oyster populations developing on experimental reefs near the mouth of Chesapeake Bay, we model the nitrogen uptake and release attributable to the oysters and develop nitrogen budgets for the reefs on an area-normalized basis. We then explore the potential effects of fisheries exploitation of these reefs by modeling the harvest of market-sized oysters and examining the effects on nitrogen removal. Finally, we consider the economic returns from oyster harvesting in relation to the costs associated with alternative nitrogen removal. The results give context to water quality benefits to be derived from oyster reef sanctuaries and should help to guide fisheries management decisions related to balancing conservation and exploitation.

REDUCTION IN THE *VIBRIO VULNIFICUS* LOAD OF OYSTERS BY A NOVEL SHORT-TERM COMBINATION BIODEPURATION TREATMENT.

R. B. Luftig and **W. Pelon,** Department of Microbiology, LSU Health Sciences Center, New Orleans, LA 70112-1393.

Based upon an improved method, *Vibrio vulnificus* phage can be maintained and stored at high titer. Further, mass spectroscopic analysis of Gulf coast oysters, clams and shrimp has shown stimulation of a unique anti-molluscan protein that varies in MW 4 to 22 kd and has anti-*Vibrio vulnificus* activity. When the protein and phage are used together, eradication of *Vibrio vulnificus* occurs to more than 8 logs. Analysis by Edman degradation of the 22-kd oyster protein revealed a unique N-terminal 16 amino acid fragment, as did analysis of two cyanogen bromide gel purified fragments. The proteins were not detected in Japanese or Olympia (Washington) oysters (kindly provided by Dr. C. Kaysner, FDA). Finally, a new rapid assay to study the effect of temperature and brief bacterial exposure has been developed, suggesting the possibility that *Vibrio vulnificus* could undergo a non-culturable state under certain conditions (K. Johnston, pers. comm.). Our intention is to isolate the genes expressing the 4- and 22-kd proteins; then express them in large amounts to use with the specific phage in a biodepuration procedure. This work was supported by SK Grant #NA97FD0062 to RBL from NOAA.

COMING SOON TO A RESTORATION SITE NEAR YOU: THE INVADING, PREDATORY ORIENTAL GASTROPOD *RAPANA VENOSA*.

R. Mann and **J. M. Harding,** School of Marine Science, Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062.

Rapana venosa Valenciennes 1846 (Neogastropoda, formerly Muricidae, currently Thaididae) is a predatory gastropod native to the Sea of Japan, Yellow Sea, East China Sea, Bohai Sea, and Taiwan. The species has been introduced to the Black Sea, Adriatic Sea, and Aegean Sea, where it is generally considered to be responsible for decimation of local commercially valuable mollusc species. It was first reported in the Chesapeake Bay in 1998. Ballast water transport of larval stages from the eastern Mediterranean or Black Sea is the suspected vector of introduction. To date over 1200 specimens of adult *Rapana* have been collected from Hampton Roads and a limited region of the Southern Chesapeake Bay. Population demographics, records of *Rapana* egg cases in the field and our ability to culture early life history stages at prevailing temperature and salinity strongly suggest active breeding in this receptor location. Temperature and salinity tolerance data for *Rapana* suggest that it can both invade the higher salinity regions of most East Coast estuaries and survive on exposed shorelines from Cape Cod, MA to Charleston, SC. Dispersal is facilitated by pelagic development, and may be exacerbated by ballast water transport of larval stages originating in Hampton Roads. Hard substrate habitat, typical of many current shellfish restoration efforts, appears optimal for post settlement stages, but larger adults may invade soft sediments. Predation has been demonstrated on a range of commercially valuable shellfish species including *Mercenaria mercenaria, Crassostrea virginica, Mya arenaria* and *Mytilus edulis.*

UP CLOSE AND PERSONAL: A SUGGESTED QUANTITATIVE APPROACH TO BROODSTOCK ENHANCEMENT ON SHELLFISH RESTORATION SITES. R. Mann, School of Marine Science, Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062.

Shellfish broodstock are typically added to restored habitat to facilitate rapid recruitment by aggregating spawning adults and thus increasing fertilization efficiency. Although this is conceptually attractive there exist few data on which to build quantitative guidelines to optimize the practice. For example, published size versus fecundity relationships for oysters are based on data that has both methodological and size limitations. Similarly, fertilization models are based on sea urchin studies from flow regimes that are arguably quite different from shellfish restoration sites. A quantitative approach is proposed wherein a variety of size-fecundity and fertilization models are proposed for examination in building guidelines to optimize both size and density of placement of shellfish used in broodstock enhancement. The biological and economic aspects of these alternatives are compared.

LINKING PUBLIC AND PRIVATE PARTNERS FOR RESTORATION AQUACULTURE IN MARYLAND'S SEASIDE BAYS. D. W. Webster[1] and D. W. Meritt,[2] [1]University of Maryland, Wye Research & Education Center, PO Box 169, Queenstown MD 21658 and [2]Shellfish Aquaculture Specialist, University of Maryland Center for Environmental Science, Horn Point Lab, Po Box 775, Cambridge, MD 21613.

Traditional harvest of the bard clam (*Mercenaria mercenaria*) in Maryland's seaside bays utilizes the hydraulic escalator dredge. This method has raised concern among environmental groups due to its perceived impact upon eel grass (*Zostera spp.*) in shallow estuarine waters. Meanwhile, an increase in demand for hard clams and strong wholesale prices have caused many clammers who normally harvest softshell clams (*Mya arenaria*) in the Chesapeake Bay to shift harvest to the seaside bays, placing increasing pressure on that area. Hard clam aquaculture is well known and may provide an alternative to harvesters, who will likely come under increasingly restrictive regulations. Differences in culture methods for the clam have evolved in many states to take advantage of local conditions. In Maryland, the clam aquaculture industry has only recently begun, with few persons currently investing in the technology to produce these animals through husbandry. During 1998, investigations were begun with cooperation from university and private companies to develop seed production and evaluate grow out techniques. The Maryland Industrial Partnership (MIPS) program has funded development of a hard clam nursery/grow out operation. University of Maryland Sea Grant Program (UMSG) funded a survey of the hard clam disease QPX to assess background levels of this potential problem. University of Maryland Cooperative Extension (UMCE) funded an extension project to assess grow out techniques, as well as conduct outreach educational programs designed to bring the technology to those who can use it. These cooperative studies are described as well as future directions for the project.

PRODUCTION OF DISEASE-FREE OYSTER SEED USING SHALLOW WATER NURSERIES IN THE MID-CHESAPEAKE BAY. D. W. Meritt and S. Tobash, University of Maryland, Center for Environmental Science, Horn Point Laboratory, Po Box 775, Cambridge, MD 21613.

Recently in Maryland, there has been an emphasis on the production of disease-free oyster spat for use in oyster restoration. Spat produced using traditional methods utilize sites where oyster parasites are common and are typically infected at the time of relay to the grow-out site. As part of the Action Plan for Oyster Recovery in Maryland, the Maryland Oyster Roundtable established oyster recovery zones in several major tributaries of Chesapeake Bay into which only disease-free oysters can be introduced. Given the problem with producing disease-free oyster seed using natural methods, hatcheries have been employed for disease-free seed production. Since 1994, the University of Maryland's Horn Point hatchery has produced over 90 broods of spat using in-water nursery systems. Dermo, the disease caused by the parasite *Perkinsus marinus,* is of greatest concern in these systems due to low salinities. Only one brood of spat has tested positive for Dermo since 1994. Based on trials conducted over the past six years, we have demonstrated that it is not only possible but also likely that uninfected oyster seed can be produced using hatcheries and shallow-water nursery systems. Disease-free seed are being used to test the idea that by prohibiting the movement of parasites into upstream portions of the oyster producing rivers, dermo will be naturally purged from oyster populations in those regions. Early data suggest that there is some validity to this concept.

A MULTIFACTORIAL APPROACH FOR DESCRIBING THE RELATIONSHIP BETWEEN THE CLASSIFICATION OF SHELLFISH HARVESTING WATERS AND ADJACENT LAND USE IN MURRELLS AND NORTH INLET, SOUTH CAROLINA. K. A. Nelson and G. I. Scott, National Ocean Service, 218 Fort Johnson Road, Charleston, SC 29412.

Urbanization poses a particular threat to the coastal areas of the southeastern United State, where the lands surrounding the wetlands are still relatively undeveloped compared with other regions. Fecal coliforms, including *Escherichia coli,* are important indicators of public health since human and/or animal feces may come in contact with and contaminate drinking water supplies or filter-feeding shellfish. The measurement of the concentration of fecal coliforms is the current criterion for deciding when and if shellfish harvesting should be approved. Predictive models that would correlate information on land use change and development would be useful so that downgrades in water quality can be predicted before they occur. The approach used for this study involved an historical comparison of land use change and fecal coliform bacterial densities on Murrells Inlet (MI) (urbanized site) and North Inlet (NI) (pristine site). Both MI and NI are bar-built estuaries are located on the northern coast of South Carolina near Myrtle Beach. The microbiological and water quality data used in this research covers the period of 1967–1995 and the following parameters were utilized: date of sampling, most probable number of fecal coliform bacteria, salinity, rainfall, and water temperature. The regressions models utilized the above parameters and a change in trend term that accounted for both instantaneous and gradual changes in water quality that may arise from a particular intervention. For MI, the 1980 intervention consisted of both the construction of a jetty and the conversion from septic tanks to a main sewer line. For NI, the 1973 intervention was the construction of Baruch Laboratory. For MI, the intervention, controlling for other parameters, was found to be significant at the alpha = 0.05 level. This means that there was a significant decrease in the increasing trend of bacteria for MI and that the conversion to the sewage line had a beneficial effect on water quality and probably dominated the jetty effect. For NI, the laboratory construction had no impact on water quality so background natural sources of bacteria probably dominated the small increase from human sources. These findings indicate that the use of Intervention Analysis may provide coastal managers with an effective process to evaluate landscape changes on bacterial water quality in shellfish harvesting areas.

INFLUENCE OF OYSTER REEF STRUCTURE ON FISH ASSEMBLAGES: DOES THE PLACEMENT OF ARTIFICIAL SUBSTRATE ENHANCE FISH POPULATIONS? **J. A. Nestlerode,[1] M. W. Luckenbach,[2] P. G. Ross,[2]** and **F. X. O'Beirn,[2]** [1]Virginia Institute of Marine Science, College of William & Mary, Gloucester Point, VA 23062, [2]Virginia Institute of Marine Science, College of William & Mary, Wachapreague, VA 23480.

The objectives of oyster reef habitat restoration within Chesapeake Bay are not only the enhancement of oyster stocks but also to restore the physical structure and ecological function of these systems. We revisit the artificial reef fisheries attraction vs. production issue by comparing transient nekton community structure among reef structures constructed of different substrates. The substrate materials (oyster shell, surf clam shell, and pelletized coal ash) used in this study offer the opportunity to examine how habitats with various degrees of structural complexity contribute to differences in habitat use in terms of microhabitat availability, predation risk, and diversity and abundance of prey. Results indicate that oyster shell reefs, which have best supported the development of an oyster population, offer the highest degree of structural complexity and support a more diverse community of both resident and transient nekton. Furthermore, increased availability of nesting sites (empty articulated oyster shells) and a high abundance of benthic prey items support the thesis of increased fish production rather than simply attracting fish to the reef structure from nearby habitats. The patterns observed here provide evidence that proper reef architecture and subsequent reef community development lead to increased finfish production and should give context to the importance of substrate selection in similar restoration activities.

SHELLFISH RESTORATION IN IRELAND: THE NEED FOR NOVEL PARTNERSHIPS. **M. Norman,** Taighde Mara Teoranta (Marine Research Limited), Carna Co., Galway Ireland.

Historically shellfish restoration projects in Ireland have been undertaken for a singular reason and driven by a single user group. Frequently, the goal has been increased commercial production of shellfish, and the restoration has been pursued by a grouping of fishermen or aquaculturists. These projects have a narrowly defined objective, profitability, and frequently "fail" when they do not achieve this. However, some recent restoration attempts have been performed by partnerships. These projects are driven by multiple user groups and thus have a range of goals. It is postulated that this partnership approach has more chance of success as the partners support each other in "staying the course" and as the goals are broader, making success more achievable.

REPRODUCTIVE BIOLOGY OF THE NORTHERN QUAHAUG, *MERCENARIA MERCENARIA*, IN PRINCE EDWARD ISLAND, CANADA. **M. Ouellette, M. Hardy, T. Landry, N. G. MacNair,** and **A. Boghen,** Department of Fisheries and Oceans, Science Branch, Gulf Fisheries Centre, P.O. Box 5030, Moncton, New Brunswick, E1C 9B6; Department De Biologie, Universite De Moncton, Moncton, Nouveau-Brunswick, E1A 3E9; and Department of Fisheries and Tourism, PO Box 2000, Charlottetown, Prince Edward Island, C1A 7N8, Canada.

The northern quahaug, *Mercenaria mercenaria*, is an important species for both the commercial and recreational fisheries as well as for aquaculture purposes in Prince Edward Island. The management strategy of the quahaug resource is largely based on the minimum legal size of 50 mm. At the same time, there is a growing concern regarding the sustainability of the clam industry and hence, an evolving interest in stock enhancement. Effective broodstock management, however, requires basic information about the animal's reproductive biology. Sexual maturity, ovocyte size, gonado-somatic ratios, and time of spawning were established for quahaugs sampled from two sites in West River, PEI. Histological methods and physiological condition indices are used to determine of the spawning activities. Findings revealed that the minimum size at sexual maturity was 25 mm and 30 mm (shell length) for males and females respectively. Furthermore, there was a positive correlation between ovocyte size and shell length. Seasonal variation coincided with spawning predictions based on conventional physiological condition indices. As well, the gonado-somatic contribution increased as a function of length. Both histological and condition index data support the likelihood that a major spawn occurs in mid-June. The study provides useful information on the reproductive biology of *M. mercenaria* and could contribute towards a reassessment of existing management and grow-out strategies. Establishment of reproductive sanctuaries is also being investigated as a method to increase the annual recruitment success in this study bay.

CONSIDERATIONS FOR OYSTER RESTORATION IN MARYLAND: DISEASE, GENETICS, DENSITY, REPRODUCTION, AND HABITAT CREATION. **K. R. Paynter, Jr.,** Department of Biology, University of Maryland, College Park, MD 20742.

Over the last 2 years, we have conducted numerous experiments and monitored several State and Federally funded restoration projects in the Maryland portion of Chesapeake Bay. A summary of the results of these activities will be presented. Field experiments have revealed that oyster seed cohorts from different broodstocks appear to have differing resistances to disease. Videographic observations from the field have shown that high-density oyster plantings result in significant community enhancement leading to diverse benthic ecosystems. Laboratory studies have shown that benthic fishes such as gobies and blennies prefer natural clumps of oyster shell compared to equal volumes of loose oyster shell. In addition, other laboratory studies have shown that eggs introduced into the water column more than a few centimeters from introduced sperm will have little chance of becoming fertilized. However, other studies have shown that high densities of oysters ($>400/m^2$) may result in deleterious effects on oysters themselves. Many aspects of oysters and their ecosystem must be considered when planning restoration projects. Those projects seeking to restore ecological function should bear in mind the complex relationships between oysters, the habitat they create as biogenic reef builders, and the water column in which they reside.

CULTURE TECHNIQUES APPLIED TO WILD BIVALVE BEDS IN GALICIA, NW SPAIN. **P. J. Pazo,** Delegación Territorial Conselleria De Pesca C/ Palma 4. 36202 Vigo Spain.

The region of Galicia is located in NW Spain. It has a coastline of 1,195 km. Galicia is the first producer of molluscs in Spain, taking advantage of natural oceanographic conditions: a seasonal upwelling and existence of positive estuary bays (Rias). Molluscs have been exploited in Galicia since prehistoric times. The present shellfishing situation is developed in two ways: the gathering of molluscs on foot, raking the substratum for macroinfaunal bivalves in the intertidal belt. The other type of shellfishing exploits the subtidal molluscs beds and involves the use of small boats. In order to maintain and enhance bivalve production in intertidal wild beds, a series of culture techniques are applied, acting on the bivalve population (lowering high densities, enlarging area beds, sowing and repopulating new areas), fighting against predators and competitors (starfishes, drilling gastropods), removing green algae of the bed surface to avoid deleterious effects in young bivalves, changing substrate granulometry by adding coarse sand to areas with mud and silt condition, and by other means. To act on the recruitment problems of two very valued species: butterfish clam (*Ruditapes decussata*) and European flat oyster (*Ostrea edulis*), a plan was established by the Fisheries Department of Galician Regional Government: "Plan Galicia". This Plan began in 1997 and was aimed to gradually transform traditional intertidal shellfish gathering into a professional activity by enhancing both the intertidal wild molluscan beds and the social organization of the mainly female population of shellfish gatherers. This Plan is presently developing and relevant achievements are being achieved, mainly in the social area.

THE INFLUENCE OF ENVIRONMENTAL FACTORS IN JAPANESE OYSTERS HEALTH CONDITION CULTIVATED IN THE SOUTH OF PORTUGAL. **A. L. Pereira,[1] F. A. Ruano,[1] L. Chicharo,[2] and D. Matias,[3]** [1]IPIMAR, Research Institute for Fisheries and Sea, Av. De Brasilia 1449-006 Lisbon, Portugal; [2]UCTRA, Algarve University, Campus De Gambelas, 8000-062 Faro, Portugal; and [3]CRIPsul, South Research Center of Ipimar, Av. 5 De Outubro, 8500 Olhao, Portugal.

The effect of environmental parameters as well as the organic contamination, heavy metals and tributytlin (TBT) upon the development of diseases in cultivated Japanese oysters *Crassostrea gigas* (Thunberg, 1793) was studied over 6 months. The results were also related with the condition index, growth and mortality rates. The study was performed in two different sites on a coastal lagoon in the South of Portugal. One site ("Elisamar") is located in a clean area whereas the other (Olhao), due to its proximity to urban areas and to an important fishing harbour, is exposed to higher contamination levels. In Olhao, nosological examinations showed the higher levels of lesions and the greatest incidence of parasites. Two ciliates, *Ancistrum* sp. and *Trichodina* sp., were the most abundant at the two areas. The intensity of the infections and the lesional picture observed at the two sites, didn't seem to affect significantly the condition, growth and mortality of the studied animals. However, the differences in the infection intensity registered in both sites could be an indicator of a lack of defensive response from the individuals submitted to more intense stressful conditions.

THE "EEEOHM" (EASTFIELDS' ENVIRONMENT ENHANCING OYSTER HOLDING MODULE). **P. Perina** and **D. Perina,** Eastfields Farms, Box 275, Mathews, VA 23109.

The "EEEOHM" (Eastfields' Environment Enhancing Oyster Holding Module) was originally developed to be used commercially, but the system is extremely versatile and is adaptable to a small garden size operation. The emphasis in developing the EEEOHM was on "Keep It Simple, Keep It Cheap." The EEEOHM module consists of three ADPI square-sided oyster cages (also called bags). Each cage has attached four 2-liter soda bottles for flotation. The cages are strung together with a 13-foot piece of crab pot rope or clothes line running laterally through their centers. The modules can also be separated into single floats as the needs of the grower dictate. The reason for using just three cages per module is simply "ease of handling". Whether employing the system from a dock or a skiff, it's a lot easier to detach and lift just three cages at a time than to struggle with maybe 40 or more cages all attached to a single rope. No heavy lifting. The EEEOHM can be floated under or along side of a dock, tied between posts, or deployed in rows secured to two parallel ropes anchored to the bottom at each end. The latter usually requires the use of a skiff. During the last 14 years, we at Eastfields have tried many ways of growing oysters. We've found the EEEOHM to be one of the most efficient and cost effective systems of off bottom culture. The ADPI cages last for many years, and the soda bottles are free. We at Eastfields Farms are proud to have developed the EEEOHM and would appreciate the opportunity to answer any questions concerning this environment enhancing system.

A BIOCHEMICALLY-BASED MODEL OF THE GROWTH AND DEVELOPMENT OF *CRASSOSTREA GIGAS* LARVAE. E. A. Bochenek,[1] E. N. Powell,[1] J. M. Klinck,[2] and E. E. Hofmann,[2] [1]Haskin Shellfish Research Laboratory, Rutgers University, Port Norris, NJ 08349 and [2]CCPO, Old Dominion University, Norfolk, VA 23529.

A biochemically-based model was developed to simulate the growth, development, and metamorphosis of larvae of the Pacific oyster, *Crassostrea gigas*. This model, which is the first of its type, defines larvae in terms of their gross biochemical composition: protein, neutral lipid, polar lipid, carbohydrate, and ash content. The model includes parameterizations for larval filtration, ingestion, and respiration, which determine growth rate, and processes controlling larval mortality and metamorphosis. Changes in the initial ratios of protein, carbohydrate, neutral lipid, and polar lipid occur as the larva grows and in response to the biochemical composition of available food. The model results show increased larval survival when low protein food sources are available. High-protein food sources result in insufficient carbohydrate and neutral lipid to cover metabolic costs and to permit successful metamorphosis. The result is larvae that are unable to successfully complete metamorphosis. Thus, food quality as well as food quantity appear to be primary controls on the ability of *Crassostrea gigas* larvae to reach the body condition needed for metamorphosis. Other simulations show that initial egg size (lipid content) controls the ability of the larva to sustain itself until it reaches a size where it can effectively filter and assimilate food. Large eggs produce larvae that are more able to withstand food-poor environments, suggesting that egg size variability may account for the range of larval sizes at which metamorphosis is attempted.

A FISHERIES MODEL FOR MANAGING THE OYSTER FISHERY DURING TIMES OF DISEASE. J. M. Klinck,[1] E. N. Powell,[2] J. N. Kraeuter,[2] and S. E. Ford,[2] [1]CCPO, Old Dominion University, Norfolk, Virginia 23529 and [2]Haskin Shellfish Research Laboratory, Rutgers University, Port Norris, NJ 08349.

In Delaware Bay, market-size oysters have been produced by moving oysters from the seedbeds to planted grounds in higher salinity, where oysters increased in size and meat condition. In 1989, the oyster disease Dermo became active on the planted grounds and lower seedbeds. The increase in disease reduced the desirability (loss of shell resource from seed areas) and profitability (high mortality) for moving oysters into higher salinity areas. As such, oyster production has focused on two production schemes: (1) direct harvest of oysters produced on the lower seedbeds, essentially a wild fishery and (2) the transplantation of oysters from the mid-estuary seed beds to the lower estuary seedbeds. Transplanted oysters are then harvested after the meat condition improves. One of the consequences of these approaches is the need to estimate the allowable production from the seedbeds each year, which is equivalent to setting a yearly quota. It seems clear that present oyster populations are below pre-disease levels, and that continued high disease levels will prevent recovery to pre-disease levels. The presentation describes a model developed for the management of fished oyster populations that lie over a salinity gradient and for which disease mortality is a controlling influence. We will present a review of the Delaware Bay stock assessment for 1998 and 1999. We will then describe a model developed to address management issues when B_{msy} and K are not appropriate options and apply it to Delaware Bay oyster populations.

SHELLFISH DATA MANAGEMENT AND REPORTING SYSTEM (SDMRS). J. Power[1] and D. B. Walker,[2] [1]Environment Canada, 224 West Esplanade, North Vancouver, British Columbia, V7M 3H7, Canada, and [2]E-Carta Services, 419 N 18th Ave. E, Duluth, MN 55812-1352.

The objective of this work was to design a user-friendly interface to digital watershed maps and hydrographic charts, thematic layers such as clam harvesting areas, farms, shellfish leases, and closures, and databases relating to pollution sources, water quality sampling, shellfish growing areas, locations of marine mammals and seabirds, fish farms and weather, for Canada's West Coast. Such an interface will allow scientists in the shellfish program of Environment Canada, Pacific and Yukon Region to readily generate data reports including maps detailing shellfish closures and shoreline assessments. The Shellfish Data Management and Reporting System (SDMRS) is an ArcView GIS application linked to an Access database, which requires no special knowledge of SQL queries of databases or GIS. From ArcView the user chooses the sector to be mapped and the additional area around the sector to display map information from drop down menus. The system then generates the appropriate base map by clipping out the underlying hydrographic charts and/or watershed maps. Then the user selects the themes and data sets to add to the map, again by choosing from drop down menus. The system adds the themes, uses ODBC to query the database and retrieve the appropriate data sets, converts them to the proper projection, and adds them to the map. When completed the map is then exported to the report document.

RESTORING OYSTER REEFS FOR FISH: ESTIMATING ENHANCED SECONDARY PRODUCTION OF RESTORED OYSTER REEFS.

S. P. Powers, C. H. Peterson, and **J. H. Grabowski,** Institute of Marine Sciences, University of North Carolina at Chapel Hill, 3431 Arendell Street. Morehead City. NC 28557.

The recognition that oyster reefs provide an important resource, but also provide habitat for a variety of other species, has encouraged restoration of oyster reefs as a method to enhance production of finfish and shellfish within estuaries. Here, we describe an approach for determining the augmented secondary production of bottom areas that were sand/mud flats and restored to oyster reefs. First, through a review of published and unpublished studies, we compared densities of animals on oyster reefs to nearby areas without biogenic structure. We divided those species that showed enhanced densities on reefs into three groups: (1) species that recruited exclusively to reefs, (2) species that had higher recruitment to reefs, but still recruited and used non-structured habitats, and (3) species that showed higher aggregations around reefs, but were not limited by reef habitat based on diet and life-history analyses. For this first group, all production is attributed to the reef. Because some proportion of the enhanced density of species belonging to this second group would probably have recruited to other habitat, the production attributed to the reef is adjusted by a coefficient of reef-habitat exclusivity (CRE) that we developed using diet analysis and life history information. For the final group of animals, the reef only receives credit for that fraction of growth that is enhanced by the presence of the reef, this determination is made through the application of a CRE. Applying this approach to proposed oyster reef restoration in Tampa Bay, FL, we estimated the augmented secondary production of 10 m^2 of oyster reef to be 2.57 kg y^{-1}.

RESTORING THE LITTLENECK CLAM RESOURCE FOR NATIVE AMERICAN SUBSISTENCE USE IN THE PRINCE WILLIAM SOUND, ALASKA.

R. RaLonde, University of Alaska, School of Fisheries and Ocean Sciences, Anchorage, AK 99508-4140.

Natural and man caused disasters decimated the littleneck clam (*Protothaca staminea*) populations on the intertidal beaches of Prince William Sound. Alaska. Subsequently, Native American Villages have been unable to harvest clams to meet their subsistence needs. Since 1995, the Quteckak Native Corporation has been actively pursuing restoration of the clam populations by developing seed production technology, conducting site selection studies, and managing growout trials. The initial success of their restoration efforts now enables communities to harvest clams from the restored beaches and broaden the program. This presentation will describe the research and restoration results of the project and the human impact of the restored resource on the Native Villages of Prince William Sound, Alaska.

DEVELOPMENT OF *CRASSOSTREA VIRGINICA* MICROSATELLITE MARKERS FOR A GENETIC LINKAGE MAP AND GENETIC MONITORING OF RESTORATION PROJECTS.

K. M. Reece, W. L. Ribeiro, K. L. Hudson, and **S. K. Allen Jr.,** Virginia Institute of Marine Science, The College of William and Mary, Gloucester Point, VA 23062.

Dermo and MSX have had significant impacts on natural populations of the eastern oyster *Crassostrea virginica* and have been a detriment to oyster aquaculture development. A potential solution to this problem is genetically improved disease-resistant strains of *C. virginica* that can grow to market size despite disease challenge. Traditional selective breeding programs have resulted in strains of oysters that are being assessed for disease resistance. One means of accelerating selective breeding programs is to identify genetic markers associated with traits such as disease resistance or growth rate. A goal of this project is to develop genetic markers for constructing a linkage map and to identify markers associated with disease resistance to use in marker-assisted selection programs. In addition, markers developed in the genomics project are being surveyed for use in genetic monitoring of reef restoration projects. To assess relative genetic contributions of wild and planted stocks to restored reefs; markers are being identified that are able to genetically distinguish selected strains and natural populations in Chesapeake Bay. *C. virginica* microsatellite markers are being developed in an ODRP funded genome mapping project. Several di-, tri-, and tetranucleotide repeat sequences have been identified. Primers for use in the polymerase chain reaction have been designed to anneal to regions flanking 39 microsatellites and amplification reactions for 21 loci have been optimized. F1 individuals from four reference families have been screened at twelve microsatellite loci for generating a genetic linkage map. Microsatellite allelic profiles of selected strains and natural populations are being examined.

OYSTER REEF RESTORATION RESEARCH IN MOBILE BAY, ALABAMA.

D. B. Rouse,[1] **R. K. Wallace,**[2] and **F. S. Rikard,**[2] [1]Department of Fisheries and Allied Aquacultures, Auburn University, Auburn, AL 36849 and [2]Mobile, AL 36615.

Oyster reef restoration in Mobile Bay has consisted primarily of shell planting on active reefs in the lower sections of the bay.

Efforts are now underway to restore reefs in the mid-bay area. Studies are being conducted to determine why these reefs are no longer productive and what should be done to restore them to a productive state. Bottom surveys were performed to quantify cultch availability. Sediment traps were deployed to determine rates of sediment accretion and spat collectors were used to evaluate natural oyster set. Spat were deployed on the bottom and on platforms 20 cm and 40 cm above bottom. Data loggers were deployed on bottom and 40 cm above bottom to measure temperature, salinity and oxygen concentration. Surveys revealed hard bottoms but little exposed cultch on non-productive reefs. Sedimentation was high and consisted mainly of silt with more than 10% organic matter. Single peak oyster sets occurred in the fall. Oysters at the three experimental levels grew to approximately 60 mm in the first year. During the second year, total mortality was observed at all three levels when oxygen levels dropped to 0 mg/L for 5 consecutive days. Similar periodic low oxygen events may be occurring at the study site and on other relic reefs that will hinder their successful restoration. Water quality studies suggest that cultch mounding will be necessary to elevate oysters above anoxic bottom conditions.

TRANSPLANTING BROODSTOCK OYSTERS, *CRASSOSTREA VIRGINICA*, ONTO RECONSTRUCTED OYSTER REEFS TO INCREASE SPAT RECRUITMENT IN THE PIANKATANK RIVER. **D. C. Sherwood,** Sandston, VA 23150.

Virginia oyster reef restoration in the form of three-dimensional structures began in the Piankatank River, Virginia in 1993. From 1993 to 1998, fifteen artificial reefs were built in tributaries of the Chesapeake Bay. In December 1996, reproductively active broodstock oyster from Tangier and Pocomoke Sounds were transplanted to the Shell Bar reef in the Great Wicomico River, Virginia. Surveys in the fall of 1997 indicated a high spat recruitment both on the reefs and nearby oyster bars. With this success, broodstock oysters from Tangier and Pocomoke Sounds were transplanted in December 1997 to two of the four reconstructed reefs in the Piankatank River. Since total quantity as well as density of broodstock was believed to be limiting factors for recruitment in this river, adding stock was expected to raise spat recruitment. Spat recruitment data was collected via dive surveys on the reefs, and via dredge and patent tong surveys on the natural oyster bars. The recruitment of spat to both reefs and bars was significantly higher in 1998 ($P < 0.001$) than in the previous four years and a positive interaction ($P < 0.005$) was seen between the reefs and the year 1998. Based on these data, stock enhancements in the Piankatank River successfully improved recruitment and suggest oyster restoration may be facilitated in other areas of the Chesapeake Bay by strategic enhancement of spawning stocks.

HARMFUL ALGAL BLOOMS AND SHELLFISH RESTORATION: CAN THEY CO-EXIST? **S. E. Shumway,** Department of Marine Sciences, University of Connecticut, 1080 Shennecossett Road, Groton, CT 06340

Habitat quality is an obvious and important consideration for all shellfish restoration efforts including aquaculture and reseeding. Harmful algal blooms (HABs), worldwide threats to habitat quality, are naturally occurring phenomena and their number and frequency are increasing. These blooms impact ecosystem integrity, species interactions, aquatic animal health, population growth, human health, economy, industry, and ecology and often pose a threat to wild and cultured shellfish populations. While algal species that impact human health receive the most attention, there are numerous HABs that cause the destruction and demise of shellfish beds and aquaculture operations. These HABs can also dictate the successful citing of restoration efforts. This presentation will review our knowledge of harmful algal-shellfish interactions worldwide including threats associated with the presence of recently identified problem species, e.g., *Pfiesteria* spp. and *Heterocapsa*, and discuss ways in which shellfish restoration efforts may be undertaken successfully in the face of these imposing threats. Mitigation of these HABs has become an important focus for coastal research. Data will be presented on recent studies on the use of clay as a means of alleviating the impacts of HABs. Careful management-science interaction, not eradication, remains the only safe and functional means of mitigation currently available.

A COMPARISON OF TWO OYSTER (*CRASSOSTREA VIRGINICA*) STRAINS FOR PRODUCTIVITY AND SUITABILITY FOR USE IN OYSTER REEF RESTORATION EFFORTS. **L. A. Sorabella,**[1] **M. W. Luckenbach,**[2] and **F. X. O'Beirn,**[2] Virginia Institute of Marine Science, College of William and Mary, P.O. Box 1346, Gloucester Point, VA 23062, Virginia Institute of Marine Science, College of William and Mary, P.O. Box 350, Wachapreague, VA 23480.

Over the past 5 years, eastern oyster (*Crassostrea virginica*) restoration efforts in Virginia have focused on constructing reef structures to act as sanctuaries. Increasingly, shell plants are stocked with hatchery-produced brood stock oysters that spawn and increase recruitment to the reefs. This involves rearing hatchery-produced seed oysters in floating containers and out-planting them onto reefs when they reach an appropriate size (20–30 mm). To assist with the labor involved in this process, we recruited citizen and student oyster-gardeners who raised the bulk of the oysters for transplant onto the sanctuaries. Two strains were hatchery-reared for transplantation onto these reefs: CROSBreed oysters and wild-caught oysters from the lower Chesapeake Bay. The CROSBreed strain has been selectively bred since 1962 for resistance to the parasite Haplosporiduium nelsoni that causes MSX, and has more recently been bred for resistance to Perkinsus marinus, that causes Dermo. The second strain were large wild-caught oysters collected from the Lynnhaven River (Chesapeake Bay, VA) where the oysters were surviving under presumed high pressure from both parasites. The objective of this research is to evaluate the performance of the CROSBreed stock and wild stock oysters deployed on sanctuary reefs in the Lafayette River (Chesapeake Bay, VA). Evaluation compares the two strains based on female fecundity, growth, survival, and incidence of Perkinsus marinus and Haplosporiduium nelsoni infection measurements. As large-scale restoration projects proceed, it will be fundamentally important to assess which stock is most appropriate for use in the oyster restoration effort.

OYSTER RESTORATION AND THE UNIVERSITY OF MARYLAND: INTERACTIONS BETWEEN RESEARCH, INDUSTRY, AND THE PUBLIC.

S. M. Tobash and **D. W. Meritt**, University of Maryland, Center for Environmental Science, Horn Point Laboratory, PO Box 775, Cambridge, MD 21613.

Maryland oyster populations have been declining for many years. The University of Maryland is committed in its involvement to assist in restoration programs, placing an emphasis on the ecological contribution that oysters provide to the overall health of the Chesapeake Bay. Research efforts are focused on diseases, genetics, culturing techniques and basic oyster biology and ecology. The efforts of the Maryland Oyster Recovery Partnership and other concerned groups, along with increasing public involvement has enabled the oyster hatchery at the University of Maryland Center for Environmental Science Horn Point Laboratory to increase production of disease-free hatchery seed. These seed oysters are then used in a variety of restoration, education, and outreach activities statewide. Educational programs are targeted to a wide audience, ranging from nonprofit organizations of school-aged children to commercial watermen. Outreach projects promote the involvement of concerned citizens like the Chesapeake Bay Foundation's Oyster Gardening Program. Cooperation between commercial fishermen, management agencies, and concerned groups and combination of resources are key to a successful restoration program. The University of Maryland represents an important link in this process. The ongoing commitment of UMCES Horn Point Laboratory together with cooperative programs will continue to strengthen the future of the Chesapeake Bay oyster restoration effort.

EFFECTS OF WATERSHED ALTERATIONS ON OYSTER POPULATIONS IN SOUTHWEST FLORIDA ESTUARIES: AN ECOLOGICAL APPROACH.

A. K. Volety, **M. Savarese**, and **S. G. Tolley**, College of Arts and Science, Florida Gulf Coast University, 10501 Fgcu Boulevard South, Fort Myers, FL 33965.

Southwest Florida is one of the country's fastest growing regions. Consequently, watersheds are heavily managed to accommodate development. Studies on the effects of altered watershed in this region involving valued ecosystem components, like oysters, are lacking, but clearly necessary. Using the oyster, *Crassostrea virginica*, as an indicator species, we are investigating ecosystem-wide health effects of watershed management practices in altered (Faka-Union, Henderson Creek, and Caloosahatchee River) and pristine (Blackwater River) estuaries. Measurements of oyster spatial distribution, condition index, spat recruitment, energy reserves, and disease prevalence of *Perkinsus marinus* are underway using a "spatial homologue approach" (among-estuary comparisons at hydrologically and geomorphically similar locations along the salinity gradient). Preliminary results indicate that in summer months, depending on the location, mean prevalence of P. *marinus* infection in oysters varied between 33–73%, whereas the mean condition index varied between 2.4–4.7. The distribution of reefs, regions of maximum living density, and maximum oyster productivity are shifted seaward in altered relative to pristine systems when water management practices are supplying excessive freshwater to estuaries. These populations, however, exhibit lower *P. marinus* prevalence because of the greater freshwater influence. This project represents the first study of watershed alteration on oysters in Southwest Florida and will help provide target environmental conditions for restoration efforts.

THE VIRGINIA OYSTER HERITAGE PROGRAM.

J. A. Wesson[1] and **L. B. McKay**,[2] [1]Virginia Marine Resources Commission, 2600 Washington Ave., 3rd Floor, Newport News, VA 23607-0756 and [2]Virginia Department of Environmental Quality, 629 E. Main St., Richmond, VA 23219.

The Virginia Oyster Heritage Program (VOHP) is a bold initiative to capitalize on recent advances and consensus on strategies for oyster restoration. The VOHP seeks to restore oyster populations and oyster reef habitat, and to, thereby, improve ecological function, water quality and the oyster industry in Virginia's portion of Chesapeake Bay and its seaside bays. Initiated in 1999 by the Department of Environmental Quality and Marine Resources Commission, the VOHP is a partnership of Federal, State, and private entities. Phase One focuses on the Lower Rappahannock River, with a goal of rebuilding 8 to 10, three-dimensional, oyster sanctuary reefs and restoration of more than 200 acres of oyster beds for direct harvest. The combination of funding from all sources totaled more than $1,500,000 in the first year, resulting in six reefs constructed, and 85 acres of harvest area restored. The Lower Rappahannock River, closed to harvest for six years, is an area of high salinity with consistent exposure to oyster diseases. Annual monitoring during this closure demonstrated that a significant proportion of the native oysters survived and grew, and that spatset became dependable. We believe that the lack of cultch has limited the increase in oyster populations and that enough natural broodstock has accumulated to colonize these restored areas. With proper management of sanctuary and harvest areas, we also believe that a sustainable fishery can be established while simultaneously increasing the standing stock of oysters. We anticipate comparable funding in 2001, and the expansion of this model into other areas.

ENHANCING AND SUSTAINING NORTH SHORE SHELLFISHING THROUGH AQUACULTURE. **J. J. Whitten**, Merrimack Valley Planning Commission, 160 Main Street, Haverhill, MA 01830.

Soft-shell clamming has long been a vital commercial fishery on the North Shore of Massachusetts. Earlier in the century, the Merrimack River Estuary alone produced up to 100,000 bushels of soft-shell clams per year (among the highest of shellfish harvesting communities on the East Coast). During the past decade, the fishery has seen significant declines and wide fluctuations in productivity. Landings have plummeted as much as 80% along the North Shore. The dramatic downturn in this once prominent industry is due to a combination of factors such as: natural "boom-and-bust" reproduction cycles, predation from non-native species such as the green crab, over harvesting, as well as regulatory closures of previously undocumented contaminated areas. The wide, unpredictable fluctuations in bed productivity make it impossible to ensure a sustainable and predictable harvest. The seeding of Massachusetts' North Shore shellfish beds with hatchery-reared soft-shell clams offers the potential to moderate this cyclical and declining nature of productivity. Efforts to improve shellfishing through restoration/enhancement efforts in other states have demonstrated several methods by which a more consistent and sustainable harvest can be achieved. This presentation examines regional efforts conducted by the Merrimack Valley Planning Commission (MVPC) in collaboration with the coastal communities of Gloucester, Ipswich and Rowley Massachusetts to enhance and sustain soft-shell clam (*Mya arenaria*) populations. Ultimately a more sustainable harvest provides more secure employment opportunities for shellfishermen as well as other marine-based job opportunities.

COMMUNITY-BASED OYSTER RESTORATION IN AN URBAN ESTUARY: DEVELOPING AN OYSTER CULTURE AND REEF RESTORATION PROGRAM IN THE HUDSON-RARITAN ESTUARY. **A. Willner**, NY/NJ Baykeeper, Building 18, Sandy Hook, Highlands, NJ 07732.

Goals, progress, and challenges to development of a restoration program led by a nonprofit organization in an urban estuary will be discussed. The Hudson-Raritan Estuary supports a sparse oyster population that has collapsed since the beginning of the 1900s. Major natural oyster beds were exhausted by commercial shellfishing in the early 1800's, since the closure of the industry in the 1920s the population has continued to decline to the current state of small groupings of individuals located in disparate reaches of the system. Prompted by the success of oyster restoration in other estuaries, NY/NJ Baykeeper, with guidance from a scientific advisory board, has begun to investigate the feasibility of restoring reefs to provide habitat for larval settlement and population recovery. Spat surveys conducted in 1998 demonstrating minimal recruitment, lead to the 1999 experiment of placing a large amount of shell on the historic footprint of an oyster population in New York Harbor to provide a greater area to increase probability of recruitment. Preliminary results demonstrate the potential for reef construction to increase oyster recruitment. To stock the reef in an effort to further improve recruitment success, a community-based oyster-culturing program has recently been established involving schools, marinas, civic groups and families. Oyster restoration in estuaries with pollution concerns such as this provide the opportunity to investigate factors affecting population recruitment and maintenance as well as challenges to public education and outreach in urban areas.

THE NATIONAL SHELLFISHERIES ASSOCIATION

The National Shellfisheries Association (NSA) is an international organization of scientists, management officials and members of industry that is deeply concerned and dedicated to the formulation of ideas and promotion of knowledge pertinent to the biology, ecology, production, economics and management of shellfish resources. The Association has a membership of more than 1000 from all parts of the USA, Canada and 18 other nations; the Association strongly encourages graduate students' membership and participation.

WHAT DOES IT DO?

—Sponsors an annual scientific conference.
—Publishes the peer-reviewed *Journal of Shellfish Research.*
—Produces a Quarterly Newsletter.
—Interacts with other associations and industry.

WHAT CAN IT DO FOR YOU?

—You will meet kindred scientists, managers and industry officials at annual meetings.
—You will get peer review through presentation of papers at the annual meeting.
—If you are young, you will benefit from the experience of your elders.
—If you are an elder, you will be rejuvenated by the fresh ideas of youth.
—If you are a student, you will make useful contacts for your job search.
—If you are a potential employer, you will meet promising young people.
—You will receive a scientific journal containing important research articles.
—You will receive a Quarterly Newsletter providing information on the Association and its activities, a book review section, information on other societies and their meetings, a job placement section, etc.

HOW TO JOIN

—Fill out and mail a copy of the application blank below. The dues are 65 US $ per year ($35 for students) and that includes the *Journal* and the Newsletter!

NATIONAL SHELLFISHERIES ASSOCIATION—APPLICATION FOR MEMBERSHIP
(NEW MEMBERS ONLY)

Name: ______________________ For the calendar year: ____ Date: ____________

____
____

Institutional affiliation, if any: ______________________________
Shellfishery interests: ______________________________

Regular or student membership: ____________
Student members only—advisor's signature REQUIRED: ______________________

Make checks (*MUST* be drawn on a US bank), international postal money orders or VISA for $65 ($35 for students with advisor's signature) payable to the National Shellfisheries Association and send to Nancy Lewis, Bookkeeper, PO Box 350, V.I.M.S. Eastern Shore Lab, Wachapreague, VA 23480, USA.

INFORMATION FOR CONTRIBUTORS TO THE *JOURNAL OF SHELLFISH RESEARCH*

Original articles dealing with all aspects of shellfish research will be considered for publication. Manuscripts will be judged by the editors or other competent reviewers, or both, on the basis of originality, content, merit, clarity of presentation, and interpretations. Each article should be carefully prepared in the style followed in prior issues of the *Journal of Shellfish Research* before submission to the Editor. Papers published or to be published in other journals are not acceptable.

Title, Short Title, Key Words, Abstract: The title of the paper should be kept as short as possible. Please include a "short running title" of not more than 48 characters including spaces, and key words. Each manuscript must be accompanied by a concise, informative abstract, giving the main results of the research reported. The abstract will be published at the beginning of the article. No separate summary should be included.

Text: Manuscripts must be typed double-spaced throughout on one side of the paper, leaving ample margins, with the pages numbered consecutively. Scientific names of species should be underlined or in italics and, when first mentioned in the text, should be followed by the authority. Common and scientific names of organisms should be in accordance with American Fisheries Society Special Publications 16 and 17: *Common and Scientific Names of Aquatic Invertebrates from the United States and Canada: Mollusks and CSNAIUSC: Decapod Crustaceans,* or relevant publications for other geographic regions.

Abbreviations, Style, Numbers: Authors should follow the style recommended by the sixth edition (1994) of the *Council of Biology Editors [CBE] Style Manual,* distributed by the American Institute of Biological Sciences. All linear measurements, weights, and volumes should be given in metric units.

Tables: Tables, numbered in Arabic, should be on separate pages with a concise title at the top.

Illustrations: Line drawings should be in black ink or laser print and planned so that important details will be clear after reduction to page size or less. No drawing should be so large that it must be reduced to less than one third of its original size. Photographs and line drawings should be prepared so they can be reduced to a size no greater than 17.3 cm × 22.7 cm, and should be planned either to occupy the full width of 17.3 cm or the width of one column, 8.4 cm. Photographs should be glossy with good contrast and should be prepared so they can be reproduced without reduction. Originals of graphic materials (i.e., line drawings) are preferred and will be returned to the author. Each illustration should have the author's name, short paper title, and figure number on the back. Figure legends should be typed on separate sheets and numbered in Arabic.

Digital Figures: Authors may provide digital figures (they are not required); they must be accompanied by hardcopy figures of equal quality, which the printer will use for comparison and backup. If digital figures are supplied, please note the following instructions:

- Each piece of art should be saved as its own file.
- Files must be one of the following formats: TIF, EPS, or JPG.
- Each file should be named according to its figure number and format (e.g., "fig2b.tif").
- Figures must not be embedded in a word-processor or spreadsheet document: the printer cannot use images stored in Word, WordPerfect, Excel, Powerpoint, etc.
- Resolution: *line shots:* 1000 dpi; *halftones/grayscales:* 300 dpi if no lettering, 500 dpi if figure contains lettering.
- Color figures: save the files as CMYK-encoded TIF images (preferred) or CMYK-encoded EPS or JPG images. Color figures have the same resolution requirements a B/W, above.

Color illustrations will not be accepted unless the author agrees to cover the cost of associated reproduction and printing.

Literature Cited: References should be listed alphabetically at the end of the article. Abbreviations in this section should be those recommended in the *American Standard for Periodical Title Abbreviations,* available through the American National Standard Institute, 1430 Broadway, New York, NY 10018. For appropriate citation format, see examples below:

Gonzalo Gajardo, Margarita Parraguez, and Nelson Colihueque
Karyotype analysis and chromosome banding of the Chilean-Peruvian scallop *Argopecten purpuratus* (Lamarck, 1819) 585

Mohsin U. Patwary, Akelia Wanchope, Timothy W. Short, and Edward J. Catapane
Molecular cloning and characterization of a fructose-1,6-biphosphate aldolase cDNA from the deep-sea scallop *Placopecten magellanicus* 591

Rosalío Maldonado-Amparo and Ana M. Ibarra
Comparative analysis of oocyte type frequencies in diploid and triploid catarina scallop (*Argopecten ventricosus*) as indicators of meiotic failure 597

Martin LaFrance, Helga Guderley, and Georges Cliche
Low temperature, but not air exposure slows the recuperation of juvenile scallops, *Placopecten magellanicus*, from exhausting escape responses 605

Jose L. Rueda and Aad C. Smaal
Selective ingestion of pelagic versus benthic algae by the cockle *Cerastoderma edule* (Linné, 1758) 619

Donald Brown, Bernardita Campos, and H.-Jörg Urban
Reproductive cycle of the bivalve clams *Semele solida* (Gray, 1828) (Semelidae) and *Gari solida* (Gray, 1828) (Psammobiidae) from Chile 627

K. L. Heck, Jr., L. D. Coen, and D. M. Wilson
Growth of northern [*Mercenaria mercenaria* (L.)] and southern [*M. campechiensis* (Gmelin)] quahogs: influence of seagrasses and latitude 635

C. Tirado, C. Salas, and J. I. López
Reproduction of *Callista chione* L., 1758 (Bivalvia: Veneridae) in the littoral of Málaga (southern Spain) 643

S. Novoa, D. Martínez, J. Ojea, P. Soudant, J.-F. Samain, J. Moal, and J.-L. Rodríguez
Ingestion, digestion, and assimilation of gelatin-acacia microcapsules incorporating deuterium-labeled arachidonic acid by larvae of the clam *Venerupis pullastra* 649

William S. Arnold, Dan C. Marelli, Melanie Parker, Philip Hoffman, Marc Frischer, and John Scarpa
Enhancing hard clam (*Mercenaria* spp.) population density in the Indian River Lagoon, Florida: a comparison of strategies to maintain the commercial fishery 659

Stefán Áki Ragnarsson and Gudrún G. Thórarinsdóttir
Abundance of ocean quahog, *Arctica islandica*, assessed by underwater photography and a hydraulic dredge 673

Stefano Peruzzi and Ximing Guo
Tetraploid induction by meiosis inhibition with cytochalasin B in the dwarf surfclam, *Mulinia lateralis* Say: effects of temperature 677

Alexandra Leitão, Raquel Chaves, Sara Santos, Pierre Boudry, Henrique Guedes-Pinto, and Catherine Thiriot-Quiévreux
Cytogenetic study of *Ostrea conchaphila* (Mollusca: Bivalvia) and comparative karyological analysis within ostreinae 685

Eric N. Powell, Kathryn A. Ashton-Alcox, Joseph A. Dobarro, Meagan Cummings, and Sarah E. Banta
The inherent efficiency of oyster dredges in survey mode 691

E. Kenchington, C. J. Bird, J. Osborne, and M. Reith
Novel repeat elements in the nuclear ribosomal RNA operon of the flat oysters *Ostrea edulis* C. Linnaeus, 1758 and *O. angasi* Sowerby, 1871 697

Maria Eugenia Valdez-Ramirez, Anne Donval, and Marcel Le Pennec
Ultrastructural and histochemical criteria for determining normality in mature oocytes of the Pacific oyster *Crassostrea gigas* 707

2128 057

CONTENTS

IN MEMORIAM
Harold Haley Haskin (1915–2002) 441

Eugene Burreson
Honored Life Member: Jay Donald Andrews 445

Kenneth Chew
Honored Life Member: Neil F. Bourne 447

Loren D. Coen and M. Yvonne Bobo
Honored Life Member: Victor G. Burrell 449

Richard A. Lutz
Honored Life Member: Herbert Hidu 451

George R. Abbe
Honored Life Member: Sandra E. Shumway 453

F. H. MacKintosh and E. A. Smith
Evaluation of Mist Alert™ rapid test kits for the detection of paralytic and amnesic shellfish poisoning toxins in shellfish 455

Ana María Gayoso, Stacie Dover, Steve Morton, Mark Busman, Peter Moeller, Vanesa K. Fulco, and Lucie Maranda
Diarrhetic shellfish poisoning associated with *Prorocentrum lima* (Dinophyceae) in Patagonian Gulfs (Argentina) 461

Graham C. Fletcher, Brenda E. Hay, and Margaret F. Scott
Reducing neurotoxic shellfish poison (NSP) in Pacific oysters (*Crassostrea gigas*) to levels below 20 mouse units · 100 g^{-1} 465

F. M. Harper, E. A. Hatfield, and R. J. Thompson
Recirculation of dinoflagellate cysts by the mussel, *Mytilus edulis* L., at an aquaculture site contaminated by *Alexandrium fundyense* (Lebour) Balech 471

Rodrigo Gaspar Soria, Marcela Susana Pascual, and Víctor Hugo Fernández Cartes
Reproductive cycle of the cholga paleta, *Atrina seminuda* Lamarck, 1819 (Bivalvia: Pinnidae) from northern Patagonia, Argentina 479

Qin-Feng Gao, Ka-Kei Mak, and Siu-Gin Cheung
The physiological ecology of black-ribbed mussels, *Septifer virgatus* (Wiegmann) (Bivalvia: Mytilidae) on a sub-tropical wave-exposed shore in Hong Kong 489

Néstor Fernando Ciocco and Ana María Gayoso
Microalgal food of the ribbed mussel *Aulacomya atra* (Molina, 1782) in Golfo Nuevo (Patagonia, Argentina) 497

John Brake, Jeffrey Davidson, and Jonathan Davis
Triploid induction of *Mytilus edulis* using 6-dimethylaminopurine 503

Pauline Kamermans and Aad C. Smaal
Mussel culture and cockle fisheries in The Netherlands: finding a balance between economy and ecology 509

Dirk A. Campbell and Maeve S. Kelly
Settlement of *Pomatoceros triqueter* (L.) in two Scottish lochs, and factors determining its abundance on mussels grown in suspended culture 519

Per Dolmer
Mussel dredging: impact on epifauna in Limfjorden, Denmark 529

Katherine A. Ross, John P. Thorpe, Trevor A. Norton, and Andrew R. Brand
Fouling in scallop cultivation: help or hindrance? 539

Laura Schejter, Claudia S. Bremec, Rut Akselman, Daniel Hernández, and Eduardo D. Spivak
Annual feeding cycle of the Patagonian scallop *Zygochlamys patagonica* (King and Broderip, 1832) in Reclutas bed (39S–55°W), Argentine Sea 549

Karin B. Lohrmann, Andrew R. Brand, and Stephen W. Feist
Comparison of the parasites and pathogens present in a cultivated and in a wild population of scallops (*Argopecten purpuratus* Lamarck, 1819) in Tongoy Bay, Chile 557
